Subclassification can be viewed as a very coarse version of matching. To obtain more of the benefits of

matching, subclassification has been extended to “full matching,” which creates matched sets containing either (a) one treated unit and one or more controls or (b) one control unit and one or more treated units.

Check for Balance Within the Propensity Score Groups

To check whether matching or subclassifying on the propensity score did indeed remove the initial imbalance in the covariates, it is necessary to assess the balance within the matched groups. As stated before, experts disagree on the best method to assess this balance. Some experts recommend significance tests. For example, t tests of the difference in covariate means between the matched treated units and the matched control units, or, in the case of subclassification, a two-way analysis of variance with the covariate as the dependent variable and treatment indicator and propensity score subclass and their interaction as predictors, can be used as a guide to indicate remaining covariate imbalance. Another recommendation is to calculate standardized differences, keeping the denominator the same as in the prematch balance checks. More specifically, the measure of postmatch standardized difference uses the standard deviation of the entire treatment group (and the entire control group if using the first version of the formula) in the denominator, even if some units have been dropped in the matching process because of the unavailability of a good match in the opposite treatment group.

If covariate imbalance remains at this step, the propensity score model can be reestimated, adding interaction terms or nonlinear functions (e.g., quadratic) of imbalanced covariates to try to improve the resulting balance.

Estimate the Treatment Effect

When propensity score matches balance all the covariates to the analyst's satisfaction, the simplest way to estimate the treatment effect is to calculate the difference in average outcome between the treated and control units within a matched group and then average these differences across all the groups. When subclassification is used, using a weighted average based on the number of treated units in each group will yield an average treatment effect on the treated units, and using a weighted average based on the total number of units in each subclass will yield an average treatment effect for the overall population.

When covariate imbalance remains after propensity score matching, despite repeated modeling attempts to improve the propensity score estimates, a regression-type

adjustment can be used to adjust for the remaining differences between groups. For example, the matched treated and control units can be used in a multiple regression of the outcome on the imbalanced covariates and an indicator for treatment. In the case of subclassification, this regression can be carried out within strata and the estimated treatment effects (the coefficient of the treatment indicator) can be averaged across strata.

When with-replacement matching has been used, or when treated units have been matched to different numbers of controls, this must be taken into account when estimating the treatment effect. Usually, the analysis uses the combined sample of matched pairs, with units that were selected as a match more than once receiving a larger weight (e.g., if a control was used twice as a match, then it would receive a weight of two).

Variance estimation for propensity score estimates of treatment effects is still a topic of open research. Experts are debating whether uncertainty in the propensity score estimation or the effect of sampling variability in the matching process needs to be taken into account. Therefore, any variance estimates obtained from propensity-matched data should be viewed as only approximate.

Alternative Uses of Propensity Scores

Propensity scores have also been used as covariates in models such as linear regression, and as weights.

PROPENSITY SCORE MATCHING

Propensity score matching is a research design used to minimize selection bias when comparing two or more nonrandomly assigned groups on an outcome of interest. The *propensity score* is the predicted probability that observations will be assigned to each treatment group, conditional on observed pretreatment characteristics. Through the process of propensity score matching, researchers identify virtually identical observations in different treatment conditions for comparison on outcomes of interest. Observations with similar propensity scores are *matched* for comparison in subsequent analyses. Ideally, treatment and control units could be matched on all relevant covariates so the comparison groups are identical—this perfect case would allow for a causal estimate of the treatment effect, as the main effect can be isolated from any selection bias. The practical implementation of propensity score matching involves

1. predicting *propensity scores*,
2. *matching* treatment and control groups, and then
3. checking for *balance* across the groups to ensure they are very similar on both propensity scores and all covariates.

After completing these steps, analyses can be conducted using matched samples to estimate the average treatment effect.

This entry describes the main goals and advantages of propensity score matching, implementation of the matching process and several commonly used approaches, testing for balance across treatment groups, and testing sensitivity to possible omitted variables. A simple hypothetical research situation is provided as an example.

Considerations for Causal Inference

The goal of research is often to identify differences between groups attributable to a treatment, but this goal is complicated if the groups differ in important ways prior to treatment implementation. A fundamental challenge in inferring causality is the absence of a counterfactual; an observation in one treatment condition cannot be observed in a different treatment condition. To address this limitation, random assignment is generally considered the gold standard in research, though it is not always feasible. For example, it would not be ethical to withhold educational services from a group of students in a treatment or control condition for the purposes of research. Relatedly, in an educational setting, it would be challenging to randomly assign students to classrooms or schools; beyond within school assignment systems, residential patterns and transportation logistics are just a few of the complications of randomization in social science research. Propensity score matching attempts to address the complications of data analysis in research settings when random assignment to treatment conditions is not possible due to practical or ethical research concerns.

A lack of random assignment may lead to *selection bias*, a situation when individuals do not have equal likelihood of being assigned to treatment and control groups. The result of selection bias is that there may be preexisting differences across groups, meaning that groups likely differ in important ways that will bias estimates of treatment effects. If a researcher could identify every relevant covariate (and relevant covariate interactions and transformations) for inclusion in analyses, they could isolate the main effect of a particular treatment variable. However, a very large number of covariates and interactions will also lead to too few degrees of freedom, an inflated type I error rate, and a reduction in statistical power. Instead, propensity score matching provides a *composite* score based on multiple variables and interactions as defined by the researcher. The propensity score is considered a balancing score, such that the conditional distribution of each variable is the same for both treatment and control groups. Thus, propensity score matching attempts to correct for selection bias by accounting for pretreatment group differences.

After implementing the matching process, the *average treatment effect* is provided by the coefficient on the treatment variable in the multivariate analyses performed. This coefficient provides an estimate of the effect of the treatment compared to having not received the treatment. Matching estimates the effect of treatment on participants compared to nonparticipants, and

multiple treatment groups can also be compared to a single reference group. Thus, propensity score matching provides a more precise comparison when random assignment is not feasible or ethical. In addition, propensity score matching restricts analyses to areas of commonality, meaning it reduces extrapolation beyond the overlap in distributions. Other advantages of propensity score matching include its relative ease of implementation and the opportunity for doubly robust analyses using both covariates and propensity scores for more precise estimates.

Predicting Propensity Scores

To estimate propensity scores, logistic regression is used to predict the probability of being assigned to either the treatment or control group from variables of interest as indicated by theory, literature, and data analysis. Three categories of variables are necessary: (1) a defined treatment assignment variable, (2) a defined outcome of interest, and (3) relevant covariates that predict selection into treatment group and correlate with the outcome of interest. These covariates must either exist prior to implementation of the treatment or be nontime varying, meaning the covariates cannot be affected by treatment assignment.

In the simplest case, the predicted propensity score for subject i ($i = 1, \dots, n$) is the estimated conditional probability of being assigned to one of two treatment conditions t : $T_i = 0$ or $T_i = 1$, given a vector, $\mathbf{X}_i$, of observed pretreatment covariates. Multinomial logistic regression is used to predict the probability of receiving the treatment given the selected covariates used for matching. For each treatment condition t , the probability of being assigned to treatment t is:

$$\Pr(Y_i = t) = \frac{e^{\beta_t X_i}}{\sum_{k=1}^K e^{\beta_k X_i}}.$$

Each individual's probability of being assigned to treatment t , conditioned on $\mathbf{X}$, is defined as $p_i = \Pr(T_i | \mathbf{X}_i)$. This model produces estimates for each β coefficient on each $\mathbf{X}$ covariate. This simple case can be expanded to include more than two treatment conditions as well.

Thus, propensity score matching takes multiple characteristics and combines them into one probability, so there is no need to match on exact covariates. Given that the goal is to remove bias due to all observed covariates, researchers can select a vector of variables and interactions such that the distributions of the treatment and control groups will be close to identical. Importantly, the model must be specified correctly, as

model misspecification threatens the validity of any inferences made. Any standard statistical software (e.g., Stata, R, SPSS, SAS) can easily perform these analyses.

Common Approaches to Matching

After propensity scores have been estimated, researchers examine the samples in treatment and control groups to identify eligible observations for comparison. Typically, observations in the treatment group are matched to those in the control group. At a basic level, one could simply compare only those observations for which an exact match exists in both treatment and control groups based on all relevant covariates. While compelling for comparison purposes due to the isolation of treatment effects, exact matches may not exist, and such an approach limits sample sizes in a manner too extreme for most quantitative researchers. To expand the zone of comparison somewhat, observations can be divided into strata based on the propensity scores estimated earlier. Observations in the treatment group are compared only to very similar matched partners in the control group, but observations do not need to match exactly on all covariates. For example, observations may be divided into propensity score quintiles or deciles for comparison. Within the selected number of strata, treatment and control group observations are presumed to be equivalent for analysis (an assumption that is tested in the next step of the process). Within strata, groups may have similar ranges but different distributions.

In nearest neighbor matching, instead of creating strata, observations are matched based on proximity of propensity scores. Each observation in the treatment group is matched with an observation from the control group. In one-to-one matching, each observation has a single match. Alternatively, if the sample is large enough and groups have enough overlap, researchers may choose to match one treatment observation to more than one control group observation, which allows for more observations to be included in the analysis. Typically, matching is done with replacement, meaning an observation that has been matched is returned to the sample for subsequent matching, so a single control group observation may be matched with multiple treatment observations.

Inverse probability weighting is an approach to propensity score matching that allows for inclusion of all observations in all treatment conditions. To determine matched samples, propensity scores are used to create inverse probability weights (IPWs) as follows: $IPW = 1/p_i$. As the name implies, the IPWs are the inverse of the estimated propensity scores. Subsequent analyses are

then weighted using the IPWs. This approach down-weights the contribution of individuals whose propensity to be in a condition is higher (i.e., a more typical profile of an observation in that condition) based on the covariates relative to those whose likelihood is lower. Then, all observations in the data set can be included in the analysis, weighted by how likely they are to be in that condition (i.e., the IPWs).

Balance Across Treatment Conditions

After estimating propensity scores, *balance checks* are used to test that the means and variances of the propensity scores and all other variables are similar across all treatment conditions after matching or reweighting. These checks ensure the covariates used in estimating the propensity scores effectively account for differences across groups. For each variable X in the matrix of k ($k = 1, \dots, K$) covariates, the following regression is performed, using the β estimates described previously: $X_{ki} + \alpha_k + \beta_k T_i + \epsilon_{ki}$.

These simple regression models estimate whether the treatment condition significantly predicts the variable, showing any remaining differences between groups. After matching, the comparison groups should not be significantly different on the propensity score or any of the pretreatment covariates. Importantly, balance must be achieved within each stratum when implementing a stratified approach. Ideally, mean differences between groups should differ by less than 0.5 standard deviations. In addition, the ratios of group variances should be as close to 1 as possible, with ratios below 0.5 and above 2.0 demonstrating a lack of balance. Differences in both propensity scores and all covariates in the models should be examined. Distributions of propensity scores should be examined to be sure analyses are restricted to observations in the region of commonality, and researchers must also ensure each stratum includes an appropriate region of common support, including sufficient observations from both treatment and control groups within each stratum. Observations outside the area of commonality must be excluded, as this indicates there are insufficient matches between groups.

Falsification tests can also be used to look for differences pretreatment. If the data set includes a pretest, the treatment assignment can be used as a predictor of that pretest, along with other relevant covariates, as in the balance-checking process. As the pretest is measured prior to treatment group assignment, the estimated coefficient should be insignificant, which indicates that at the pretest all differences between the two groups have been eliminated.

Balance must be achieved before moving ahead using propensity scores and matched groups for

analyses. If the groups are not balanced, researchers should reconsider the model specification. Researchers may choose to add or remove covariates, transform variables based on skewness or the possibility of non-linear relationships, or add interactions or higher order terms. Decisions regarding model specification should always be based on sound theoretical decisions and assumptions. When balance is achieved across groups, analyses can be performed using the matched/weighted samples that are arguably very similar, allowing for estimating isolated treatment effects. Conversely, similar enough comparison groups may not exist, or data sets may not contain appropriate variables for matching. Any remaining differences after balance should be reported, though these exceptions should be limited.

Considerations for Addressing Limitations

Regardless of selected matching approach, researchers should be cautious in making causal claims, as groups may differ in ways the researcher cannot account for. Propensity score matching rests on the assumption that the researcher has included all relevant pretreatment covariates in the matching process. However, observations may differ on unobservable characteristics, or observable characteristics not measured in the data set or not included in the models, potentially introducing *omitted variable bias*. Thus, selection into treatment groups may be based on unobserved and/or unobservable variables in addition to any observed variables.

Sensitivity analyses can help examine how sensitive results might be to possible omitted variable bias. After conducting an analysis using propensity score matching, researchers can estimate the potential influence of possible omitted variables using various combinations of (a) the estimated differences between groups on propensity scores and covariates and (b) the regression coefficients estimated in predicting the outcome of interest. The sensitivity analysis thus considers both how similar or different the treatment and control groups are, as well as how influential different variables are on the outcome. Based on the estimates found in the propensity score matching process, researchers select hypothetical values of the residual differences in standardized units between matched pairs, η , and hypothetical standardized regression coefficients, ϕ . Considering a range of values for each allows for analysis of the sensitivity of the models to a variety of possible omitted variables. Large η values assume the observations in various treatment conditions differ greatly on the covariate prior to matching, whereas smaller values assume the groups are more similar. Large ϕ values assume the covariate has a particularly large impact on the outcome estimate, while smaller

values assume the variable is less important. Maximum hypothetical values can be based on the largest relative absolute values of observed covariates such that they are large but still plausible; using these extreme values provides the researcher with a sense of how large any possible bias may be.

The two values are multiplied together and first added to the estimated average treatment effect, Δ , to produce a new estimated adjusted treatment effect if the omitted variable bias were negative and then subtracted from the originally estimated average treatment effect to produce an adjusted treatment effect if the bias were positive, resulting in two new estimates of the average treatment effect $\hat{\Delta} : \hat{\Delta} = \hat{\Delta} \pm \hat{\eta}\hat{\phi}$.

Because omitted variables may bias estimates in either direction, either by underestimating or overestimating the treatment effect, examining the impact of either a positive or negative effect gives a sense of the true range of possible estimates. In the case of significant treatment effects, this analysis provides a sense of whether the inclusion of an unobserved pretreatment covariate would have substantially changed the results and led to insignificant findings. Conversely, when no significant treatment effects are found, this sensitivity analysis tells how big the difference between groups on an omitted variable would have to be, or how influential the variable would have to be in the full model, to make the small result significant.

Example

Suppose a researcher is interested in comparing math achievement between students attending public schools and those attending private schools. Students either attend a public school or they attend a private school, meaning there are two treatment groups, and the outcome of interest is the math achievement score as measured by a standardized assessment in this example. The researcher may be concerned that selection into groups is not random, as students attending private schools tend to come from wealthier families than those attending public schools, and family income is also predictive of math achievement, on average. Thus, differences in the assessment may reflect selection bias rather than the isolated effect of the school type, as the two groups differ in meaningful ways.

Provided a robust data set, the researcher could use propensity score matching to match students attending private schools (a smaller number of students) to matched students attending public schools. Important covariates would likely include age, gender, and socioeconomic status, to name only a few. If possible, the robustness of the propensity score matching process would benefit from a pretest, as this will likely be the

strongest predictor of the outcome, and the inclusion also allows for the falsification test described earlier. Still, analyses could suffer from omitted variable bias due to unobserved/unobservable differences in students; for example, groups may differ in motivation, a variable difficult to measure and often not included in data collection.

Final Notes

Group comparisons may produce biased estimates due to selection bias from nonrandom treatment assignment, which propensity score matching can help mitigate or at least help identify. Matched estimates are less susceptible to bias, though even the most robust set of covariates can only account for observed variables. Sensitivity analyses can be useful for understanding the possible effects of omitted variables. Propensity score matching can be used as a robustness check even if one is hesitant to make causal claims, and a particular advantage is its ease of implementation using standard statistical packages.

PROPORTIONAL SAMPLING

Proportional sampling is a method of sampling in which the investigator divides a finite population into subpopulations and then applies random sampling techniques to each subpopulation. Proportional sampling is similar to proportional allocation in finite population sampling, but in a different context, it also refers to other survey sampling situations. For a finite population with population size N , the population is divided into H strata (subpopulations) according to certain attributes. The size of the h th stratum is denoted as N_h and $\sum_{h=1}^H N_h = N$. Proportional sampling refers to a design with total sample size n such that

$$n_h = n \frac{N_h}{N}$$

and

$$\sum_{h=1}^H n_h = n.$$

Following that, a simple random sample with sample size n_h would be selected within each stratum. This is essentially the same as the stratified random sampling design with proportional allocation, and the inference of the population quantity of interest can be established accordingly. n_h usually would not be an integer, so the closest integer can be used. For example, in an opinion survey, an investigator would usually prefer a sample with the sample structure as close as possible to the population structure with respect to different population characteristics, such as age, gender, race, and so forth. Suppose the population structure of gender by age for people more than 20 years of age is as summarized in Table 1, and the total sample size n is

Table 1 Population Structure

		Age				
		20–29	30–39	40–49	50–59	≥60
Gender	Male	22,306	25,264	28,231	22,306	17,350
	Female	24,785	27,646	29,742	22,906	24,785

Table 2 Sample Sizes

		Age				
		20–29	30–39	40–49	50–59	≥60
Gender	Male	97	110	123	97	76
	Female	108	120	129	100	108

determined to be 1,068. The sample sizes of each stratum can be determined as shown in Table 2.

For example, the sample size of females between the ages of 30 and 39 can be determined by

$$1,068 \times \frac{27,646}{245,321} = 120.3563 \cong 120,$$

where 245,321 is the total population size.

For other sampling survey situations—for instance, the selection of sites to monitor the air population level in a region or time points to observe a production process for quality control purposes during a period of operation—the study region can be viewed as a compact region and the number of possible sampling units is infinite. Suppose that the study region D is divided into H disjoint domains D_h , $h = 1, \dots, H$, according to the practical or natural demands; that is,

$$D = \bigcup_{h=1}^H D_h, D_h \cap D_{h'} = \emptyset, \forall h \neq h'.$$

For example, for ecological research on Florida alligators, the study region can be a collection of several lakes, and the domains are the lakes. To study the ecosystem in a certain lake, the investigator might divide the study region, a three-dimensional compact space of the lake, by water depth. The investigator would like to allocate the sample sizes proportional to the area D_h to ensure a fair devotion of sampling effort to each domain. Proportional sampling can also be used such that

$$n_h = n \cdot \frac{\text{area of } D_h}{\text{area of } D}$$

and

$$\sum_{h=1}^H n_h = n.$$

For example, an investigator would like to take samples of water from several lakes for a water pollution study. Suppose that there are five lakes, denoted

Table 3 Areas of Lakes in Acres

	<i>Lakes</i>				
	<i>A</i>	<i>B</i>	<i>C</i>	<i>D</i>	<i>E</i>
<i>Area</i>	36.7	48.2	15.3	26.1	79.6

Table 4 Sample Sizes in Each Lake

	<i>Lakes</i>				
	<i>A</i>	<i>B</i>	<i>C</i>	<i>D</i>	<i>E</i>
<i>Area</i>	27	35	11	19	58

from A to E, and the areas of these lakes are summarized in Table 3. If the sample size is determined to be 150, then the sample sizes in each lake are as summarized in Table 4.

For example, the sample size in Lake C can be determined as

$$150 \times \frac{15.3}{250.9} = 11.14619 \approx 11,$$

where

$$250.9 = 36.7 + 48.2 + 15.3 + 26.1 + 79.6$$

is the total area of the study region.

The principle of proportional sampling is widely used in practical sampling survey cases, either to determine the sample sizes of each domain or to evenly spread sampling units over the study region. Numerous researchers recommend proportional sampling because it is relatively more efficient than the uniform sampling or simple random sampling on the whole study region. To name a few, José Schoereder and colleagues described the application of proportional sampling in an ecological survey. Saul Blumenthal discussed proportional sampling on a time interval, in which the study region is a one-dimensional compact space. T. Y. Chen and colleagues studied the performance of proportional sampling on software testing and found it is a better choice than the random testing.

PROPOSAL

A program research plan, or proposal, is a comprehensive description of a potential study that is intended to examine a phenomenon in question. The main purpose of research is the increase of knowledge, either in a specific disciplinary field or in the practice of a professional field. Research is usually associated with a planned, systematic investigation that produces facts and ideas that contribute to human thought, reflection, and action. Because there is no single way in which to approach research, an inquirer must weigh many factors in designing a program research plan.

Throughout the centuries, basic research structures have developed as models for each subsequent generation of knowledge-seekers. One who chooses to research a particular concept or phenomenon within one's field may look to the historic development of research methodology in that particular field to guide him or her in designing an appropriate research protocol. Regardless of the field of study, the potential researcher will find that scholarly investigation is guided by two overarching systems of inquiry—*quantitative* and *qualitative* research methodologies. Both are viable avenues of study that address inquiry in multiple disciplines. However, they are guided by different principles and are, therefore, best applied when matched to the characteristics of the problem that is to be studied.

Generally, postsecondary institutions of education require that a proposal or prospectus be submitted, reviewed, and approved prior to embarking upon a thesis or dissertation study. This requires that the researcher complete a preliminary review of related literature and formulate a hypothesis or research question that will provide focus for the study. Following these initial steps, the remainder of the program research study is designed and defended as part of the approval process. This plan must also be submitted to the college or university's research department for approval through the institutional review board. The

approvals process has many steps, but a fully developed, well-designed plan saves time and effort in the long run; provides structure for the study; and normally produces a higher quality of research.

Although the exact titles, formatting, and subsections may vary based upon the research design and researcher preferences, research plans, whether quantitative or qualitative in nature, have several elements that are commonly included in their designs. Both usually include introductory components that present the phenomenon to be studied, a review of relevant literature, descriptions of the research design and procedures, and discussion of the data analysis methods to be used within the study.

Quantitative Research Versus Qualitative Research

Quantitative research methodologies are most often associated with scientific investigation of quantifiable properties and their relationships. It uses mathematical models, theories, and hypotheses to measure and portray the empirical associations found in natural phenomena. It is frequently the research methodology employed for inquiry in natural science and social science fields such as physics, biology, psychology, and sociology. Characteristically, quantitative methods use large, random samples from which to gather data, and they require that the researcher remain in a neutral, noninteractive role so as to remove any bias that could affect the outcome of the study. Data are often numerical in nature, collected using reliable and valid tools and methods, and analyzed using statistical techniques. Results and findings are methodically presented following statistical data analyses, focusing on deductive, logical reasoning.

Qualitative research methodologies provide a means of gaining deeper understandings of human behaviors and the factors that influence those behaviors. The nature of human interactions is dynamic and may be reshaped by myriad factors. Therefore, qualitative methodology offers multiple means of inquiry that are flexible and adaptable within a more fluid research protocol. In essence, the researcher does not present a typical hypothesis at the onset of the study. Instead, he or she develops the research questions and focus during the study. The questions and focus of the study may change as the researcher investigates and collects data for the project. The broad range of human behaviors dictates that qualitative research use smaller samples in order to limit the scope of a study and allow the inquiry to focus more deeply on the phenomena to be examined. Unlike quantitative research, qualitative research is often subjective in nature, relying on

interaction between the researcher and study participants. Qualitative data are characterized by their descriptive qualities, collected through personal accounts and interviews. Instead of using statistical analysis techniques, the qualitative researcher investigates patterns and common themes within the data. Study results are written in narrative form, using inductive reasoning to present findings.

Both research methodologies offer advantages and disadvantages; therefore, the researcher must look to the focus and purpose of his or her inquiry to determine which methodology is the better match for a proposed study. Some of the basic features of qualitative and quantitative research are highlighted in Table 1.

Quantitative Proposed Program

The choice of a quantitative research design requires the researcher to formulate an initial, specific hypothesis that will serve to guide the study. Thought and planning must be incorporated into the development of instruments and methods for measurement. Variables must be identified and their control and manipulation must be factored into the research design.

Selection of a quantitative research methodology brings with it structure and format that are commonly accepted as the scholarly progression to conduct such a study. Table 2 provides an outline of the elements that are contained within that academically sanctioned format.

Approaches to a Quantitative Research Plan

Quantitative research is the method of choice for a researcher who seeks to clarify phenomena through specifically designed and controlled data collection and analysis. Within that methodology lies a broad spectrum of approaches.

Experimental Research. Identifies at least one independent variable for interventions and is manipulated, whereas other, related variables are controlled; effects on dependent variables are observed (e.g., measuring student achievement levels by examining and controlling selected variables such as age, grade level, reading level, time, teacher characteristics, etc.); two subgroups fall within this category: true experimental and quasi-experimental research.

- *True Experimental Research.* Participants are randomly selected and placed into control and experimental groups prior to the intervention; the experimental group receives the intervention and the control group does not; random selection and

Table I Basic Features of Quantitative and Qualitative Research Methodologies

<i>Qualitative</i>	<i>Quantitative</i>
Generates detailed descriptions portrayed in creative, narrative forms	Generates models, theories, and hypotheses portrayed in mathematical expressions
Role of the researcher is interactive and may include participation in the study	Role of the researcher is a neutral stance in order to eliminate any bias
No hypothesis—the researcher may begin a study with a concept but without knowing in advance what he or she is specifically looking for	Hypothesis is stated—the researcher clearly knows in advance what he or she is looking for and seeks to prove or disprove the problem
The design may be flexible and aspects may be adapted and changed as the study progresses	All aspects of the design are clearly structured prior to the start of the study and remain intact
Researcher is the main data collection tool—use of interviews, observations, and so on rest with the researcher and require a departure from value neutrality	Researcher uses tools or instruments to collect numerical data—questionnaires, assessments, scales, and so on provide data through a neutral stance
Smaller samples of data are used because of the greater bulk of data generated	Large samples are used to provide maximum insight into numerical data
Data collection and analysis require extensive expenditure of time	Data collection and analysis are more efficient, requiring less time
Data analysis uses both subjective and objective means to determine findings	Data analysis is determined objectively through the use of mathematical calculations
Findings are presented in the form of words, pictures, or other objects	Findings are presented in comparative mathematical expressions
May be more specific rather than generalizable	Generalizable, but has less contextual detail

placement of the participants allows the researcher to control for extraneous variables; this method provides for true causal relationships between independent and dependent variables.

- *Quasi-Experimental Research.* This type of research is used when the researcher cannot or should not randomly assign participants to control and experimental groups; lack of random assignment limits the researcher's ability to control for extraneous variables; results should be interpreted cautiously; these types of designs cannot prove cause and effect, although they can show relationships between variables.

Correlational Research. Seeks to examine the degree of relationship that may exist between two or more variables in a single group of participants through collection of relevant data; this type of research cannot definitely identify cause-and-effect relationships because of a lack of random selection and assignment of participants, and because of a lack of variable manipulation; lack of randomization also limits the generalizability of results.

Causal-Comparative Research. Investigates the causes or consequences of existing differences in groups of individuals; may also be referred to as ex post facto research due to the nature of dealing with groups that have already been established (e.g., whether students whose parents have attended college enter postsecondary education at a higher rate than students whose parents who have not attended college); because the events have already occurred, variable manipulation is impossible; results must be interpreted with caution and generalizability is limited.

Survey Research. Collects descriptive data from a targeted population in order to determine the current status of one or more specific variables (e.g., the status of health care in a given community); questions are not standardized, which may lead to issues with instrument validity and reliability.

Components of a Quantitative Research Plan

For a solid proposal, the researcher needs to write in such a way that the study can be envisioned by the

readers. The proposal should be clear and concise, with attention to detail. The following subgroups represent the sections of a written plan for conducting quantitative research. Although the subtitles may not be the same for every proposal, this information serves as an outline for developing the plan of research. The researcher will need to determine the exact subgroups and titles based upon research methods and type of study being conducted.

Introduction and Statement of the Problem

When writing a quantitative research plan, the researcher must first set the scene for the project. The introductory section of the plan allows the researcher to discuss the framework for the project, as well as provide vital background information. The researcher wants to draw in the audience, creating interest and intrigue. In this section, the researcher discusses the

topic that is the focus of the research, including its importance to the advancement of knowledge in the particular field of study.

Review of Related Literature

The goal of the literature review section is to link current research and information to the researcher's focus of study, providing a foundation for the project. The literature review should provide adequate background information, current trends in the field of study, and prior research that relates to the project, as well as any gaps in the literature. The literature review will assist the researcher in developing research questions and hypotheses by relating the review findings to the goals of the project. The researcher should aim at including the most current literature and research available, relating it to the study at hand. Ideally, the researcher should demonstrate that his or her research

is theoretically based, yet unique in its approach and what it intends to prove.

Statement of the Hypothesis

As mentioned previously, current literature and research trends should help the researcher determine the basic research questions and goals of the study. The literature review should guide the researcher in formulating the hypothesis or hypotheses for the project. The statement of the hypothesis in a quantitative research proposal should be succinct and include the variables upon which the study will focus. In the proposal stage of the study, it is not always necessary for the researcher to know what type of effect the variables will have on one another. However, it is important that the researcher define clearly and operationally any variables that will be manipulated in the proposed program of study. In addition, if several research questions and/or hypotheses will be examined, all of these should be listed as part of this section. The final statement of the hypothesis or hypotheses must be written in such a way that anyone reviewing the proposal knows exactly what will be studied.

Methodology

The methodology section of the proposed program of a quantitative study describes exactly how the research will be conducted. The researcher needs to include methods involved in selecting participants, any instruments that will be used in the project, and the general research design.

Selecting Participants. When formulating a quantitative research proposal, the researcher needs to include a detailed section on how participants will be selected. The researcher must also describe pertinent demographic information regarding the selected participants and the overall pool from which the participants are being chosen. The researcher must include the type of sampling procedures that will be used to select the participants, as well as how many participants will be included in the project.

Instruments. The researcher should discuss any data collection tools that may be used in the study. Instruments must be described clearly, and the researcher should specify how each will be used. In this section, it is important to indicate which are existing instruments, as well as which instruments will be developed by the researcher. It is also appropriate to discuss validity and reliability of instruments, details of how the instruments will be administered and scored, and why the specific instruments were selected or developed for the study. Because this is the proposal phase of the study, the researcher may not have all of the data collection

tools selected or developed at the time of submission. In such cases, the researcher should, at a minimum, discuss the type of instruments that will be used, such as interview questions, pretests, and so on.

Research Design. The research design outlines the framework for how the study will be conducted, including the research goals and questions that will be answered through the study. The goal of quantitative research is to examine relationships among or between variables. Several designs accomplish this objective as mentioned previously, including experimental and quasi-experimental, correlational, and causal-comparative research. The intention is for the researcher to select the design that best suits the current study's objectives and goals.

Data Collection

Some researchers include the data collection section within the methods section, but it may also be discussed separately. Regardless of how the proposal is organized, it is important for the researcher to effectively share the steps of collecting data for the project. This section should include how the participants will be selected, as well as the details regarding the data collection instruments and any other pertinent information relating to the data. The researcher must specify who will administer each tool, as well as how and to whom the tool will be given for data collection purposes. The researcher may also give an estimated time line for when the data will be collected. If the study claims any assumptions, these should be detailed, as well as any limitations that may influence the data and study outcomes.

Data Analysis

Although the researcher may not yet know the results of data analysis, he or she should be prepared to discuss the methods of how the data will be analyzed. This includes any inferential and descriptive statistical testing and techniques. The types of statistical methods chosen should flow from both the research goals and objectives and the design of the study. A variety of techniques can be employed in a study, but they depend upon the type of participant sampling methods, research design, independent and dependent variables, and data that are collected. The researcher can strengthen the proposal if he or she determines the specific techniques to analyze the data.

Report of Findings

Once the data have been analyzed, the final step is to report the findings of the study. The researcher conveys

whether or not the study provided enough evidence to accept the hypothesis as true, the extent of how the results can be generalized and to what populations, and any other findings that were discovered during the study. This section should also point out any limitations of the study and discuss ways that further research could strengthen the study's hypothesis. Finally, the researcher should note the significance that the study has with regard to furthering knowledge in the field.

Qualitative Proposed Program

Qualitative research explores the *why* and *how* of a phenomenon and provides opportunities for a researcher to go beyond the quantitative questions of *how many* and *to what extent* an experience may occur. According to Norman Denzin and Yvonna Lincoln, a qualitative research project permits the researcher to depart from the value neutrality usually associated with scientific research and delve into the variant factors surrounding a phenomenon—natural settings, characteristics of participants, interactions, thoughts, and discoveries—that are brought to light through interaction with the research participants themselves.

Characteristically, qualitative methodology allows the researcher to collect data through participation, observation, interviews, and analysis of artifacts and documents. With this information, the researcher may then attempt to interpret or make sense of the phenomenon through the meanings that the participants bring to them. Reporting of findings is most frequently done in a more literary form rather than being graphed, charted, or put forth in mathematical terms.

Qualitative methods have their early roots in sociology and anthropology as researchers sought to investigate lived human experiences. Usage expanded to include other social and behavioral sciences. Currently, researchers in multiple fields such as education, health services, clinical research, women's studies, and societal reform movements use qualitative methods to gain greater insight into specific experiences or phenomena. As an example, a researcher studying the importance of mental attitude in the success of chemotherapy for specific cancer patients may, through qualitative methods, explore the various attitudes of the patient, his or her family and friends, and any other factors that produce positive and/or negative feelings regarding the cancer treatments. In educational settings, qualitative methods allow the researcher to take on the role of the researcher/practitioner, thus enabling a teacher to engage in deeper evaluation of instructional techniques, resulting in improvements in both teaching and learning within the classroom.

Qualitative research methodology also lends itself to a *mixed methods* approach that employs both

qualitative and quantitative procedures to expand the depth and scope of a research study. This inherent flexibility allows room for human variance and, as such, is a characteristic that has made qualitative research the methodology of choice for a broad range of social, behavioral, and biomedical sciences.

Approaches to a Qualitative Research Plan

Qualitative researchers have an array of approaches that may be used to design a research study. Selection of a specific approach provides a framework that serves to guide the structure and sequence of a qualitative research study. Specific methods of collecting and analyzing data within each approach are determined by the nature of the phenomenon and should be selected to provide consistency between the occurrence and the data derived through that occurrence.

A researcher who elects to pursue a qualitative study faces the task of determining the approach that will fulfill the research goals. Consideration must be given to the research question and the audience for whom the research is targeted. John Creswell identifies five general models that are usually associated with qualitative research approaches.

1. *Ethnography*. Studies an intact culture in its own setting over a prolonged time period through direct observation.
2. *Grounded theory*. Seeks to establish a generalized theory regarding an experience or process that is grounded in the perspectives of the research participants. Constant comparison of data collected in multiple stages is a primary characteristic of this approach.
3. *Case study*. Explores events, processes, or activities in depth through the perspective of one or more participants over a specified time period. Detailed data collection using a wide range of measures is a hallmark of this approach.
4. *Phenomenological study*. Seeks to gain understanding of the lived experiences of a small number of participants in order to shed light on the phenomenon of such experiences.
5. *Narrative research*. Relies on the stories of individual participants to form the basis of a chronological account that merges the views of the participants with the views of the researcher into a collaborative narrative.

Each of these qualitative approaches carries with it characteristics and procedures that can dictate whether or not that approach will be consistent with the problem or phenomenon to be studied. Matching the

approach with the problem will produce the most accurate and informational results for the researcher.

Components of a Qualitative Proposed Program

The researcher's choice of qualitative approach directs the design and development of the research study. Research questions, review of relevant literature, and all aspects of data collection and analysis are formulated relative to the qualitative approach selected for the study. The following information provides the basic structure for writing the qualitative research proposal. However, it is important to keep in mind that the subgroups may be slightly different from those presented here depending on the researcher, methods used, and type of study.

Statement of the Problem

Qualitative research is often the method of choice for those who seek to examine societal issues, especially those that confront marginalized people, political issues, and issues that affect specific groups of people. An effective statement of the problem sets the stage for

the research and provides continual focus as the study progresses.

Review of Relevant Literature

The literature review defines the importance of a qualitative study. Through this review, a researcher can determine whether there is a gap in knowledge or if there are other relevant studies that could serve as the basis for further examination of a specific problem. A thorough review of relevant literature suggests direction for a potential study and helps the researcher to determine the research questions. Furthermore, it contributes to the formulation of ideas throughout the study and serves to confirm the need for continued exploration of a phenomenon.

There is, however, another option within qualitative research methodology for examining relevant literature. According to Michael Quinn Patton, reviewing the literature prior to the study has the potential to predispose the researcher's thinking, which could diminish openness to developments that occur during the study. Therefore, an alternative approach is to conduct the literature review simultaneously with the study so that emerging data and relevant literature

create a collaborative source that informs the researcher’s perspective as it continually develops. Regardless of whether the researcher decides to examine the literature in the initial stages of a study or to review it throughout a study, the literature review is an essential factor to position a qualitative study and provide focus for its merit.

Organizational Format

Academic expectations and standards dictate that any research study be organized in a logical and scholarly fashion. A commonly accepted format for the organizational progression of the “pieces and parts” of a qualitative study includes classic research elements but also allows expanded creativity because of the flexible nature of qualitative research. For example, emerging data may suggest that an additional data source be added or expanded. In like manner, data analysis may point the researcher to a different body of relevant

literature that supports or disputes those themes and categories that emerge throughout the analysis process. However, an overall consistency is provided through use of those elements that are widely accepted as necessary parts of a qualitative study. A summary of the common elements found within the organizational format for a qualitative research study is delineated in Table 3.

**Organizational Format
for a Qualitative Research Study**

Data Collection

Qualitative research studies use small, in-depth samples from which to derive data. The most frequently used data collection strategies include the following:

- *Interviews.* These may be done one-on-one or in a group setting either in person or via telephone;

information may be audio- or videotaped for transcription analysis.

- *Observations.* These are direct, firsthand accounts as derived by the researcher in either a concealed or known role; they may also include the participant as an observer.
- *Documents.* These include the researcher's field notes, journals, or other printed materials such as newspapers, minutes of meetings, or other public documents.
- *Audiovisual materials.* Photographs, videotapes, or artwork are among materials used in data collection procedures.

Of these methods, interviews are the primary source of production of qualitative data. According to Donald Polkinghorne, interviews allow the qualitative researcher to obtain first-person accounts of participants' experiences. John Creswell noted that interviews with participants provide historical information that enhances understanding. The researcher designs the interview protocol so as to elicit the information needed to enlighten the research questions that focus the study. The use of open-ended questions allows participants to respond at greater depth and opens the opportunities for the researcher to ask questions that clarify any comments revealed within the context of the interview.

Data Analysis

Interpretive qualitative research designs have several key characteristics in common. The first is that the researcher strives to understand the meaning that people have constructed about an experience; he or she looks for a depth of understanding not for the future but for the present situation, the "here and now" of a setting. The second key characteristic is that the researcher serves as the primary instrument to collect and analyze data. Because understanding the human experience is the goal of the research, this human mechanism is the most ideal means of collecting and analyzing data due to the flexibility, adaptiveness, and immediacy brought to the task by the researcher. This brings inherent biases, but another characteristic of such research is to identify and monitor these biases, thus including their influence on data collection and analysis rather than trying to eliminate them. Finally, data analysis in an interpretive qualitative research design is an inductive process. Data are richly descriptive and contribute significantly as the text is used to build concepts and theories rather than to deductively test hypotheses.

It is the task of the researcher to include in the research design the method of data analysis that is to be used. Commonly accepted procedures include

phenomenological analysis, hermeneutic analysis, discourse analysis, and a variety of coding procedures. Validity and trustworthiness of findings may be achieved by using multiple data collection methods and triangulating the data gleaned from those processes.

Reporting Findings

Findings derived from a qualitative research study are commonly presented in a narrative style. The flexibility that is the hallmark of qualitative research is also present when the researcher designs the manner for presentation of findings. Sharon Merriam noted that no standard format is required for reporting qualitative research but that a diversity of styles is allowable with room for creativity. Narratives may be accompanied by commonly accepted methods such as charts and graphs or may be illustrated by photographs or drawings.

PROSPECTIVE STUDY

The term *prospective study* refers to a study design in which the documentation of the presence or absence of an exposure of interest is documented at a time period preceding the onset of the condition being studied. In epidemiology, such designs are often called *cohort studies*. Characteristic features of these designs include initial selection of study subjects at risk for a condition of interest but free of disease at the outset. The occurrence/nonoccurrence of the condition is then assessed over a time period following recruitment. The time sequencing of the documentation of the exposure and outcome is an important feature and is related to a commonly cited form of evidence toward drawing

causal inference about the relationship between the exposure and the outcome. The terms *prospective study* and *cohort study* also are usually used for observational or nonexperimental designs in which the investigator has not assigned study participants to the levels of exposure or intervention, distinguishing this design from prospectively conducted experiments or trials. In this entry, the distinction between prospective studies and retrospective studies is provided, followed by a discussion of the advantages and analysis of prospective studies and examples of influential studies.

Prospective Versus Retrospective Studies

Prospective studies may be contrasted against retrospective studies, a term that is sometimes applied to case-control studies, in which subjects are selected based on the presence or absence of disease, and exposure history is then documented retrospectively. Prospective studies, however, may use data collected entirely or partially in the past (such as through analysis of existing records for exposure or both the exposure and outcome); in this case, the distinguishing feature remains that the exposure of interest existed, and was documented, prior to the onset of the condition. Across disciplines, there is some overlap in the use of the terms *prospective study*, *cohort study*, and *panel study*. All of these terms imply a prospective design (appropriate time sequence in the assessment of exposure and outcome).

In early publications, many authors used the term *prospective study* synonymously with the term *cohort study*. In essence, *retrospective* and *prospective* can be terms that are used in conjunction with study designs such as case-control and cohort. It is possible to have both prospective and retrospective case-control studies. A case-control study would be considered prospective if the exposure measurements were taken before the outcome is ascertained (often called a nested case-control study). Likewise, it is possible to have both a prospective and retrospective cohort study. A cohort study can be classified as retrospective if the outcome has occurred before the exposure is ascertained. Cohort studies are often used as the foundation for related study designs such as case-control studies nested within cohort studies and case-cohort designs.

Confusion can exist given that both case-control and cohort designs can have both prospective and retrospective measurement elements. The prospective and retrospective distinction is often applied to the timing of subject identification and does not necessarily refer to the timing of outcome assessment relative to exposure assessment. For example, sometimes

a cohort study is identified as a retrospective cohort study, indicating that it is a cohort study that involves the identification and follow-up of subjects, but subjects are identified after completing the follow-up period.

Experimental designs, such as a randomized control trial, would always be considered prospective because the study investigators assign subjects to various exposure groups and then follow these subjects forward in time to determine some outcome.

Advantages

General advantages of prospective designs over case-control studies in terms of reduction of risk of bias include less opportunity for information error in documentation of the exposure (because this cannot be influenced directly by knowledge of the disease outcome). Potential sources of error in nonrandomized cohort studies include observer bias, respondent bias, and selection bias. Cohort studies may not include blinding to the exposure, and therefore observer and respondent bias may occur. If the exposure is known, study personnel may introduce a bias when assessing the study outcome. Likewise, if respondents are self-reporting, the outcome bias may be introduced.

Analysis

Participants may be selected purposively on the basis of being at risk of the outcome of interest and representing varying levels of the exposure of interest. Custom-designed prospective studies are often designed to select individuals at risk of the outcome within a feasible period of follow-up—for example, recruitment in middle age. Prospective studies have also been generated from representative samples (such as national-level health surveys) and combined with active or passive follow-up (such as vital statistics and hospitalization records). At the design or analysis stage, cohort studies typically require that participants be free of the condition. To ensure this, baseline screening or a wash-out period may be used (e.g., excluding the first few years of mortality).

The outcome of cohort studies is often the incidence of first occurrence of the disease. Common forms of statistical analysis procedures are based on single time-to-event data structures, including most survival analyses. More sophisticated modern analytic approaches may take into account multiple occurrences of the outcome, time-dependent covariates and studies of competing risks, as well as sensitivity analyses for loss-to-follow-up.

Historical Moments and Influential Prospective Studies

Historically, prospective studies have been conducted for more than 100 years. Richard Doll, in a 2001 article that examined the history of the method, reflected on his own work examining cigarette smoking and lung cancer. Doll noted, in response to his case-control study, that very few scientists at the time accepted the conclusion of the case-control study and that only a prospective study would be suitable. Hence, Doll and Austin Bradford Hill launched the British Doctors Study, a prospective cohort of 40,000 doctors examining their smoking habits with linkage to the vital statistics registry to obtain death records.

Further examples of influential prospective studies include the Framingham Heart Study, with more than 50 years of prospective follow-up, and the Nurses' Health Study, which started in 1976 and is tracking more than 120,000 registered nurses in the United States.

PROTOCOL

In research, *protocol* refers to the written procedures or guidelines that provide the blueprint for the research study, as well as good and ethical practices that should

be observed when conducting research, such as good etiquette when dealing with participants, adherence to ethical principles and guidelines to protect participants, compliance with institutional review board requirements, not engaging in academic dishonesty, and so on. Good protocol is a critical component of high-quality research. A well-written research protocol is particularly important for obtaining institutional review board clearance for the research, as well as for seeking funding opportunities. In addition, the written research protocol serves as a manual to guide the entire research effort, and it can also be used as a monitoring and evaluation tool to monitor progress throughout the research and to evaluate success at the completion of the research. This entry describes the structure of the written proposal and discusses other types of protocols.

Structure of the Written Research Protocol

The written research protocol is a detailed descriptive text of how the research will be conducted, and its length and complexity are affected by the nature and scope of the research. The principal investigator generally has some flexibility in determining the comprehensiveness and layout of a particular protocol; however, each research protocol must comply with the requirements (i.e., structure, context, format, length, etc.) for the institutional review board that will grant its approval. A well-written research protocol can contribute greatly to making a research effort high quality. Comprehensive information provides not only guidance and clarity on how to conduct each and every aspect of the research but also advice on what should be done (e.g., whom to contact) if an unusual situation occurs that was unforeseen. The aforementioned structure and details are fundamental to good research protocols.

Cover Page and Title

The cover page should include the full title of the study, the version number, and version date (e.g., Version 1.0 dated May 1, 2010). The document should also indicate if the protocol is a “draft” or “final” document (e.g., Draft Protocol). The title should be short and concise and also include key words such as the proposed research design, population to be investigated, and location of data collection. For example, a study on juvenile delinquency might be titled “Study of Juvenile Delinquency in Country A Using Convenience Sampling.” These key words are important to facilitate

classification/indexing of the project. A short title should also be specified for use throughout the document. The short title should be first abbreviated in the project summary. The cover page should also include the names, roles, and contact information for the primary authors/investigators/advisors, as well as any major sponsors. If this information is too much to place on the cover page, it should be placed on a separate page after the cover page.

Signature Page

This page should include the signatures of the individuals listed on the cover page.

Contents Page

This page details the various sections and appendixes contained in the protocol, along with corresponding page numbers.

Acronym/Abbreviation Page

This page provides a list of all acronyms and/or abbreviations used in the protocol, along with a definition for each one.

Summary or Abstract

The summary is the most important section of most documents/reports—the research protocol is no exception. It provides a succinct sketch (i.e., a snapshot) of the entire protocol. It is located at the front of the document but is generally prepared after the entire protocol is written. It summarizes the research objectives; presents the main research question or hypothesis; provides a brief description of the methods and procedures that will be used to conduct the research (e.g., research design, study population, place, timing of interventions); discusses the anticipated study outcomes; and provides the dates for important milestones as well as the estimated time frame and budgeted cost for the research.

Background

The background describes existing knowledge and research in the area of study. It is supported by a comprehensive literature review of both published and unpublished work that should highlight any deficiencies or gaps in existing knowledge. The justification for the study, a clear articulation of the research questions or hypotheses, and a detailed discussion of the study objectives (general and specific) are also generally

included in this section. Some protocols, however, may use separate sections to discuss one or more of the aforementioned issues. For example, objectives may be discussed under a section titled “Specific Aims of the Study,” research questions may be discussed under “Problem Statement,” and so on. Alternatively, some protocols use a section called “Introduction” instead of “Background.”

The justification should clearly outline the nature of the problem, its size, and its effect; the *raison d'être* for the study; the feasibility of the study; the potential benefits or outcomes that are expected to be derived from the study (categorized into participant, short-term/long-term, population, knowledge base, etc.); how the results might be used (e.g., national policy, organizational policy, community level, future research); how the study might help to correct the deficiency; how the study will add to the existing body of knowledge, and so on. The objectives should follow from the research questions or hypotheses—they should be smart, measurable, achievable, relevant, and time based (SMART).

Methodology

The methodology provides a detailed description of the methods and procedures that will be used to conduct the study. It includes a description of the following but may not necessarily be discussed under the separate subheads outlined below.

1. *Study Design.* This subsection describes the proposed study design (e.g., experimental, cohort, case-control) and provides justification for the choice. The selection of a particular study design is linked to the particular study objectives, ethical considerations, and availability of resources. Where an intervention is part of the research design, the protocol must discuss the intervention and note the following: frequency and intensity of intervention, venue, and entity or person in charge of the intervention.
2. *Sample Size, Selection, and Location.* The protocol should provide details on the sample size and the justification for the sample size (including chosen levels of significance and power), explain how the sample was selected (e.g., probability—random selection or nonprobability—nonrandom selection), explain how the locations and sites were selected, provide a clear listing of the inclusion and exclusion criteria for participant selection, and so on. Where informants and/or focus groups are being used, the selection criteria, number of persons participating, and so on will also need to be discussed.

3. *Unit of Analysis.* The unit of analysis—individual or group—must be discussed.
4. *Sampling Frame.* The protocol should discuss and justify the sampling frame selected for the study.
5. *Operationalization of the Variables.* All variables being investigated should be defined and operationalized.
6. *Measurement of Variables.* The protocol should specify how the variables will be measured.
7. *Incentives for Participation.* Any incentives that are being offered for participation, as well as the time and mode of delivery, should be outlined clearly.
8. *Data Collection Procedures.* Both primary and secondary data collection procedures (e.g., surveys—face-to-face/telephone/mail, focus groups, nonparticipant observation, content analysis) must be outlined and justified. In the case of secondary data sources, the source, content, and quality will also need to be discussed. Instruments being used, including interview guides, registration forms, and so on, must be appended to the protocol.
9. *Quality Control Procedures.* The protocol should clearly outline the strategies that will be used to safeguard data integrity, and thus by extension enhance overall (a) reliability (e.g., to ensure high interrater reliability, raters will be properly trained and monitored, and a code manual will be prepared to ensure that the coding process is consistent); (b) validity (e.g., face and content validity will be established by having an expert panel review the instrument); and (c) data quality (e.g., all interviewers will receive 12 hours of training that will include several demonstration exercises, the interview guide and the questionnaire will be discussed in-depth, and a pilot study will be conducted). The discussion on quality control may be incorporated under specific subheads.
10. *Data Management.* The procedures for data storage and data security should be discussed. This discussion should identify where the data will be stored or located, as well as the duration of retention (e.g., federal regulations in the United States require data retention for at least 3 years), who will have access to the data, the level of access, and so on. The procedures for data collection, coding, and validation should also be discussed.
11. *Project Management.* The procedures for managing the study should be outlined. Issues to be discussed will include staff requirements, staff training, supervision of personnel, responsibility matrix, the project schedule and work breakdown structure (generally prepared using Microsoft Project), and the project budget. If only an overview is provided of the project schedule and budget, then the detailed schedule and budget should be appended to the report.
12. *Data Analysis.* The software packages that will be used for data analysis should be described, as well as the types of analyses that will be performed (e.g., statistical, nonstatistical, analytical). In addition, other issues such as the handling of missing data, outliers, and so on should be discussed.
13. *Ethical Issues.* Ethical issues are central to research protocol. Any potential risks (e.g., physical, psychological, social, economic) to participants should be fully discussed. Measures to protect participants from possible risks or discomforts should also be fully disclosed. The manner in which informed consent is to be obtained should also be addressed. For example, in research involving certain groups (children, mentally challenged, elderly), informed consent must be obtained from a third party. In such cases, the protocol must explain how the third party will be contacted, and so on. Participants' rights to withdraw any time without risk of prejudice, penalty, or otherwise, as well as their rights to refuse to answer particular questions, should also be outlined clearly. The protocol should also outline who will provide debriefing and indemnity if participants are harmed through negligence or otherwise while participating in the study.
14. *Anonymity and Confidentiality.* Procedures for keeping the data anonymous and confidential should be outlined, as well as the procedure that will be used to assure participants that this will be done (e.g., official letter backed up by verbal assurance stating that all data will be aggregated and no individual-level data will be revealed). This is particularly important when sensitive data are involved. This discussion should be linked to data management. The data coding procedures for participant identification should also be discussed.

Limitations of the Study

The limitations of the study should be clearly outlined so that the users of the information can make informed judgments in light of the limitations.

Dissemination or Publication of Results

This section should discuss the stakeholder groups that will have access to the research findings and how the results will be communicated (e.g., written report, presentation, town hall meeting, journal article, news media). It should also discuss who will have publication rights.

References

A list of all references quoted in the preparation of the protocol should be listed in sequential order.

Appendixes

Research instruments, consent and assent forms, letter to participants assuring anonymity and confidentiality, interview guides, detailed schedules and budgets, and so on should be appended to the protocol. The curriculum vitae of each principal and secondary investigator should also be appended. If advertising is done in order to recruit participants, all recruitment materials, such as press releases and radio, television, and newspaper advertisements, should also be appended to the protocol that is being submitted for institutional review board approval.

Other Types of Protocol

In addition to the written protocol that is important for institutional review board purposes, written protocols for interview guides and schedules may also be prepared to guide the research effort in its quest for high-quality data. In addition, other types of protocol, such as appropriate behavior when dealing with participants (e.g., greeting, listening attentively to participants, keeping an appropriate distance from the participants, etc.) and dress protocol, are usually discussed in training sessions.

“PSYCHOMETRIC EXPERIMENTS”

“Psychometric Experiments” is an article written by Sir Francis Galton that described new methods for measuring human thought. He believed that if one wished to study the mind, there must be some replicable, verifiable means of measuring and quantifying its operation.

Beginning no later than 1876, Sir Francis Galton turned his extraordinarily prodigious mind to the development of a science of psychometry in Great Britain. At the same time that Wilhelm Wundt opened his experimental psychology laboratory in Germany, Galton conducted suggestive early research in psychometry. These two individuals’ approaches were similar in some ways but differed fundamentally in others. Both men were committed to the study of the human mind through introspection—Wundt by establishing rigorous experimental research methods and Galton by applying observational techniques to establish an understanding of the character of human thought. Wundt would likely agree with Galton that a discipline cannot attain the status of a science until its phenomena have been measured reliably and validly.

Wundt influenced the early development of psychology to a far greater extent than Galton; Wundt’s laboratory was associated with the University of Leipzig and attracted students internationally (e.g., J. M. Cattell, G. Stanley Hall, E. B. Titchener, and William James, to name a few), all of whom published prolifically for many decades. On the other hand, Galton, like his cousin Charles Darwin, was a wealthy individual and largely worked alone. His only disciple of considerable note was Karl Pearson. Consequently, psychological research during most of the 20th century was driven by the experimental and quasi-experimental designs formulated by Wundt and his followers. It was only in the last quarter of the 20th century that Galton’s (much-evolved) concepts of correlation and regression (e.g., multiple regression analysis, exploratory and confirmatory factor analysis, canonical correlation, and structural equation modeling) began to characterize much of psychological research.

Galton was particularly interested in the development of instruments with which to measure human mental attributes. For him, psychometry was the art of measuring and assigning numbers to the attributes of the mind (e.g., determining the response latency of

individuals). British, European, and American psychologists adopted many of his measurement tools, and some remain in use today (e.g., the questionnaire, word association tests).

In his paper “Psychometric Experiments,” Galton proposed to provide a new form of psychometric investigation in which he attempted to quantify the processes of the human mind. Two studies were reported in his paper. In the first “experiment,” Galton walked down the Pall Mall a distance of some 450 yards, focusing intently on each successive object that caught his eye. When he had generated one or two thoughts directly associated with the object, he made a mental note of each idea, then moved on to the next object. Afterwards, he calculated that he viewed approximately 300 objects during his walk that evoked a wide array of memories formed throughout his life. He noted that he recalled previous incidents of which he was not consciously aware until after the recollection occurred. Galton repeated his 450-yard walk along the Pall Mall and discovered there were many repetitions of associations from his first walk. These results, although intriguing, were not systematically recorded, and thus they were not available for statistical analysis.

In an attempt to refine his previous study, Galton constructed a list of 75 printed words. He placed the list beside himself and positioned a book on top so that when he sat back in his chair, the words would be obscured. Subsequently, he would lean forward and only one word on the list would be visible at a time. Galton sat with his pen resting on a book in his right hand and a watch in his left. He then leaned back in his chair, allowed his mind to become blank, and leaned forward to read the word and simultaneously begin timing. Once one to four ideas culminated, Galton ceased timing, recorded the associations that had occurred, the word that had been displayed, and the time shown. Trials required a maximum period of about 4 seconds. He repeated this procedure on four separate occasions at 1-month intervals.

Galton conducted 300 separate trials during this study, which resulted in a total of 505 ideas during a time span of 660 seconds. Upon completion of his experiment, Galton expressed dismay at the fact that, of the 505 ideas suggested after the culmination of four sets of trials, only 289 of the ideas had occurred without repetition. He found he could place the origin of 124 of his associations in chronological order using the following categories: boyhood and youth, subsequent manhood, and quite recent events. The majority of his ideas resided in the first two categories (39% and 46%, respectively), with 15% in the third category. He

concluded that earlier associations were better established than more recently formed associations.

Galton classified his ideas according to the nature of the word that was employed as the stimulus. He used three categories: (1) the imagined sound of words, such as one’s name or verbal quotations; (2) sense imagery; and (3) histrionic types of actions that could be performed by oneself or others. He further classified the words presented into three groups: (1) words that represented a definite image, such as abbey, aborigines, and abyss; (2) words that spawned a histrionic association, such as abasement, abhorrence, and ablution; and (3) abstract words, such as afternoon, ability, and abnormal. Within the abbey category, 43% were sense images, 11% histrionic, and 46% verbal. The abasement category consisted of 33% histrionic, 32% sense images, and 35% verbal. The afternoon category consisted of 53% verbal, 22% sense images, and 25% histrionic. At bottom, Galton found that abstract words were the most difficult about which to form associations; they took longer to generate and fewer associations were produced.

Although one may marvel at Galton’s seemingly endless desire to quantify, measure, and investigate the human condition (his motto was “Whenever you can, count”), his psychometric studies lacked technical soundness. There were few controls, and when controls were mentioned, they were not clearly described. For instance, he claimed that he ensured the complete fairness of the experiment by instituting several small precautions but failed to mention what they were. Despite this fact, Galton’s paper provided an excellent qualitative narration of the process of free association, detailed his mental processes of verbal association and generalization, and noted that the human mind has a tendency to be recursive when dealing with stimuli. Galton proposed that ideas come to fruition as associations, such as when one views an object that evokes a fresh idea or causes one to revisit a previous notion. When associations have been formed with a particular stimulus, the mind has a tendency to return to the associations when the same stimulus is encountered again. Galton hypothesized that ideas were committed to long-term memory when current associations were revisited often and were fueled by an individual’s sustained interest. The same memories become degraded when they are neglected across time.

Galton viewed the method of forming associations as automatic. He noted that this process would not normally be detected by an individual and would barely cross the threshold of his or her consciousness. He described the practice of bringing clandestine thoughts to light as laborious and mentally taxing.

Galton described the unconscious as an essential component of the human mind. Although for some, the existence of unconscious mental processes seemed highly unlikely, Galton spoke of such processes as vital and acknowledged that if the human brain was limited to only the part of it that exists within one's consciousness, it would greatly interfere with one's ability to complete daily tasks. Contemporary researchers, such as Joseph LeDoux, have made similar statements and have described the unconscious as being responsible for a myriad of mental processes that encompass the majority of mental life (e.g., evaluating, believing, judging, feeling, and imagining).

Galton has been referred to as the father of differential psychology. He noted how two individuals shown the same stimulus could have very different reactions. In 1967, John Lacey coined the term *situational stereotypy* in reference to how individuals encode and react to the same stimuli differently. Galton spoke of the difficulty of attempting to compare two persons' mental processes and acknowledged that even if both individuals were presented with a verbal sentence at the same time, the first response to any given word would differ broadly with respect to each individual.

The introspective method that both Galton and Wundt used has been criticized for its use in systematic research. For example, Galton studied his own introspections in both naturalistic and laboratory situations, but he became progressively disillusioned with the method and eventually claimed that different brain components fail to work cooperatively. Indeed, he believed that conscious thought comprised but a small fraction of the brain's largely automatic activity. The concept of consciousness traditionally implies both an *awareness* of the process of thought and also a control of behavior through *intentions*. Galton clearly questioned both of these assumptions regarding the majority of human thought and behavior.

Although his research was clearly outstripped by the overwhelming number of publications coming from Wundt and his many disciples, Galton's work in instrument development and statistical analysis was second to none. Over the course of his life, he published more than 58,000 pages of research findings. Considering his achievements in geographical exploration and mapping, meteorology, fingerprint analysis, causes of snoring, the intelligence of earthworms, and many more endeavors, it is difficult to imagine how he found time for his work in human psychology. Had he devoted his entire life to psychological studies, one can only speculate what additional discoveries he might have accomplished.

PSYCHOMETRICS

Psychometrics refers to the measurement of abilities, traits, and attitudes with questionnaires and tests. While such techniques as factor analysis and structural equation modeling can be thought to fall under the umbrella of psychometrics, this article focuses on item response theory (IRT), which studies the relationship between traits of individuals and their responses to items on a test. Although the roots of IRT are in educational testing, it has applications in many other disciplines. Much of the pioneering work in the field is attributed to Frederick Lord.

The trait studied in IRT is most often a latent trait, one that cannot be measured directly. IRT describes how a person's observable behavior, or his or her performance on a test, is related to this latent trait or ability. Characteristics of each item on the test determine the likelihood of a particular response at a given level

of ability. The purpose of IRT modeling is usually to estimate respondents' abilities, although the item characteristics may also be of interest.

Test items need to discriminate well in order to inform researchers about respondents' abilities. That is, people with lower values of the trait should tend to respond one way to an item while people with higher values of the trait respond differently. The relationship between values of the trait under consideration and the probability of a particular response is modeled with the item characteristic curve (ICC), sometimes called an item response function. The most basic IRT models are presented first, and then more sophisticated models are discussed.

Logistic and Ogive Models

Logistic and ogive curves are natural choices for modeling ICCs when items have only two response options (or are coded to be binary) because they are monotonically increasing in the latent trait and they allow the probability of a correct response, conditional on the trait, to vary from 0 to 1. Ogive curves are defined by the cumulative normal distribution and logistic curves by the cumulative logistic distribution.

Before stating the models, the notation used to refer to the test is given. θ is the ability parameter or level of the trait, and the true ability of individual i is denoted θ_i . Items are indexed with the letter j , and Y_{ij} is the response of individual i to item j . The number 1 denotes a correct answer and 0 an incorrect answer. $P_j(\theta)$ represents the probability that an individual with ability θ answers item j correctly; it is the height of the ICC curve for item j at θ . For notational convenience in working with logistic curves, define $\psi(\theta, a, b) = \{1 + e^{-a(\theta-b)}\}^{-1}$. This is the height of the cumulative distribution function (c.d.f.) of the logistic distribution with location parameter b and scale parameter a at θ . Also, define $\Phi(\theta, a, b)$ to be the height of the normal c.d.f. with mean b and standard deviation a at θ .

The Rasch model, or one-parameter logistic model, is the most basic of the logistic models for IRT. The single-item parameter b_j is a location parameter that is interpreted as the difficulty of item j . Under the Rasch model,

$$P_j(\theta) = \frac{1}{1 + e^{-(\theta - b_j)}} = \psi(\theta, 1, b_j).$$

Thus, the limit as θ approaches negative infinity of $P_j(\theta)$ is 0 and the limit as θ approaches infinity is 1. The center of the curve, b_j , is the point at which $P_j(\theta) = 1/2$.

The two-parameter logistic model (2PL) adds a scale or discrimination parameter a_j to the Rasch model. Under the 2PL model,

$$P_j(\theta) = \frac{1}{1 + e^{-a_j(\theta - b_j)}} = \psi(\theta, a_j, b_j).$$

To maintain the increasing monotonicity of the ICC, a_j must be positive. The limits of this curve are the same as for the Rasch model, and $P_j(b_j)$ is also 1/2. a_j is the slope of the ICC when $\theta = b_j$. In the Rasch model, a_j is fixed at 1. Larger values of a_j indicate better discrimination for item j . Items with better discrimination provide more information about individuals' abilities.

The three-parameter logistic model (3PL) adds a parameter c_j to account for the probability of guessing the correct answer. The ICC for the 3PL model is specified by

$$\begin{aligned} P_j(\theta) &= c_j + \frac{1 - c_j}{1 + e^{-a_j(\theta - b_j)}} \\ &= c_j + (1 - c_j)\psi(\theta, a_j, b_j), \end{aligned}$$

with $0 \leq c_j \leq 1$. The lower asymptote of this curve is c_j rather than 0, and the point at which $P_j(\theta) = 1/2$ is shifted to the left of b_j .

In the two-parameter normal ogive model,

$$P_j(\theta) = \Phi(\theta, a_j, b_j).$$

b_j is again the point at which $P_j(\theta) = 1/2$, and a_j determines the slope of the curve. The shapes of the normal ogive and logistic curves are very similar to one another. Early work in the field began with the normal ogive, but logistic models are now more popular for ease of computation. Sometimes, a scaling constant is used with a logistic curve to match it as closely as possible to the ogive curve.

The next subsection discusses methods for fitting a basic IRT model in which individuals are assumed to respond independently of one another, items are assumed to be independent of one another, and individuals and items are independent. It is also assumed that the test is unidimensional, measuring a single trait. In this case, the likelihood of observing the data matrix Y is

$$\prod_{i=1}^N \prod_{j=1}^M P_j(\theta_i).$$

Here, N denotes the number of respondents and M the number of items.

Model Fitting and Software

Analyzing a test with the above IRT model involves estimation of both the parameters of the ICCs and the ability levels of the test takers. There are many

parameter estimation techniques, a few of which are mentioned here.

Joint maximum likelihood estimation (MLE), proposed by Alan Birnbaum, alternates between estimating abilities and item parameters until these estimates meet a convergence criterion. Initial ability estimates based on the raw test score are used and the Newton-Raphson technique is used to find the MLEs. Fixing the location and scale parameters of the ability distribution ensures identifiability of the curve parameters. The computer program LOGIST uses this method. The algorithm is not well-suited for fitting the three-parameter logistic model, however, as the estimates often fail to converge.

Marginal maximum likelihood estimation, proposed by R. Darrell Bock and Marcus Lieberman and reformulated by Bock and Murray Aitkin, does not involve iterating through item and ability estimates. It is assumed that the examinees represent a random sample from a population where abilities follow a known distribution, most commonly the standard normal distribution. This allows the analyst to integrate the likelihood over the ability distribution and estimate item parameters in the marginal distribution via the expectation-maximization algorithm. The computer program BILOG implements this procedure.

A problem with maximum likelihood methods is that item parameters cannot be estimated for items that all respondents answer correctly or all respondents answer incorrectly. Similarly, abilities cannot be estimated for individuals who respond correctly to all items or incorrectly to all items. Such individuals and items are discarded before maximum likelihood estimation is carried out. A Bayesian approach to modeling IRT resolves this problem, retaining the information about abilities contained in these items and also allowing the analyst to incorporate prior information about model parameters. Prior distributions are placed on all model parameters, and then Bayes's rule is used to update the information about model parameters using the data. This results in posterior distributions for model parameters that are used for inference. A hierarchical Bayesian version of the two-parameter logistic model may be defined as follows:

$$\begin{aligned} Y_{ij} | \theta_i, a_j, b_j &\sim \text{Bernoulli}(\psi(\theta_i, a_j, b_j)) \\ \theta_i | \mu_\theta, \sigma_\theta^2 &\sim \text{Normal}(\mu_\theta, \sigma_\theta^2) \\ b_j | \mu_b, \sigma_b^2 &\sim \text{Normal}(\mu_b, \sigma_b^2) \\ a_j | \mu_a, \sigma_a &\sim \log \text{Normal}(\mu_a, \sigma_a). \end{aligned}$$

The discrimination parameter a_j is sometimes given a gamma or truncated normal prior distribution. James H. Albert proposed using the Gibbs Sampler to fit a

model similar to this one and to compute posterior means and standard deviations for item and ability parameters. A Metropolis-Hastings within Gibbs sampling strategy can also be used for this problem, and both can be extended for more complex models. WinBUGS software can be used to fit this model.

Test Information

Item and test information functions indicate how well ability is estimated over the ability scale. The Fisher information for θ is the reciprocal of the variance of the MLE for θ when item parameters are known. The test information function is given by

$$I(\theta) = \sum_{j=1}^M \frac{[P'_j(\theta)]^2}{P_j(\theta)[1 - P_j(\theta)]}.$$

Information depends only on item characteristics, not individuals' responses. It is highest for abilities in regions where the ICCs are steepest and adding items to a test increases the information. Administrators of large testing operations typically have a test bank of items whose characteristics are known and thus can design a test with the test information function in mind. If the aim of the test is to measure abilities accurately across a wide range of abilities, a mixture of difficulties is called for, whereas a test to determine if respondents meet a particular threshold ability should have many questions with difficulty levels near the threshold. Computerized adaptive testing involves estimating respondents' abilities as they take the test and choosing the next items from an item bank in such a way as to maximize the information. This generally leads to shorter tests and more accurate estimates of ability for individuals in the tails of the ability scale.

With a variety of IRT models available for explaining test responses, the questions of model choice and assessment arise. Models produce estimates of both individual abilities and the ICCs. Models with better fit should estimate both of these sets of parameters well. The fit of the ICC is often considered on an item-by-item basis. It is important to note, however, that item fit statistics are dependent upon the accuracy of ability estimates. For short tests (fewer than 15 items), ability cannot be estimated well, and ICCs, even when correctly modeled, may not appear to fit well.

A common approach for measuring the fit of a model with a categorical response is to compare observed and expected proportions of correct responses for individuals who fall in intervals of the predicted value of the latent trait. Ronald K. Hambleton and H. Swaminathan provided a list of methods for checking

the model predictions. They first recommend visual inspection of “residuals.” Individuals are placed in groups based on sorted values of ability estimates. The fitted curve is plotted along with the group average estimated ability versus group proportion correct. Along these same lines, a chi-square statistic may be calculated by forming 10 groups based on sorted ability and forming the 210 table of observed and expected frequencies where the rows correspond to correct and incorrect responses. Let $\hat{P}_{ij}$ represent the probability that respondent i answers item j correctly according to the model, and let $\bar{P}_{kj}$ be the average of these probabilities for individuals in ability group k . Also, let O_{kj} be the observed number of correct responses by individuals in group k , and let n_k be the number of individuals in group k . The statistic for item j is given by

$$Q_j = \sum_{k=1}^{10} \frac{(O_{kj} - n_k \bar{P}_{kj})^2}{n_k \bar{P}_{kj} (1 - \bar{P}_{kj})}.$$

A high value of the statistic indicates poor fit. These chi-square statistics can be difficult to use in practice as items with low or high difficulty often end up with low cell counts. They also may not have very high power for detecting misfit as deviations from the curve get averaged over a range of abilities. Cross-validation is a good tool for assessing model fit but can be too computationally intensive. A few other model fit techniques have been proposed, but a universally satisfactory statistic or method has yet to be established.

IRT allows one to evaluate the abilities of individuals who have taken different tests measuring the same latent traits by directly comparing their ability estimates. The fact that the model incorporates item characteristics makes possible this easy comparison of tests that may have different difficulty levels. This is in contrast to classical test theory, an earlier model for testing, which decomposes the observed score on a test into a “true” score and an error term. True scores are test-specific, and thus comparing abilities of individuals who have taken different tests may not be possible. Test equating is a large subfield of psychometrics. The literature gives recommendations for designing tests for equating scores of similar populations at different times (horizontal equating) and for equating tests given to populations of differing abilities such as different grade levels in school (vertical equating).

Extended Models

IRT is a rich and actively researched field. In this section, a few extensions of the basic IRT model are discussed.

One assumption of IRT mentioned earlier is that of unidimensionality. Factor analysis techniques can be used to assess the validity of this assumption. When unidimensionality is not satisfied, as may be the case in a mathematics exam that tests both computational ability and critical thinking skills, the incorrect model specification leads to bias. A few multidimensional IRT models have been proposed thus far, including the Multidimensional 2PL Model and the Multidimensional Random Coefficients Multinomial Logit Model.

One way that independence of respondents may be violated is with differential item functioning. Differential item functioning refers to differences in the probability of a correct response to an item for groups of respondents having the same standing on the latent ability measured by a test. Checking for and understanding the effects of differential item functioning are crucial for maintaining the fairness of tests.

When groups of items are dependent on one another, as is the case when a set of questions refers to the same reading passage, a testlet model may be employed. Several Bayesian testlet models that account for item dependence have been proposed.

Many questionnaires use scaled response, and test items may also have a scaled or ordinal response. Fumiko Samejima’s graded response model handles this type of data. The idea behind graded response is that a respondent’s hypothetical “true” response falls along a continuous scale, and the scale categories offered as responses encompass a range of responses on the continuum. The probability of giving a particular response is calculated as the area under a normal curve in the region of the range of the response. The mean and variance of the normal curve are conditional on the respondent’s trait level. Graded item response models can be fit with the programs MULTILOG and PARSCALE. Other models for polytomous items include the partial credit model, generalized partial credit model, and the rating scale model.

Models also exist for nominally scored data. In standardized tests that use a multiple-choice format, the responses are typically scored as correct or incorrect and analyzed with a model for binary data. Information about a respondent’s ability can be lost in this recoding of data as ability level may influence which wrong response is chosen. Bock’s nominal model makes use of the multivariate logistic distribution to provide item response functions for the nominal responses. MULTILOG also fits this model.

The logistic and normal ogive parametric models that are the base for all models described so far assume a specific shape for the ICC. If the model is incorrect, ability estimates are biased. Nonparametric approaches offer more flexible models for the ICC that may

provide a better fit than the parametric alternative. Kernel smoothing, or local averaging, is one approach for nonparametric estimation of ICCs. It is implemented in J. O. Ramsay's computer program Testgraf. Raw scores are used for initial estimates of ability, and the height of the ICC at a point is a weighted average of responses of examinees with abilities near this value. After the ICCs are computed, new MLEs for ability are estimated. This method may result in nonmonotonic curves if restrictions are not placed on the kernel smoother. Bayesian semiparametric and nonparametric methods for modeling monotonic ICCs make use of Dirichlet process priors.

IRT has provided the community of psychometric practitioners with a versatile tool for modeling tests and abilities. Advances in the field are bringing more accurate models, which in turn give more accurate ability estimates. This is an important achievement with the prevalence of high-stakes testing in today's society.

PURPOSE STATEMENT

A purpose statement is a declarative statement that summarizes a research project's main goal or goals. A purpose statement provides some guidance in establishing a research question and serves as an introduction to the resultant paper or dissertation chapter.

Developing the Purpose Statement

At the beginning of a research project, it is helpful for the researcher to use a declarative sentence to state the main goal or goals of the project in specific terms. Statements that begin with the phrase "I wish to learn . . ." or "I plan to examine . . ." can be helpful insofar as they can move the topic's abstract notions to a concrete research question, which is the springboard for the resultant research design. Furthermore, a purpose statement can ground the researcher, providing a point of reference to which the researcher may return, particularly as the study increases in complexity. However, this does not imply that the purpose statement is final, because the researcher may revise the statement as needed. If external factors such as unavailability of relevant data force the researcher to make substantial changes to his or her research design, he or she may want to update the purpose statement to reflect those changes.

Using the Purpose Statement

In addition to serving as a catalyst for the underlying research project, a purpose statement can be worked into subsequent papers or dissertation chapters derived from the project. Always near the end of the introduction, a purpose statement states the paper's intent, scope, and direction. Specifically, it provides for an abbreviated preview of the paper's main topic, while avoiding a discussion of the author's specific conclusions.

In research papers, purpose statements often start with phrases such as "This paper examines . . .," "The main purpose of this study is to . . ." or "The aim of this article is to . . ." Purpose statements should be specific and precise, and should avoid vague, ambiguous, or confusing language. This ensures that there is no doubt in the reader's mind as to the research project's intended direction.

Introductions: Purpose Statements Versus Thesis Statements

A purpose statement also serves as the foundation for a thesis statement, which provides assertions about the topic at hand and summarizes the author's conclusions. Unlike a purpose statement, a thesis statement provides a cursory answer to the question and is developed after the researcher has gathered evidence, which is presented in the body of the research paper.

The decision to use a thesis statement in the introduction is determined by the underlying norms of the specific discipline, as well as the author's preferences. In

some cases, the author may simply state the paper's intended purpose at the outset, delaying the discussion of any results until the end of the paper. At the very least, a research paper introduction should provide a discussion of the research question and some information about how the author intends to explore the question, even if the answers are not presented until the conclusion.

Examples of Thesis and Purpose Statements

Ineffective purpose statement #1: "This paper examines the impact of elites upon elections." It is unclear about what types of elites, what types of elections, or even which potential electoral effects the researcher intends to examine.

Effective purpose statement #1: "This paper examines the extent to which public endorsements by political elites shape electoral participation, particularly in proposition elections where the traditional information shortcut of partisanship is absent."

Thesis statement #1: "Elite cues help increase electoral participation because they provide information shortcuts to potential voters who may not be fully

informed about the details of a given electoral contest."

Ineffective purpose statement #2: "This paper examines changes to election laws." In addition to being nonspecific as to what types of election laws are being examined, it is unclear as to whether the author is examining the sources of those changes, or the potential impact of those changes.

Effective purpose statement #2: "This paper examines the potential impact of the straight-ticket voting option upon electoral down-ballot outcomes."

Thesis statement #2: "Although Illinois Republicans appeared to eliminate the straight-ticket option in 1997 for partisan reasons, evidence suggests that Democrats might have actually benefitted from this ballot format change."

Q METHODOLOGY

Q methodology is a combination of conceptual framework, technique of data collection, and method of analysis that collectively provides the basis for the scientific study of subjectivity. This is distinguished from R methodology, which provides the basis for the study of what is objective in human behavior. Innovated in the mid-1930s by British physicist–psychologist William Stephenson, Q methodology focuses on opinions and perspectives that are gathered using the well-known Q-sort technique. These data are then submitted to factor analysis, pioneered by Stephenson’s mentor Charles Spearman, which reveals the segmentation of subjectivity inherent in the substantive domain under consideration. Given the ubiquity of subjectivity, Q methodology applies to all areas of human endeavor—social attitudes, decision making, administration, the arts and humanities, cultural values, policy, economics, education, and so on, and including the natural and physical sciences insofar as subjective substructures undergird the theories and understandings used to explain objective facts. The focus on subjectivity in Q methodology requires departures from conventional applications of sampling, experimental design, and factor analysis. This entry provides information on the conceptual framework, data collection, and analysis of Q methodology, along with resources for additional information.

Concourse of Subjective Communicability

Q methodology has its roots in *concourse*, a term coined by Stephenson that refers to the universe of

subjective communicability surrounding any topic, of the kind found in ordinary conversation, back-fence gossip, commentary deposited on Internet blogs and exchanged in chat rooms, and extending to the high-level discourses of epistemic communities across all the sciences. Facts are invariably interlaced with opinions and the division between the two turns on the principle of self-reference, its absence in R methodology, and its centrality in Q. Hence, it is one thing to state that “free-flying wild birds can be a source of avian influenza,” which is a matter of fact, and another to assert that “scientific surveillance of wild birds should be maintained worldwide,” which is an opinion. The latter is self-referential to those who assert it, and it is apt to be accompanied by other opinions from the same concourse—for example, that “compartmentalization would reduce risk for introduction of AI viruses via trade,” that “there is an immediate need to promote international research programs to develop better vaccines,” and so forth.

The volume of opinion constitutes the universe of communicability that, in principle, is infinite in magnitude. Unlike sampling in surveys, where population boundaries can be specified and the number of cases is finite, the boundaries of communicability cannot be fixed and its content is limitless. Concourse is not restricted to statements of opinion. The population of impressionist art also constitutes a concourse, as do the universes of novels, musical compositions, political cartoons, landscapes, and flavors of ice cream; in short, any collection of stimuli, linguistic or otherwise, for which individuals might express preferences. A defining feature of concourse is that its contents are generally untestable and incapable of falsification; however, they remain subject to measurement.

Q-Sample Structuring and Experimental Design

Concourses are typically voluminous, as are person populations in survey research, and one of the steps in Q methodology involves reducing the concourse to a small sample of statements suitable for experimentation. As an illustration, consider the following statements, which were among more than 200 drawn from the media and interviews prior to the 2003 U.S. war with Iraq:

1. We should take this opportunity to free the Iraqi people from a dictator.
2. War will make more terror attacks likely.
3. I feel divided. On the one hand, we have to take a stand so that the world knows we mean business. On the other hand, I don't want America to start a big war.

As a counterpart to random sampling in survey research, the statement population in Q methodology is modeled theoretically (typically according to R. A. Fisher's experimental design principles), and statements are then selected in terms of the model. In this instance, examination of the concourse revealed statements compatible with the view of the U.S. administration (such as statement 1 above) and statements that were contrary to the regime's position (statement 2), but also statements that expressed ambivalence or reticence (statement 3), and virtually all of the statements in the concourse found easy placement in one of these three categories.

As a device for increasing diversity and breadth in the Q sample, all statements were reexamined and located in one of the three categories comprising Harold Lasswell's concept of *perspective*: For example, statement 1 expressed a *demand* (from a pro-regime standpoint), statement 2 an *expectation* (from an anti-regime standpoint), and statement 3 an *identification* (from a reticent point of view). All 200 statements were subsequently placed in one of the $(3)(3) = 9$ cells of the factorial design in Table 1, and $m = 5$ replicates from each cell were selected, for a Q-sample size of $N = (5)(9) = 45$ statements. Each of the statements was then typed on a separate card, resulting in a pack of 45 cards for subsequent Q sorting.

Q Sorting

Q technique is the most widely known feature of Q methodology, and its popularity far exceeds awareness of the more abstract methodology that it was invented to serve. Q sorting consists of ranking the items in a Q sample according to some condition of instruction, typically from *mostly agree* to *mostly disagree*. Table 2 provides an example in terms of the Iraq War study; hence, this person agreed with statements 18, 22, and 45:

18. We have a professional army and the best military technology on the planet. The Iraqi army is no match.
22. The world would be safer without Saddam.
45. The United States has a duty to protect itself and the world.

and disagreed with statements 17, 30, and 40:

17. We're acting like a terrorist regime ourselves and only seem to be in this for self-interested capitalist motives.
30. This is a racist war, a campaign of genocide. We're just taking our 9/11 frustrations out on Iraq.
40. I must admit the idea of war scares me, and frankly I'd rather not hear about it.

This person obviously supports the impending conflict and at least manifestly embraces assertions emanating from the regime while denying with equal intensity propositions issued by counter elites.

The width of the range in Table 2 is relatively unimportant and has no statistical impact (nor does the shape of the distribution), but several principles concerning the Q sort are of considerable importance. First, as should be apparent, there is no correct way to perform the Q sort: It is a wholly subjective affair, which means that issues of validity are largely irrelevant. In a science of subjectivity, there can be no external criterion by which to validate "my point of view." Second, the distribution should ideally range from *mostly agree* to *mostly disagree*, with *nonsalience* in the middle. This principle draws on 19th- and early 20th-century psychophysics, such as the work of Gustav Fechner and J. G. Beebe-Center, as well as

Table 1 Q-Sample Structure (Iraq War)

Main Effects	Levels			n
(A) Regime	(a) pro	(b) reticent	(c) anti	3
(B) Perspective	(d) demand	(e) identification	(f) expectation	3

observations dating from the earliest times down to Sigmund Freud's principle of pleasure-unpleasure and including the extremes of Likert scales. Third, meaning distends in opposite directions from zero and becomes most vivid at the extremes, as indicated in the tendency for Q sorters to feel most strongly about statements placed at the extremes and to be relatively nonengaged with respect to those located near zero. (Both of the above principles depend on a Q sample that is balanced in terms of the perspectives at issue; e.g., pro-regime vs. anti-regime.) Fourth, the forced distribution in Table 2 has the status of a *model*, in this case, a model of the Law of Error. Virtually all of the literature that has promoted an unforced (free) distribution has done so under the mistaken assumption that the forced distribution distorts how people would actually behave if unconstrained, rather than that it is an intentional constraint (although not without behavioral support) for inducing participants to reveal their preferences. Fifth, the statements in the Q sort are entangled; that is, they interact in a single Q-sort setting, and each is implicitly compared to, and achieves its score in relationship to, all others. (Entanglement is a signal feature of quantum mechanics, with which Q methodology demonstrates striking parallels.) This is in marked contrast to the situation in R methodology where a score obtained on a measured trait by any single individual is wholly independent of the scores obtained by other individuals for the same or any other trait. Sixth, the subjective character of both concourse and Q sorting necessitates (where feasible) a post-sorting interview so as to permit participants to elaborate upon their Q sorts; that is, to clarify the meanings that they attributed to the statements (which may be other than the meanings assigned in Table 1) and to justify the salience (from +4 to -4) that they assigned to each.

This a posteriori determination of meaning is in marked contrast to R methodology, where scale meaning is achieved a priori in terms of validity and reliability tests that are carried out before responses are obtained.

Based on the 3×3 factorial design in Table 1, the Q sort in Table 2 could be analyzed in terms of the following variance components:

$$\Sigma d^2 = \Sigma A^2 + \Sigma B^2 + \Sigma AB^2 + \Sigma R^2$$

$$df(44) = (2) + (2) + (4) + (36),$$

where Σd^2 is the Q-sort total sum of squares, ΣA^2 is the regime effect, ΣB^2 is the sum of squares due to perspective, ΣAB^2 is the regime $\times$ perspective interaction, and ΣR^2 is the replication variance (within-cell error). As noted at the beginning, however, the focus on subjectivity in Q methodology necessitates departures from conventional research assumptions, among them that items have an agreed-upon meaning as they do in scaling and as they would be required to have for the calculation of means and variances necessary for the application of ANOVA. It is for this reason that the utility of variance designs is restricted to the composition of Q samples where they serve the important purpose of ensuring stimulus *representativeness*, a principle first advanced by Egon Brunswik. Beyond that, variance analysis yields to the operational principle and is superseded by correlation and factor analysis, which respond to the way in which participants actually operated with the statements rather than the way in which the investigator structured them.

It is to be noted that the sample of persons who perform the Q sort (P set) is also usually selected on the basis of experimental design procedures and is typically

Table 2 Q-Sorting Distribution

<i>Mostly Disagree</i>					<i>Mostly Agree</i>			
-4	-3	-2	-1	0	+1	+2	+3	+4

			(6)	39	(6)			
				(7)				

balanced or semi-balanced for gender, age, party identification, or other salient variables arranged factorially. The P set is normally small (typically in the range of 30–50 participants), but as diverse as possible. The goal is for a representative set of participants to respond to a representative set of stimuli so as to maximize the likelihood that whatever subjective segmentations are in circulation will have an opportunity to reveal themselves.

Correlation and Factor Analysis

Data analysis is illustrated in terms of an experiment on literary interpretation, an area of study rarely examined by other quantitative methods but easily attended to using Q methodology due to the subjectivity involved. The focus in this instance is on the poem *Piano* by D. H. Lawrence, the reading of which produced a diversity of reactions that were subsequently reduced to a Q sample of size $N = 30$ critical comments including three levels of *reaction* (positive, negative, mixed) cross-classified with three kinds of *poetic concern* (emotion, technique, sense) in a 3×3 factorial arrangement. After reading the poem, eight graduate students of literature were instructed to provide their appraisals of the poem by Q sorting the statements from *agree* (+4) to *disagree* (–4), and Table 3 contains an abbreviation of the scores given the 30 statements by two of the students, X and Y.

The formula for Pearson's correlation when means and standard deviations are the same (as they are when Q sorts adhere to the same forced distribution) is $r_{XY} = 1 - \frac{\Sigma d^2}{2N\sigma^2}$, where $N = 30$ statements, σ^2 is the variance of the Q-sort distribution, and Σd^2 is the sum

of squared differences in statement scores between the two Q sorts. Under these conditions, $2N\sigma^2$ is a constant and equivalent to the composite sums of squares of the two Q sorts (182 + 182 in this case); hence, the

correlation between X and Y is $r_{XY} = 1 - \frac{82}{364} = .77$, which signifies a high degree of similarity between the two interpretations of the poem. The standard error of the correlation is given by $\sigma_{r=0} = \frac{1}{\sqrt{N}} = \frac{1}{\sqrt{30}} = .18$, and $2.58(.18) = .47$ indicates that correlations exceeding $\pm .47$ are significant ($p < .01$).

Given the $n = 8$ Q sorts, their intercorrelations result in an 8×8 correlation matrix, which is then factor analyzed using either of the two dedicated software packages, QMethod and PCQ (both of which can be accessed at www.qmethod.org), or by SPSS. Although principal components analysis (PCA) and varimax rotation are the most commonly used procedures in R methodology, investigators who use Q methodology are more inclined toward centroid factor analysis and increasingly toward theoretical rotation, although varimax is frequently used. Centroid analysis and theoretical rotation are both supported by the QMethod and PCQ programs, as are PCA and varimax.

The reasoning behind these analytic preferences again turns on the phenomenon of subjectivity and the alteration in conventional analytic practices that this focus demands. The centroid solution is indeterminate (i.e., is one of an infinite number of solutions), and although varimax injects determinacy into the solution, it does so based on a statistical principle (simple structure) that is assumed to apply in any and all situations. Theoretical rotation, by way of contrast, takes context into consideration (in conformity with J. R. Kantor's principle of specificity) and as a result is increasingly relied upon as a way to find solutions that are *operant* (i.e., genuinely functional) as opposed to merely statistical. Implementation of theoretical rotation involves the graphical plotting of factor loadings in two-dimensional Cartesian space and manually rotating them so as to reveal suspected or hypothesized effects, and thereby relies on the abductive logic of Charles Peirce.

Table 4 shows the factor loadings for the eight participants, who offered three different interpretations of the poem, with Participant 1 advancing one interpretation (Factor A), Participants 2–5 advancing another (Factor B), and Participants 6–7 yet another (Factor C); Participant 8's response is mixed. The standard errors for correlations shown above apply to factor loadings, which are therefore significant in this case if in excess of $\pm .47$. The Q sorts comprising a factor are merged to provide a single Q sort, and this is effected by first weighting each response in terms of its factor loading:

Table 3 Q-Sort Scores

	X	Y	d^2	X^2	Y^2
1	1	1	0	1	1
2	–1	2	9	1	4
3	4	4	0	16	16
⋮	⋮	⋮	⋮	⋮	⋮
28	3	–1	16	9	1
29	0	1	1	0	1
30	–1	3	16	1	9
Σ	0	0	82	182	182
σ	2.46	2.46			

Table 4 Factor Loadings

	A	B	C
1	71	27	-04
2	-21	68	-21
3	-12	67	28
4	09	67	21
5	-23	56	-21
6	-19	-03	57
7	-06	31	59
8	50	-52	28

Note: Decimals omitted; significant loadings are in boldface.

$w = \frac{f}{1-f^2}$, where f is the factor loading and w is the weight. Consequently, in the case of Factor 2, Q sort 2 is weighted $w_2 = 1.26$ and Q sort 5 is weighted $w_5 = .82$, the latter therefore weighing only 65% of the former in the calculation of the factor scores. The factor scores are then calculated by multiplying each statement's Q-sort score by the weight and then summing each statement across the weighted Q sorts comprising the factor, with weighted statement sums then being converted into a factor array presented in the form of the original +4 to -4 metric.

Examining Factor A, it is apparent that the persons comprising this factor have responded favorably to the poem, as shown in the four statements below (factor scores for A, B, and C, respectively).

The determination of significant differences among factor scores depends on factor reliability, which depends in turn on the reliability of the individual Q sorts. Adopting $\bar{r}_{1,2} = .80$ as a conservative estimate of average individual test-retest reliability, factor reliability is given by $r_{xx} = \frac{(.80)p}{1+(p-1).80}$, where p is the number

of persons defining the factor; hence, for Factor B, with $p = 4$ persons defining the factor, $r_{BB} = .94$. The standard error of factor scores is given by $\sigma_f = \sigma\sqrt{1-r_{xx}}$, where σ is the standard deviation of the Q-sort distribution (in this instance, from Table 3, $\sigma = 2.46$) and σ_f is the standard error; hence, for Factor B, $\sigma_{fB} = .60$. Given that Factor A has only $p = 1$ defining Q sort, its factor reliability is $r_{AA} = .80$ and the standard error of its factor scores is $\sigma_{fA} = 1.10$. The standard error of the difference in factor scores between Factors A and B is obtained by $\sigma_d = \sqrt{\sigma_{fA}^2 + \sigma_{fB}^2} = \sqrt{1.10^2 + .60^2} = 1.25$, which, when multiplied by 1.96 and rounded up to the nearest whole number, indicates that differences of 3 or more between scores for Factors A and B can be considered significant ($p < .05$). Based on this criterion, statements (a), (c), and (d) below can be seen to distinguish Factor A from the other two factors; statement (b) distinguishes Factor A from Factor B, but not from Factor C. Statistical information of this kind, which is routinely provided by the QMethod and PCQ software packages, along with postsorting interviews, comprise the main ingredients for the interpretation of factors.

Factor Interpretation

Arguments and inferences in R methodology typically depend on the matrix of factor loadings, which reveals the connections among variables, but the factor loadings in Table 4 are of lesser interest in Q methodology inasmuch as the person sample is small and non-representative by survey standards. Interest in Q methodology instead focuses on the array of factor scores, as with statements (a) to (d) above, because the factor scores reveal the subjectivity at issue, in this case concerning poetic interpretation. Interpretation is also more intricate in Q methodology because statements can, and frequently do, take on different meanings to different people, and to the same people in different settings, as opposed to scale items carrying meanings that have been established a priori.

+4	-2	-2	(a) The striking thing is that the poet knows quite well that this reversion to a childhood incident is sentimental, but he does not try to make capital out of the sentiment.
+4	-2	+4	(b) One is made keenly aware of the strange relationship of past and present experience—one feels the emotion the poet experienced through his identity with and separation from his past self.
-4	+3	+2	(c) The triviality of the sentiment is equaled only by the utter puerility of the versification.
-4	-1	+4	(d) This poem is false. One worships the past in the present, for what it is, not for what it was. To ask for the renewal of the past is to ask for its destruction.

In this regard, consider the Q-sort responses of 15 pediatric oncology patients concerning the fatigue that they experienced during treatment. The responses resulted in three factors, the first of which (Factor X) assigned positive scores to the following distinguishing statements (scores in parentheses for Factors X, Y, and Z, respectively):

I had energy (+4, 0, -3). I felt great (+4, +2, -4). I had enough energy to play as hard as I wanted (+3, -3, -3). I was so tired that I needed to rest during the day (+2, 0, -1). I had enough energy to play sports (+2, -2, -4).

The statement about needing rest provided a clue indicating that these patients had incorporated a rest period into their regimen that enabled them to regenerate and lead otherwise normal lives. Factor Y, on the other hand, told a different story (scores for Factors X, Y, and Z, respectively):

Being tired made it hard to keep up with my friends (-1, +4, +1). Being tired made it hard to concentrate (+1, +4, +1). Being tired made me sad (-3, +3, -3). My tiredness was hard on my family (-2, +2, -1). I was too tired to watch television (-1, -4, 0). I felt sleepy (+3, -2, +3).

The relative emphasis on concentration and sadness led to a conclusion that fatigue was affecting these patients in cognitive, emotional, and social ways that might require counseling to reactivate them and get them out from in front of the television. Note, however, that their fatigue did not spill over into sleepiness. Finally, Factor Z:

I feel tired (+2, -1, +4). I felt weak (+1, +1, +4). Being tired made me mad (-3, +1, +3). I had trouble finishing things because I was too tired (0, -1, +2).

These patients felt weak and not just tired, and unlike Factor Y, their emotional reaction was one of anger rather than sadness, hence providing them with a motive force for improvement that Factor Y lacked.

The above are bare caricatures of the three factors, which contained interesting nuances that could be drawn out only through careful and prolonged examination of the factor arrays. The results led to suggestions for crafting a questionnaire, based on the Q factors, that could serve as a screening device aimed at distinguishing patients who were experiencing one of these three reactions to fatigue. Factor X patients already have control over their lives and require little in the way of assistance, whereas the Factor Y and

Factor Z patients require different therapeutic interventions. The interpretive phase of a Q study has much in common with hermeneutics as well as narrative and discourse analysis, and it is at this point that Q methodology resembles qualitative methods, despite its roots in variance design and factor theory. As a practical matter, the factors that it produces represent the vital signs of human subjectivity and serve as decision structures that point in promising directions of implementation.

Resources

Additional information about Q methodology can be found at www.qmethod.org, including information on an electronic discussion group and the International Society for the Scientific Study of Subjectivity. Three journals specialize in Q-related studies: *Operant Subjectivity*, *Journal of Human Subjectivity*, and the Korean language *Q-Methodology and Theory*. Books on Q methodology are also now available in Korean, Persian, Romanian, and Thai.

Q-STATISTIC

Q-statistic is a nonparametric inferential test that enables a researcher to assess the significance of the differences among two or more matched samples on a dichotomous outcome. It can be applicable in a situation in which a categorical variable is defined as success and failure. The data are distributed in a two-way table; each column, j , represents a sample and each row, i , a repeated measure or a matched group. Thus, the Q -test is

$$Q = \frac{k(k-1) \sum_{j=1}^k (T_j - \bar{T})^2}{k \sum_{i=1}^n u_i - \sum_{i=1}^n u_i^2}, \quad (1)$$

where T_j is the total number of successes in the j th sample (column), u_i is the total number of successes in the i th row, and k is the total number of samples. A most convenient equation to compute the Q -statistic is

$$Q = \frac{(k-1) \left[k \sum_{j=1}^k T_j^2 - \left(\sum_{j=1}^k T_j \right)^2 \right]}{k \sum_{i=1}^n u_i - \sum_{i=1}^n u_i^2}. \quad (2)$$

Cochran developed this test under a permutation model because the population of possible results in the i th row consists of the $\binom{k}{u_i}$ different combinations of the u_i successes among the k columns, and their results pertaining to the null case are asymptotic (Blomqvist, 1951). If the true probability of success is the same in all samples, the limiting distribution of Q , when the number of rows is large, is the χ^2 distribution with $k - 1$ degrees of freedom because the joint distribution of the column totals T_j may be expected to tend to a multivariate normal distribution with a common variance-covariance matrix.

Approximations to Q-Statistic

Usually, the χ^2 test is used to make inferences about ratios or percentages, but when the samples are correlated, the use of this test violates the assumption of the independence among the samples compared.

The Q -test is an inferential statistic developed by the statistician William Gemmell Cochran (1909–1980) that arises as an extension of the McNemar test.

The McNemar test examines the significance of the differences between ratios or percentages of two correlated samples. The Q -statistic allows for the evaluation of the null hypothesis of equality between ratios or percentages for more than two matched samples under a permutation model, so it can be simplified to McNemar's test when there are only two samples.

The Q -statistic is also equivalent to the sign test when the samples are small and there are no significant outliers. The sign test was developed for testing the median difference of independent paired observations.

The distribution of the Q -test for small samples has been approximate to the χ^2 and F test using a correction for continuity. However, rows containing only 1s or 0s can yield quite different results using the F approximation without affecting the value of the Q -statistic. Although the F test, corrected for continuity, can get a better approximation than the corrected or not χ^2 in the same cases, the latter has been taken as the common approximation because it is easier to calculate. Nevertheless, as those computations are run by computers today, the possible application of the corrected F approximation should be considered.

The accuracy of the Q -statistic in small samples depends on the number of conditions as well as the sample size; the χ^2 approximation seems good enough with a total of 24 scores or more, deleting those rows with only 1s or 0s. After deleting those rows without variation, if the total product, columns by rows, is less than 24, the exact distribution should be constructed. The distribution of Q -test can be obtained by the method that Patil proposed in 1975 or by Tate and Brown's 1964 $r \times c$ tables, where the probabilities vary in dimensions from 3 columns and 12 rows to 6 columns and 4 rows.

Finally, the Q -statistic has been also tested under a model for dichotomous responses obtained in experiments within which randomization is not necessarily incorporated, and it remains appropriate for testing the null hypothesis that all measured conditions yield the same percentage of successes.

Example

A hypothetical example is presented here to make clearer the context and how the Q -statistic is used. Imagine we want to examine the effect of an intervention to give up smoking. A sample of $n = 8$ subjects was evaluated immediately after the intervention and in three more time periods, $k = 4$, to assess the maintenance effect of the intervention. At each assessment (T_j), the participant's response was dichotomized as

smoking or not, and giving up smoking (u_{ij}) was considered the success. Their distribution is presented in Table 1.

In this example, the four times that the participants were evaluated are like four samples with the same group of subjects (repeated measures), so either this kind of design or one in which there are different groups of matched individuals are considered correlated samples. The Q -statistic is used in those cases to test the hypothesis that the percentage of successes does not change across samples or, in our example, across time

$$H_0 : P(T_1) = P(T_2) = \dots = P(T_j),$$

versus the alternative hypothesis that at least two of the samples present statistically significant differences.

Following our example, and considering the total data in Table 1 with $n = 8$, $k = 4$, and row and column total as shown, the differences across time can be tested:

$$\sum_{j=1}^{k=4} T_j^2 = 8^2 + 5^2 + 4^2 + 1^2 = 106,$$

and

$$\sum_{i=1}^{n=8} u_i^2 = 1^2 + 3^2 + 4^2 + \dots + 3^2 + 3^2 = 50.$$

Table 1 Effect of the Intervention for Eight Individuals to Give Up Smoking at Four Evaluations Across Time

Individual	Time Period				Total, u_i
	T_1	T_2	T_3	T_4	
1	1	0	0	0	1
2	1	1	1	0	3
3	1	1	1	1	4
4	1	1	0	0	2
5	1	0	0	0	1
6	1	0	0	0	1
7	1	1	1	0	3
8	1	1	1	0	3
Total, T_j	8	5	4	1	$\sum_1^{32} u_{ij} = 18$

Substituting in Equation 2, we obtain

$$Q = \frac{3[4(106) - 18^2]}{4(18) - 50} = 13.64.$$

The Q value obtained with $k - 1 = 7$ degrees of freedom has a probability in its approximation of a χ^2 distribution (because the total of scores is higher than 24) of $p = .003$. Therefore, it is possible to conclude that the effectiveness of the intervention differs significantly across time. After this analysis, some post hoc multiple comparisons can be carried out to analyze the linear, quadratic, and/or cubic trends across time or across the matched samples.

Another design for which we will apply this technique is when the groups are matched and it is necessary to know if it is possible to assume homogeneous percentages of the dichotomy response among the matched groups. Matched groups is an experimental method for controlling different individual characteristics (e.g., age, sex, race, socioeconomic status) because of their possible influence on the results. Thus, the subjects in one group are matched on a one-to-one basis with subjects in other groups concerning those different individual characteristics that have been previously tested.

Several software packages (e.g., IBM® SPSS® Statistics, formerly called PASW® Statistics, and Stata) contain this statistic, and usually the input is the columns for each sample with the outcome, coded with 0s and 1s, and the output is the Q -statistic, number of subjects, number of repeated measures or matched groups, degrees of freedom, and upper-tail p value.

The Variability of a Combination of Estimates From Different Experiments

It is important to note that a statistic also called Q -statistic was developed by Cochran in 1954 in order to have a test of significance of the variation in response among effect sizes from different experiments. Thus, it is usually used to assess whether there is true heterogeneity in research synthesis methodology.

The Q -test is computed by summing the squared deviations of each study's effect estimate from the overall effect estimate, weighting the contribution of each study by its inverse variance as

$$Q = \sum w_i (T_i - \bar{T})^2, \quad (3)$$

where w_i is the weighting factor, inverse of the estimated variance of the effect size, $\hat{\sigma}_i^2$, for the i th study assuming a fixed-effects model ($w_i = 1/\hat{\sigma}_i^2$), and $\bar{T}$ is

$$\bar{T} = \frac{\sum_i w_i T_i}{\sum_i w_i}. \quad (4)$$

If we assume that the conditional within-study variances, σ_i^2 , are known, under the null hypothesis of homogeneity ($H_0 : \delta_1 = \delta_2 = \dots = \delta_k$; or also $H_0 : \tau^2 = 0$), the Q -statistic has a χ^2 distribution with $k - 1$ degrees of freedom, k being in this case the number of integrated studies. Thus, Q values higher than the critical point for a given significance level (α) enable us to reject the null hypothesis and conclude that there is statistically significant between-study variation. If the homogeneity assumption is not met, the meta-analyst has to look for moderator variables to explain the heterogeneity; sometimes, assuming a random-effects model, which includes the within- and between-study variability, allows one to accept the null hypothesis.

A weakness of the Q -statistic is that it has poor power to detect true heterogeneity among studies when the meta-analysis includes a small number of studies and excessive power to detect negligible variability with a high number of studies.

Example for Q -Statistic in Meta-Analysis

Some data sets from a meta-analysis about the efficacy of tailored intervention through computers for health behavior are introduced here. The treatment and control groups were compared using the standardized mean difference, d , as an effect size metric (T). The effect size values for eight studies are presented in Table 2.

Substituting in Equations 4 and 3 the values of our example,

$$\bar{T} = \frac{(68.1446 \times 0.25) + \dots + (222.8813 \times 0.12)}{68.1446 + \dots + 222.8813} = 0.24$$

$$Q = (68.1446 \times (0.25 - 0.24)^2) + \dots + (222.8813 \times (0.12 - 0.24)^2) = 45.66,$$

it is possible to conclude that the distribution of the effect sizes is not homogeneous because the probability of the Q value with 7 degrees of freedom is lower than .05.

QUADRATIC ASSIGNMENT PROCEDURE

The quadratic assignment procedure (QAP), also known as the *Mantel test*, was initially designed for two-dimensional associations by Nathan Mantel in the 1960s and was further developed by Lawrence Hubert in the 1980s. The Hubert test is appropriate for any problem formulated as a correlation between a Cartesian product of two matrices. This entry discusses the development and use of the QAP, the details of the procedure, and the extension of the QAP to multiple regression QAP.

QAP is a nonparametric significance test for correlating one-mode and two-mode networks (after

conversion to a one-mode network) and matrix-like network attributes. Many square matrices with the same dimensions can be correlated (e.g., actors for which the type of relation or attributes have been defined). QAP is usually based on Pearson's r correlation (the Pearson product-moment correlation coefficient) in which we use a point-biserial correlation coefficient for binary and continuous variables, and a phi-coefficient for binary only variables. Matrices with binary and value data (e.g., interval, ordinal) are allowed, which indicate the strength of the relationship. Correlating matrices of a different nature of data does not change the interpretation of the correlation coefficients in which we control the effects due to the dependencies of the observations.

Researchers in social sciences use QAP to study various types of relationships and dependencies between formal and informal networks of relationships in the education and health-care systems, pointing to the transfer of knowledge, the organization of hospital work, or the motivation and psychological behavior of the studied population. Each social or nonsocial relationship in the system (e.g., education, health) influences the behavior of others, the interactions, and the flows that shape a given network structure.

Procedure

The empirical confidence interval is around the zero value and not around the sample value, making QAP consistent with classical hypothesis testing. Samples in QAP permutation tests are randomized without replacement. This permutation (reestimation) is repeated to obtain an empirical sampling distribution. QAP uses this permutation procedure to create an observed sampling distribution that reflects the new null hypothesis of no association that correctly takes into account the correlation between observations. The procedure repeats the permutations multiple times and recalculates the association measure on each iteration. The resulting distribution corresponds to the distribution under the null hypothesis. This test allows researchers to check how often the observed network structure could have evolved by chance. The larger the N , the greater the ability to reject the zero value when it must be rejected. If the number of nodes is n , the number of observations will be $n(n-1)/2$ for undirected networks and $n(n-1)$ for directed networks. The p value will be lower with a larger N . Using a large number of permutations stabilizes the p values. The node order changes randomly, but not the lattice structure. The generated distribution allows researchers to calculate the statistical significance of the variable. The correlation remains unchanged, but the p values are smaller

and the standard deviation of the correlation between the permuted matrices is smaller. A low percentage ($p < 0.05$) suggests a correlation between matrices that is unlikely to occur by chance.

To obtain random permutations, the popular UCINET program, which utilizes a random number generator, is used. This generator creates a stream of arbitrary numbers based on a random seed. The same seed, the same stream of random permutations. UCINET switches the seed randomly each time it is started. To re-create any result to the same value, the same seed setting is needed. The QAP test does not offer the possibility of modeling the dependency structure or obtaining standard errors. Only the correlation coefficient and its p value are available. Permutations affect only the significance, not the parameters of the model. QAP is immune to the autocorrelation problem (especially when the observations are interdependent), often adopted in networks.

Multiple Regression QAP

Correlating the network of relationships with QAP enables researchers to use innovative statistical tools, in which the QAP test is only a starting point for more advanced tools in cross-sectional or longitudinal studies, with a particular emphasis on multiple regressions in network analysis. QAP is used to make a statistical statement on the correlation coefficient based on vectorized network data, usually omitting the diagonal. QAP uses a row and column permutation; hence, the dependent and independent variables are used to simulate the null condition, resulting in a simulated null distribution of regression coefficients. Typically, one network is the observed network, while the other is the model or expectation network. Dyadic hypotheses assume that if a given pair of actors has a specific type of relationship, they are more likely to have a different kind of relationship.

QAP is mainly limited to examining the relationship between at least two networks (variables), but it is not, however, used to assess the impact of one network variable on another network variable. For this purpose, network variable regression tools are used. QAP has been extended to a multiple regression called MRQAP, in which multiple matrices (independent variables) are used to predict the dependent variable. The regression coefficients are estimated in the same way as for standard regression. MRQAP regresses many independent variables on dependent variable, allowing researchers to test the overall R^2 and the intersection with the random null hypothesis. The observed matrices are compared with the permutations of the random matrices for the p value calculation, while the

regression coefficients are computed using ordinary least squares (OLS). The OLS regression is then repeated with this new permuted matrix, resulting in different beta coefficients.

QUALITATIVE DATA ANALYSIS SOFTWARE

Qualitative data analysis software (QDAS) packages, also referred to as *computer-assisted qualitative data analysis software* (CAQDAS), can be used not only to analyze data but also to collect data, transcribe audio and video recordings, conduct literature reviews, and write up findings. Different from statistical software, with these platforms, researchers can choose how to organize, store, and structure their semi- or unstructured data alongside other documents related to a given study in a systematic way that is aligned with their methodological approach. Thus, researchers can use QDAS packages as comprehensive project management platforms. This entry highlights the ways in which QDAS packages can be used to carry out a variety of research tasks, presents best practices for describing the use of QDAS in research reports, and provides guidance on selecting a package.

Analytic Activities Supported by QDAS

QDAS packages provide a suite of various management and analysis tools. These activities can be supported

using QDAS platforms but are not necessarily used by all researchers in all studies. Different QDAS packages can support these activities to a greater and lesser extent. As part of the adoption process, researchers should investigate a package's available features, which are often found on the product website.

Organizing and Managing Data

At the most basic level, QDAS packages can be used to organize data and other project-related documents in one place. In many ways, this organizational system serves to support researchers in generating a rich and detailed audit trail of their decision-making process. QDAS packages support importing not only various data sources (e.g., audio- and video-recorded interactions, observational field notes, web pages, documents, social media conversations, photographs, interviews, responses to open-ended survey questions) but also relevant research project files (e.g., ethics board approval forms, data collection instruments, researcher journals). Furthermore, even relevant literature can be imported and associated with the broader project file. Social media data (such as Twitter feeds) and spreadsheet files of survey data can be imported into many of the QDAS packages for analysis. Using these platforms makes sharing data (with collaborators or in relation to a data repository) more straightforward. In addition, data can be stored and organized in ways that are relevant to the unique project focus. The organizational capacities of QDAS packages allow for greater transparency of the research process and support collaboration in ways that paper-based files cannot.

Reviewing the Literature

Features within QDAS can be used to carry out the entire literature review in a given package. Because literature reviews are very similar to conducting a thematic analysis of a qualitative data set, QDAS can be leveraged to conduct a paperless literature review process. Some of the available QDAS packages support directly importing bibliographic data from reference management software packages (e.g., Endnote, Mendeley, Zotero), streamlining the workflow.

Generating Data

QDAS packages can also help with generating data. Some packages have mobile apps or can be synchronized with cloud-based tools such as Evernote to record notes, take photos or videos, or record geographical locations in the field. These data points then can be exported and uploaded to the full project via file

shares. Research journals can be generated using the writing tools in QDAS packages, and, if appropriate, journal entries can be treated as data to be analyzed alongside the rest of the data set.

Transcribing Audiovisual Data

Most QDAS packages support the transcription of audio and video recordings. Keyboard shortcuts, foot pedals, and in some instances, specialized transcription symbols (e.g., Jeffersonian) are supported. The researcher must still do the transcription, but the software allows synchronization of the transcript with the original media files (audio and/or video recordings). This means that by simply clicking on a particular line in a transcript, the researcher can listen to or watch the original recording. By doing this, a researcher can read and listen to both *what* was said and *how* it was said, while keeping close to the data. Notably, many of the QDAS packages provide tools to analyze audio or video recordings directly without first transcribing them. This is particularly useful for researchers working with large, interactional data sets in which they do not transcribe the data set in its entirety.

Analyzing and Interpreting Sources of Data

QDAS packages provide multiple tools for analyzing data. These tools include text searches, word frequency counts, word clouds, and auto-coding, among other features. Memo tools support the annotation of data while reading, viewing, or listening to it. Coding tools allow labeling of segments of data—be it text-based data, video or audio recordings, or even images or photographs—in analytically meaningful ways. Once all related segments are labeled with codes, they can be retrieved together and reviewed. This is particularly useful as a researcher moves from low-level to high-level inferences. Once all the data are coded, the researcher can then query the data set for patterns of codes among various groups to help answer research questions that may require such comparisons. Visualization tools are also available in most packages, providing a way to see various relationships between data sources, coded data, memos, and the previously reviewed literature.

Writing and Reporting Research Findings

The reporting features output all coded data and other analytic outcomes to be reviewed and integrated into the final research report. This report can be written up within the same QDAS package or exported into text files or spreadsheets for writing outside of the package.

Accounting for the Use of QDAS in the Research Report

Since there is more than one way to use software to support a qualitative research study, researchers should articulate in their Methods section how the tool was used. This includes indicating which version of the software was used; using active voice rather than passive voice when describing their use of the software so as not to attribute agency to the tool; providing a brief description of what the software is, what it is used for, why it was selected, and which features or tools were used and how; providing software outputs as part of the data display and findings; and substantiating any claims of increased study rigor with specific details of how software use improved quality.

Selecting a QDAS package

Determining which QDAS package can be overwhelming for novices. Many of the packages are not natively Mac or Linux programs, though most are now cross-platform. An initial consideration is to identify which packages offer the needed features for the platform that will be used (e.g., check to see whether transcribing directly within a package is possible in the Mac version of the software). Generally, a list of features is available on the company website or within the user manual, so one can review it to ensure that the selected software can support the intended use. Among the critical questions to ask prior to adopting a QDAS package are

- Is it possible to import XML files from citation management software in order to analyze annotated PDFs for a literature review?
- Can the needed data type be easily imported and analyzed (e.g., video files, social media data, survey data)?
- Are there mobile apps that might be used for data collection purposes?
- Is it possible to import, transcribe, and synchronize audio/video files?
- Is it possible for research team members to view and analyze the data synchronously?
- Will research team members need to work within the same QDAS package or is working across platforms possible?

Table 1 outlines some of the main QDAS packages, their country of origin and date of initial release, as well as the supported platform (as of 2020).

When deciding which QDAS package to adopt, it is helpful to turn to the software reviews available online via the CAQDAS Networking Project at the University

Table I Some Current QDAS Packages

<i>Software</i>	<i>Country of origin and date of initial release</i>	<i>Supported platform (as of 2020)</i>
ATLAS.ti	Germany, 1993 (Scientific Software Development GmbH)	Windows Mac Cloud Android iPad
Dedoose	USA, 2009 (originally EthnoNotes)	Web-based
Elan	The Netherlands, 2002 (The Language Archive, Max Planck Institute)	Windows Mac Linux
EXMARaLDA	Germany, 2011 (Hamburg Centre for Language Corpora)	Windows Mac Linux
f4analyse	Germany, 2012 (audiotranskription)	Windows Mac Linux
Heurist	Australia, 2005 (University of Sydney)	Open-source MySQL database
HyperRESEARCH	USA, 1991 (ResearchWare)	Windows Mac
Leximancer	Australia, 2005 (University of Queensland)	Windows Mac Cloud
LiGRE	Canada, 2017	Web-based
MAXQDA	Germany, 1989	Universal Windows/Mac Android iOS
NVivo	Australia, 1981 (originally NUD*IST, now QSR International)	Windows Mac
QDA Miner	Canada, 2004 (Provalis Research)	Windows Mac via virtual machine Linux using CrossOver or Wine
Quirkos	Scotland, 2013	Windows Mac Linux Quirkos Cloud
RQDA	Hong Kong, 2008	Windows Mac Linux
SONAL	France, 2009	Windows
Transana	USA, 2001	Windows Mac Transana Cloud
WebQDA	Portugal, 2010 (Universidade de Aveiro)	Web-based

of Surrey. The project's website is particularly helpful in assisting researchers in their decision-making process. Other considerations include whether a researcher has institutional access to and support for a particular QDAS package. Generally, it is best to start with the QDAS package supported at one's institution with campus-wide licenses and/or training and support. If collaborators are using a particular software package, it may be useful to adopt the same one. Usefully, the majority of software companies offer free trial versions, as well as reduced-rate student versions. Free virtual introductions, face-to-face trainings, and specialized online trainings are available for most packages. YouTube is a source of a range of tutorials. Attending in-person training whenever possible is important, given that many QDAS packages can be challenging to learn on one's own. Finally, an important recent development is the launch of the open REFI-QDA standard that enables exchange of processed data between various QDAS platforms. This means that the programs can now "talk" to each other, making it possible to work across more than one platform. Packages participating in this exchange are ATLAS.ti, Dedoose, f4analyse, MAXQDA, NVivo, QDA Miner, Quirkos, and Transana.

QUALITATIVE RESEARCH

Qualitative research, also known as qualitative inquiry, is an umbrella term used to cover a wide variety of research methods and methodologies that provide holistic, in-depth accounts and attempt to reflect the complicated, contextual, interactive, and interpretive nature of our social world. For example, grounded theory, ethnography, phenomenology, ethnomethodology, narratology, photovoice, and participatory action research (PAR) may all be included under the qualitative label, although each of these individual methods is based on its own set of assumptions and procedures. What unifies these various approaches to inquiry is their primary reliance on non-numeric forms of data (also known as empirical evidence) and their rejection of some of the underlying philosophical principles that guide methods employed in the physical and natural sciences and frequently in the social sciences. This entry focuses on the philosophical frameworks positioning qualitative research and on qualitative research designs.

Positioning Qualitative Inquiry

At the heart of the distinction between these various scientific methods are differing ontological, epistemological, and theoretical worldviews. Ontology refers to the nature of reality. Ontological questions interrogate fundamental ideas about what is real. Epistemology refers to a theory of knowledge. Epistemological discussions interrogate how we know the world, who can know, and what can be known. Theoretical perspectives are the philosophical stances that provide the logic and the criteria that organize methodology (the overall research strategy) and methods (the specific tools or techniques used in collecting and interpreting evidence). In short, basic philosophical differences in these worldviews have a direct impact on the research design. Coherent research designs demonstrate consistent and integrated ontological, epistemological, theoretical, and methodological positions.

Most qualitative research starts from a constructivist epistemological position and from one of a variety of theoretical perspectives, such as interpretivist, feminist, or critical inquiry. Constructivists believe in the socially constructed nature of reality. This idea that reality is generated through social interaction and iterative processes has dramatic implications for addressing the basic epistemological questions raised above and thus for the methodologies and methods employed. Constructivists reject the basic premise that an objective researcher discovers truths from preexisting data. Instead, they believe in what Norman Denzin and

Yvonna Lincoln have called an “intimate relationship” between the researchers and the phenomenon under investigation. Marianne Phillips and Louise Jorgensen argue, based on the work of Vivien Burr and Kenneth Gergen, that constructivist approaches share four basic premises: a critical approach to taken-for-granted knowledge that is often overlooked or ignored, an interest in historical and cultural specificity, a link between knowledge development and processes, and a link between knowledge development and social action.

Within the constructivist epistemological tradition, there are many different theoretical schools of thought. Interpretivism has spawned a family of related traditions such as symbolic interactionism, phenomenology, and hermeneutics. For example, in his classic work on symbolic interactionism in 1969, Herbert Blumer summarized the three basic premises underlying his work: Humans act toward things on the basis of meaning that those things have for them; meaning is derived from, or arises out of, social interaction with others; and meanings attach and are modified through an interpretative process during interactions. Note that at the heart of symbolic interactionism is a belief that reality is not stable and pre-existing but rather is socially constructed and given meaning only through ongoing interactions. Critical theorists believe that social action and social reform are an integral part of any research endeavor. Today’s critical inquiry was heavily influenced by the 1972 work of Paulo Freire, *Pedagogy of the Oppressed*, which fueled important discussions about power relationships, oppression, exploitation, empowerment, democracy, social justice, and action-based research. Feminists in the 1970s and beyond have furthered these theoretical discussions, raising basic questions such as those posed by Sandra Harding in the title of her seminal book published in 1991, *Whose Science? Whose Knowledge?*

In general, qualitative researchers are interested in studying social processes, how people make sense and create meaning, and what their lived experiences are like. They are interested in understanding how knowledge is historically, politically, and culturally situated. They concern themselves with notions of power, privilege, positionality, and social justice. They are likely to acknowledge research as a value-laden activity and embrace the idea that the researcher himself or herself is an instrument in the process. Often, they try to re-create experiences, understanding, and meanings from the point of view of those being studied rather than positioning themselves as the final interpretative authority or expert.

Qualitative research is sometimes contrasted with quantitative research. It is worth considering the distinctions. Most quantitative endeavors start from an

objectivist epistemological perspective and a positivist theoretical position. Because quantitative analysis and statistical techniques are consistent with positivist assumptions about both the nature of social reality (an ontological issue) and the relationship between the “knower” and the “known” (epistemological issues), they tend to dictate how studies are designed and evaluated. Positivists are apt to believe in a stable reality and attach a premium to the objectivity, neutrality, and expertise of the scientist studying it. The research process is considered value-neutral. Variables or standardized instruments are used to measure phenomena and test relationships. Research designs must be carefully constructed in order to ensure that the mathematical assumptions that underlie statistical tests are met. The goal is often to generalize findings to larger populations.

Constructivist critiques of the objectivist perspective include concerns that these positivist methodologies tended to ignore or minimize contexts (such as political, historical, or cultural factors); they ignored the meanings people attached to their actions or experiences; they were divorced from real-world settings; they focused on generalizable results that were of little use to individual decision makers; they tended to favor testing pre-existing hypotheses and theories rather than generating new ones; they favored deductive logic over inductive approaches; and they were reductionistic rather than holistic and thus did not adequately account for the complexity of social phenomena. An oft-repeated characterization holds that quantitative research is a mile wide and an inch deep, whereas qualitative research is a mile deep and an inch wide.

In short, it is critical to understand that qualitative inquiry starts with a very different relationship to social reality than that of most quantitative researchers. Constructivists challenge positivist views about the nature of reality, how to study it, who can know, what knowledge is, and how it is produced. This influences every aspect of the research design. So qualitative research will look markedly different—at every stage of the design and implementation process—than quantitative research.

Qualitative Research Designs

Because a variety of different methods fall within the scope of qualitative research, it is difficult, even dangerous, to make generalizations about designs. Readers should consult methodologists who specialize in a particular form of inquiry to learn about the rules of that particular method. That said, what follows is a summary of features that tend to be associated with qualitative inquiry.

Overall Design

Qualitative designs are emergent and flexible, standing in stark contrast to quantitative research designs in which a hallmark feature is their fixed and predetermined nature. Qualitative work is sometimes characterized as “messy,” not because the researcher is sloppy but because the process is not strictly controlled and must be adapted to the realities of the environment. Designs often rest on inductive approaches to knowledge development. They may be value-driven, acknowledge the politics of the research endeavor, be attentive to power differentials in the community, and promote social justice or social change.

Role of the Researcher

In qualitative inquiry, the researcher is often called an “instrument” or “tool” in the process. This characterization acknowledges that all interpretations and observations are filtered through the researcher, who brings his or her own values and identity to the process. Qualitative researchers talk about situating themselves relative to the research project and participants. For example, they may be insiders (share characteristics with those studied) or outsiders or some combination of both. Furthermore, the researcher’s role can fall anywhere on a continuum of action from unobtrusive observer to full participant. Many designs call for the researcher to be a participant-observer. Action-based approaches to inquiry tend to characterize the role of the researcher as collaborator.

In short, qualitative research designs are more apt to require the researcher to make his or her position, role, and influence transparent. This is unlike approaches that try to minimize or neutralize the researcher’s presence. Qualitative researchers are expected to critically examine and disclose their position. They do this by being “self-reflexive.” Michelle Fine has written about “working the hyphen,” a metaphor that is useful in acknowledging actors on both sides of the researcher-participant equation.

Research Question

The framing of a qualitative research question will depend on the method. However, such questions tend to be both broad and flexible. They are not variable-driven, so they do not seek to link concepts and posit relationships. A common feature is that the research question evolves during the process. For example, Elliot Liebow, an ethnographer, started his study on homeless women by asking the research question: How do homeless women see and experience homelessness? His

initial position was that he knew nothing about what their lives were like. However, in his final report, he ended up asking and answering the question “How do homeless women remain human in the face of inhuman conditions?” This occurred because during the process of his data collection and analysis, he learned enough about homeless women’s experiences to answer a more sophisticated, complicated, and interesting research question about their lived experiences.

Study Site

Qualitative studies most often take place in natural environments. Researchers want to observe how people live and act in the real world, not when they are removed from these settings. For this reason, they are likely to study people and things “in the field,” which can refer to any natural environment such as social agencies, prisons, schools, rural communities, urban neighborhoods, hospitals, police stations, or even cyberspace.

Study Sample

Qualitative researchers use very different sampling strategies from quantitative researchers. Large, random, representative samples are rarely, if ever, the goal. Qualitative researchers are more apt to use some form of purposive sampling. They might seek out people, cases, events, or communities because they are extreme, critical, typical, or atypical. In some qualitative methods, sampling may be based on “maximum variation.” So, the idea is to have as diverse a pool on the characteristics under investigation as possible. These studies are likely to be exploring the breadth and depth of difference rather than similarities. Sampling may be theoretically driven. For example, grounded theory is a method that seeks to generate mid-level theory as a research product. For this reason, it uses theoretical sampling strategies, picking new cases on the basis of the emerging theory.

“Data” or Empirical Evidence Collection

In general, the empirical evidence used in qualitative inquiry is non-numeric and is collected in one or more of three basic forms: through *interviews and/or conversations* (either one-on-one or in groups), through *observations* (either unobtrusive or as a participant), and/or through *documents and artifacts* (either pre-existing or generated as part of the research process).

Interviews can be unstructured, semi-structured, or structured (although this is rarely favored). Questions are usually open-ended and seek to give the participant

an opportunity to answer fully. Their purpose is often to explore meaning, understanding, and interpretations rather than to treat the interviewee as a vessel for retrieving facts. Interviews can be conducted with multiple individuals, such as in focus groups. They are often audiotaped or videotaped. These tapes can then be transcribed (using any number of different formats and transcription techniques) for easier analysis.

Observations occur in natural settings. The researchers must spend considerable time recording observations (through memos, jottings, and field notes) to preserve them for future use. It is critical that these notes be written during field observation or as soon thereafter as possible while they are fresh in mind because they serve as the empirical evidence for use during analysis.

Documents or artifacts used in qualitative work can be pre-existing, such as newspaper articles, client case files, legislative documents, or policy manuals, and are collected by the researcher. Alternatively, documents or artifacts may be generated as part of the research process itself, such as asking subjects to keep journals, take photographs, or draw pictures. For example, in a neighborhood safety study, children might be asked to draw a map of their route between home and school and to mark the scary places. In an action-based method known as photovoice, participants take community-based photographs that are then used as a springboard for advocacy efforts.

Empirical Evidence Analysis

Obviously, the form of empirical evidence analysis must be appropriate for the methods employed. Some common methods of qualitative analysis include thematic analysis, constant comparative methods, discourse analysis, content analysis, and narrative analysis. For example, some researchers conduct thematic analysis where they closely examine their texts (interviews, field notes, documents), apply codes, and develop themes. Researchers engaged in narrative analysis look at the way life stories are structured, such as the divorce narratives studied by Catherine Reissman. Discourse analysis seeks to reveal patterns in speech. Similarly, conversational analysis looks closely at the structure, cadence, and patterns in ordinary conversations such as Douglas Maynard's study on how "good news" and "bad news" are delivered in clinical medical settings. Ethnographers review their field notes, interview transcripts, and documents and may take an interpretative approach to analysis. Action-based research methods often call for the study participants to play an active role in co-constructing information, so the analysis and interpretation do not reside solely in the hands

of the "expert" researcher. Many qualitative researchers employ a procedure known as "member checking," where they take their preliminary interpretations back to participants to check whether those interpretations ring true.

Some qualitative researchers use computer software programs to aid them in their work; others do not. There are a number of different software packages available, such as HyperResearch, NVivo, Atlas.ti, QDA Miner, and AnSWR, among others. They can be useful in helping the researcher manage, organize, and retrieve large amounts of text, videos, images, and other forms of qualitative evidence. However, unlike statistical software, it is important to recognize that qualitative programs are not designed to "analyze" data itself. Virtually every aspect of qualitative analysis process relies heavily on the interpretative and analytic procedures carried out by the researcher.

Findings and Writing Reports

Qualitative research reports often read very differently from traditional scientific reports. For example, it is common for qualitative researchers to use the first person in their writing rather than the third person often found in quantitative reports. These voice preferences are traceable to the epistemological roots discussed above. First-person narrations may appear odd to those trained to read and think about the researcher as a detached, objective, neutral observer, but they are consistent with epistemological and theoretical worldviews that posit that the researcher plays an active role in the process. Furthermore, because qualitative researchers do not attempt to measure phenomena, they rarely report quantity, amounts, intensity, or frequency and are more likely to present their findings as complicated and detailed narratives. In 1973, Clifford Geertz first introduced the term *thick description* to describe the rich and contextual writing that is often the product of ethnography or other cultural studies. However, this can be controversial. Norman Denzin and Yvonna Lincoln have noted the "crisis in representation" that first occurred among anthropologists, who worried about the politics and ethics of their textual representation of "others." Qualitative researchers often speak of "giving voice" to their study participants and attempt to stay close to the words and meanings of their informants.

Quality and Rigor in Qualitative Research

It is important to evaluate the quality of qualitative studies relative to standards that are applicable to the specific research method used. Sometimes, qualitative

researchers refer to negotiated validity, trustworthiness, transferability, transparency, and credibility as quality indicators. For example, Joseph Maxwell has argued for a broad understanding of validity with multiple dimensions such as descriptive validity, interpretive validity, theoretical validity, internal generalizability, and evaluative validity. Yvonna Lincoln and Egon Guba argued for judging case studies based on resonance, rhetoric, empowerment, and applicability.

QUALITY EFFECTS MODEL

The quality effects model is a method of statistical synthesis of data from a set of comparable studies of a problem, and it yields a quantitative summary of the pooled results. It is used in a process called *meta-analysis* where there is an aggregating of the data and

results of a set of studies. The process is widely used in the biomedical sciences, especially in epidemiology and clinical trials.

Weighting by Inverse Variance

Because the results from different studies investigating different independent variables are measured on different scales, the dependent variable in a meta-analysis is some standardized measure of effect size. One of the commonly used effect measures in clinical trials is a relative risk (RR), when the outcome of the experiments is dichotomous (success *vs.* failure). The standard approach frequently used in meta-analysis in clinical research is termed the *inverse variance method* or *fixed-effects model* based on Woolf and first proposed by Gene Glass in 1976. The average effect size across all studies is computed, whereby the weights are equal to the inverse variance of each study's effect estimator. Larger studies and studies with less random variation are given greater weight than smaller studies. In the case of studies reporting an RR, the logRR has a standard error (SE) given by

$$SE_i = \sqrt{\frac{(1 - P_{iT})}{P_{iT}n_{iT}} + \frac{(1 - P_{iC})}{P_{iC}n_{iC}}},$$

where P_{iT} and P_{iC} are the risks of the outcome in the treatment group and control groups, respectively, of the i th study and n is the number of patients in the respective groups. The weights (w) allocated to each of the studies are inversely proportional to the square of the standard error. Thus,

$$w_i = \frac{1}{SE_i^2},$$

which gives greater weight to those studies with smaller standard errors. The combined effect size is computed by the weighted average as

$$\overline{ES} = \frac{\sum (w_i \times ES)}{\sum w_i},$$

where $\overline{ES}$ is the effect size measure, and it has a standard error given by

$$SE_{\overline{ES}} = \sqrt{\frac{1}{\sum w_i}}.$$

Assuming these estimates are distributed normally, the 95% confidence limits are easily obtained by $Lower = \overline{ES} \pm 1.96(SE_{\overline{ES}})$.

The Conventional Approach to Heterogeneity

As can be seen above, the variability within studies is incorporated in the current approach to combining the effects by adjusting based on the variance of the estimates in each individual study. So, if a study reports a higher variance for its RR estimate, it would get lesser weight in the final combined estimate and vice versa. Although statistically very appealing, this approach does not take into account the innate variability that exists between the studies arising from differences in the study protocols and how well they were executed and conducted. This major limitation has been well recognized and gave rise to the random effects model approach. Selection of the random effects model is often carried out using a simple test of homogeneity of the studies involved because of the demonstration that, in the presence of even slight between-study heterogeneity, the fixed effects model results in inferences that substantially underestimate the variation in the data and in parameter estimates. Nevertheless, despite widespread use of this adjustment for heterogeneity, it is now thought that the choice of fixed effects or random effects meta-analysis should not be made on the basis of perceived heterogeneity but rather on the basis of purpose. The fixed effects meta-analysis tests the null hypothesis that treatments were identical in all trials. When and if this is rejected, then the alternative hypothesis that may be asserted is, "There is at least one trial in which the treatments differed." In other words, the random effects analysis works as a check on the robustness of conclusions from a fixed effects model to failure in the assumption of homogeneity and cannot go beyond this causal *finding*. Because

$$SE_{\overline{ES}} = \sqrt{\frac{1}{\sum w_i}},$$

the addition of an external constant will also inflate the variance much more than a redistribution of the weights—if the studies demonstrate varying effects. Furthermore, if a random variable is inserted to inflate the variance based on heterogeneity, it is not clear what aspect of between-trial differences is being assessed and fails to take into account any meaningful differences between the individual studies. Stephen Senn has provided an analytic demonstration of this in his article "Trying to Be Precise About Vagueness." Another problem is that inserting a random variable to inflate the variance based on heterogeneity does not clarify what aspect of between-trial differences is being assessed and fails to take into account any meaningful differences between the individual studies. As such, when used in a meta-analysis of poorly designed studies, it will still

result in bad statistics even though there is statistical adjustment for heterogeneity.

The Quality Effects Approach to Heterogeneity

Suhail A. R. Doi and Lukman Thalib proposed another approach to adjustment for between-study variability by incorporating a *relevant* component (quality) that differs between studies in addition to the weight based on intrastudy differences that are used in any fixed effects meta-analysis model. The strength of the quality effects meta-analysis is that it allows available methodological evidence to influence subjective random probability and thereby helps to close the damaging gap that has opened up between methodology and statistics in clinical research. This is done by introducing a correction for the quality-adjusted weight of the i th study called $\hat{\tau}_i$. This is a composite based on the quality of other studies except the study under consideration and is used to redistribute quality-adjusted weights based on the quality-adjusted weights of other studies. In other words, if Study i is of poor quality, the removed proportion of its quality-adjusted weight is mathematically equally redistributed to all other studies, giving them more weight toward the overall effect size. As studies increase in quality, redistribution becomes progressively less and ceases when all studies are of perfect quality. To do this, weights first have to be adjusted for quality, and one way to incorporate quality scores into such an analysis is as follows:

$$\overline{ES} = \frac{\sum (Q_i \times w_i \times ES_i)}{\sum (Q_i \times w_i)},$$

where Q_i is the judgment of the probability (0–1) that Study i is credible, based on the study methodology. The variance of this weighted average is then

$$SE^2 = \frac{\sum (Q_i^2 \times w_i)}{(\sum (Q_i \times w_i))^2}.$$

However, this probabilistic viewpoint on quality-adjusted weights fails to redistribute the removed weight, and Doi and Thalib do this as follows: Given that $\hat{\tau}_i$ is the quality adjustor for the i th study and N is the number of studies in the analysis, then Q_i can be modified to $\hat{Q}_i$ as follows:

$$\hat{Q}_i = Q_i + \left(\frac{\hat{\tau}_i}{w_i} \right),$$

where $\hat{\tau}_i = \left(\sum_{i=1}^N \tau_i - \tau_i \right)$ and $\tau_i = \frac{w_i - (w_i \times Q_i)}{N - 1}$.

This definition of $\hat{\tau}_i$ has been updated recently to make redistribution proportional to the quality of the other studies rather than equally, as in the definition of $\hat{\tau}_i$ above, and this updated $\hat{\tau}_i$ is given by

$$\hat{\tau}_i = \left(\sum_{i=1}^N \tau_i \times N \times \frac{Q_i}{\sum_{i=1}^N Q_i} \right) - \tau_i.$$

The final summary estimate is then given by

$$\overline{ES}_{(QE)} = \frac{\sum (\hat{Q}_i \times w_i \times ES_i)}{\sum (\hat{Q}_i \times w_i)},$$

and the variance of this weighted average is then

$$v_{\overline{ES}(QE)} = \frac{\sum (\hat{Q}_i^2 \times w_i)}{\left(\sum (\hat{Q}_i \times w_i) \right)^2}.$$

Although it may seem that $\hat{Q}_i$ is a function of w_i , given that $(\hat{Q}_i \times w_i) = (Q_i \times w_i) + \hat{\tau}_i$, it would mean that by multiplying $\hat{Q}_i$ with w_i , we are actually adjusting the product of quality and weight by $\hat{\tau}_i$, and by definition, the latter is a function of the quality and weights of other studies excluding this i th study. This suggested adjustment has a parallel to the random effects model, where a constant is generated from the homogeneity statistic

$$Q = \sum (w \times ES^2) - \frac{\left[\sum (w \times ES) \right]^2}{\sum w},$$

and using this and the number of studies, k , a constant (τ^2) is generated, given by

$$\tau^2 = \frac{Q - (k - 1)}{\sum w - \left(\frac{\sum w^2}{\sum w} \right)}.$$

The inverse of the sampling variance plus this constant that represents the variability across the population effects is then used as the weight

$$\left(w_{(R)i} = \frac{1}{SE_i^2 + \tau^2} \right).$$

In effect, as τ^2 gets bigger, the $SE_{\overline{ES}}$ increases, thus widening the confidence interval. The weights, however, become progressively more equal, and in essence, this is the basis for the random effects model—a form of redistribution of the weights so that outlier studies

do not unduly influence the pooled effect size. This is precisely what the quality effects model does too, the only difference being that a method based on quality is used rather than statistical heterogeneity, and $SE_{\overline{ES}}$ is not as artificially inflated as in the random effects model. The random effects model adds a single constant to the weights of all studies in the meta-analysis based on the statistical heterogeneity of the trials. This method redistributes the quality-adjusted weights of each trial based on the measured quality of the other trials in the meta-analysis.

Software

This method has been incorporated into version 1.7 of the MIX program, which is a comprehensive free software for meta-analysis of causal research data available from the MIX website.

QUANTITATIVE RESEARCH

Quantitative research studies produce results that can be used to describe or note numerical changes in measurable characteristics of a population of interest; generalize to other, similar situations; provide explanations of predictions; and explain causal relationships. The fundamental philosophy underlying quantitative research is known as positivism, which is based on the scientific method of research. Measurement is necessary if the scientific method is to be used. The scientific method involves an empirical or theoretical basis for the investigation of populations and samples. Hypotheses must be formulated, and observable and measurable data must be gathered. Appropriate mathematical procedures must be used for the statistical analyses required for hypothesis testing.

Quantitative methods depend on the design of the study (experimental, quasi-experimental, nonexperimental). Study design takes into account all those elements that surround the plan for the investigation, such as research question or problem statement, research objectives, operational definitions, scope of inferences to be made, assumptions and limitations of the study, independent and dependent variables, treatment and controls, instrumentation, systematic data collection actions, statistical analysis, time lines, and reporting procedures. The elements of a research study and experimental, quasi-experimental, and nonexperimental designs are discussed here.

Elements

Problem Statement

First, an empirical or theoretical basis for the research problem should be established. This basis may emanate from personal experiences or established theory relevant to the study. From this basis, the researcher may formulate a research question or problem statement.

Operational Definitions

Operational definitions describe the meaning of specific terms used in a study. They specify the procedures or operations to be followed in producing or measuring complex constructs that hold different meanings for different people. For example, intelligence may be defined for research purposes by scores on the Stanford-Binet Intelligence Scale.

Population and Sample

Quantitative methods include the target group (population) to which the researcher wishes to generalize and the group from which data are collected (sample). Early in the planning phase, the researcher should determine the scope of inference for results of the study. The scope of inference pertains to populations of interest, procedures used to select the sample(s), method for assigning subjects to groups, and the type of statistical analysis to be conducted.

Formulation of Hypotheses

Complex questions to compare responses of two or more groups or show relationships between two or more variables are best answered by hypothesis testing. A hypothesis is a statement of the researcher's expectations about a relationship between variables.

Hypothesis Testing

Statements of hypotheses may be written in the alternative or null form. A directional alternative hypothesis states the researcher's predicted direction of change, difference between two or more sample means, or relationship among variables. An example of a directional alternative hypothesis is as follows:

Third-grade students who use reading comprehension strategies will score higher on the State Achievement Test than their counterparts who do not use reading comprehension strategies.

A nondirectional alternative hypothesis states the researcher's predictions without giving the direction of the difference. For example:

There will be a difference in the scores on the State Achievement Test between third-grade students who use reading comprehension strategies and those who do not.

Stated in the null form, hypotheses can be tested for statistically significant differences between groups on

the dependent variable(s) or statistically significant relationships between and among variables. The null hypothesis uses the form of “no difference” or “no relationship.” Following is an example of a null hypothesis:

There will be no difference in the scores on the State Achievement Test between third-grade students who use reading comprehension strategies and those who do not.

It is important that hypotheses to be tested are stated in the null form because the interpretation of the results of inferential statistics is based on probability. Testing the null hypothesis allows researchers to test whether differences in observed scores are real, or due to chance or error; thus, the null hypothesis can be rejected or retained.

Organization and Preparation of Data for Analysis

Survey forms, inventories, tests, and other data collection instruments returned by participants should be screened prior to the analysis. John Tukey suggested that exploratory data analysis be conducted using graphical techniques such as plots and data summaries in order to take a preliminary look at the data. Exploratory analysis provides insight into the underlying structure of the data. The existence of missing cases, outliers, data entry errors, unexpected or interesting patterns in the data, and whether or not assumptions of the planned analysis are met can be checked with exploratory procedures.

Inferential Statistical Tests

Important considerations for the choice of a statistical test for a particular study are (a) type of research questions to be answered or hypotheses to be tested; (b) number of independent and dependent variables; (c) number of covariates; (d) scale of the measurement instrument(s) (nominal, ordinal, interval, ratio); and (e) type of distribution (normal or non-normal). Examples of statistical procedures commonly used in educational research are *t* test for independent samples, analysis of variance, analysis of covariance, multivariate procedures, Pearson product-moment correlation, Mann-Whitney *U* test, Kruskal-Wallis test, and Friedman's chi-square test.

Results and Conclusions

The level of statistical significance that the researcher sets for a study is closely related to

hypothesis testing. This is called the alpha level. It is the level of probability that indicates the maximum risk a researcher is willing to take that observed differences are due to chance. The alpha level may be set at .01, meaning that 1 out of 100 times the results will be due to chance; more commonly, the alpha level is set at .05, meaning that 5 out of 100 times observed results will be due to chance. Alpha levels are often depicted on the normal curve as the critical region, and the researcher must reject the null hypothesis if the data fall into the predetermined critical region. When this occurs, the researcher must conclude that the findings are statistically significant. If the researcher rejects a true null hypothesis (there is, in fact, no difference between the means), a Type I error has occurred. Essentially, the researcher is saying there is a difference when there is none. On the other hand, if a researcher fails to reject a false null (there is, in fact, a difference), a Type II error has occurred. In this case, the researcher is saying there is no difference when a difference exists. The power in hypothesis testing is the probability of correctly rejecting a false null hypothesis. The cost of committing a Type I or Type II error rests with the consequences of the decisions made as a result of the test. Tests of statistical significance provide information on whether to reject or fail to reject the null hypothesis; however, an effect size (R^2 , η^2 , ϕ , or Cohen's *d*) should be calculated to identify the strength of the conclusions about differences in means or relationships among variables.

True Experimental Designs

True experimental designs are the most rigorous quantitative research methods in that they allow the researcher to have full control over the experiment and to assign subjects randomly to groups. Full control and randomization strengthen internal validity; however, external validity may be compromised. Experimental designs are useful for establishing cause-and-effect relationships among variables. One or more variables are systematically manipulated so that effects of the manipulated variables on two or more groups or individuals can be observed. The variable being manipulated is called an independent variable (treatment), and the observed variable is called a dependent variable (measured outcome). True experimental designs satisfy the following criteria: randomization, experimental control(s), experimental treatment(s), hypothesis testing, experimental and control group(s), and standardized research instruments.

Criteria

Randomization

Random assignment of subjects to groups helps to control for bias in the selection process. Probability sampling procedures ensure that each participant in a study has an independent and equal chance of being selected for any group.

Experimental Control

The researcher should attempt to hold all variables constant that might influence the outcome of the study by allowing only the dependent variable to vary based on participants' responses to the treatment. For example, in an educational study, variables such as achievement motivation, ability level, and satisfaction with school are difficult to control, yet these variables could influence the outcomes of a study. Pretesting, matching, blocking, and using covariates are common controls.

Experimental Treatment

One or more interventions or treatments may be manipulated in an experiment. New teaching methods, alternative testing methods, and different curricula are examples of treatments used in educational research.

Experimental and Control Groups

An educational researcher could compare reading achievement of two groups of students. The manipulated variable would be method of instruction (whole language or traditional), and the dependent variable would be reading achievement scores. The experimental group is taught reading by the whole-language approach, and the control group is taught reading by the traditional approach. Both groups would be tested after the experiment using the same standardized test. Any change in reading achievement scores may be tentatively attributed to method of instruction.

Standardized Test Instruments

A test that meets certain standards or criteria for technical adequacy in construction, administration, and use is said to be standardized. A standardized test provides clear directions for administration and scoring, so that repeated administrations and scoring of the test are carried out systematically. The American Psychological Association, American Educational Research Association, and the National Council on Measurement in Education have established standards that address professional issues and technical characteristics

of standardized test development and use in the social sciences.

Basic Patterns

Donald Campbell and Julian Stanley suggested three basic patterns of true experimental research designs: pretest–posttest control group design, posttest-only control group design, and Solomon four-group design.

Pretest–Posttest Control Group Design

A pretest is administered to a control group and an experimental group prior to the administration of the treatment. After the experiment, a posttest is administered to both groups, and gain scores from the pretest to the posttest may be compared. Statistically significant differences between gain score means may be computed using a *t* test for independent samples if only two groups are involved.

Posttest-Only Control Group Design

When pretesting is not possible or desirable, the posttest-only control group design may be used. Random assignment of subjects to groups serves to ensure equality of groups. Gain scores cannot be computed; otherwise, statistical analysis for the posttest-only design is the same as that for the pretest–posttest control group design.

Solomon Four-Group Design

This design is configured so that one experimental group receives the pretest and treatment; one control group receives the pretest, but no treatment; one control group receives the treatment, but no pretest; and one control group receives neither pretest nor treatment. All groups receive the posttest. The Solomon four-group design is a combination of the pretest–posttest control group design and the posttest-only control group design. Essentially, the design requires the conduct of two experiments: one with pretests and one without pretests. The design provides more rigorous control over extraneous variables and greater generalizability of results than either of the previous designs. Because the design does not provide four complete measures for each of the groups, statistical analysis is performed on the posttest scores using a two-way (2×2) analysis of variance procedure. Thus, the researcher will be able to ascertain the main effects of the treatment, main effects of pretesting, and the interaction effect of pretesting with the treatment.

Quasi-Experimental Designs

Quasi-experimental designs are appropriate when random assignment of subjects to groups is not possible. Much of the research in education and psychology is conducted in the field or in classroom settings using intact groups. In such cases, researchers assign treatments randomly to nonrandomly selected subjects. The lack of full control and nonrandom assignment of subjects to groups pose threats to the internal and external validity of quasi-experimental designs. Matching may be used to control for the lack of randomization. In matching, researchers try to select groups that are as similar as possible on all important variables that may affect the outcomes of a study. Pretests are also recommended to control for lack of randomization. Similar scores on a pretest administered to all groups indicate that the groups were matched adequately. There is no doubt that quasi-experiments are weaker than true experiments for making causal inferences; however, information resulting from quasi-experiments is usually better than no information at all.

Nonrandomized Control Group, Pretest–Posttest Design

Using intact groups for data collection is not only more convenient for the researcher but also more palatable to other stakeholders, for example, educational administrators in educational studies. A random procedure is used to determine which group or groups will be the control and which will be the experimental. In these situations, the researcher cannot assign subjects randomly to groups, so pre-experimental sampling equivalence cannot be ensured. Similar scores on a pretest for the experimental and control groups denote a greater degree of pre-experimental equivalency. After the pretest, the treatment is introduced, and both groups are administered the same posttest. Differences in pre- and posttest mean scores for the control and experimental groups are more credible when pretest means are similar. When results of the pretest reveal that the scores are not similar, more involved statistical procedures are required to address the measurement error on the pretest.

Time Series

Periodic measures are taken on one group at different intervals over an extended time period. Essentially, a time series design involves a series of pre- and posttest measures. A treatment is introduced, and its effects are assessed based on the stability of the repeated measures and differences from one measure to another.

Single-Subject Designs

The researcher investigates a single behavior, or a limited number of behaviors, of one participant by making initial observations, administering a treatment, and observing and measuring behavior after the treatment to study the effects. Pretreatment observations are necessary to establish baseline data. A simple single-subject design is the AB design, where pretreatment observations and measures (A) are made to establish baseline data, and then treatment (B) is administered and observations and measures (A) are repeated to ascertain changes in the behavior. Monitoring of the treatment usually lasts until it is apparent that the treatment has had some effect on behavior. The sequence of observations and measures (A) and treatment (B) followed by prolonged observations and measures (A) may be repeated, as in the ABA and ABAB designs.

Factorial Designs

Many research questions require the investigation of more than one independent variable. Factorial designs permit the investigation of the effect of one independent variable on the dependent variable while ignoring other independent variables (main effect) and the combined influence (interaction) between two or more independent variables. Notation for factorial designs is usually written to identify the number of levels involved in each independent variable. For example, a “two by three” factorial design (2×3) would have two independent variables (factors) with two levels on the first independent variable and three levels on the second independent variable. All groups receive each level on each of the independent variables. A 2×3 design would require six groups. An example of a 2×3 factorial design is a study of method of teaching reading (whole language vs. traditional) and motivation (high, medium, low). Three groups would receive whole-language reading instruction and three groups would receive the traditional reading instruction. The dependent variable would be posttest scores on a standardized reading test. Interpretations of the analysis are more complex for factorial designs than for designs discussed previously.

Nonexperimental Designs

It is not always possible, practical, or ethical to manipulate the research variables of interest. For instance, whether or not parents are involved in their child’s education, the teacher’s level of job satisfaction, or whether or not a student has transferred from one

school to another cannot be manipulated by the researcher. In these cases, the variable has already occurred. For such studies, nonexperimental methods are used. Three common nonexperimental methods of quantitative research are causal comparative (*ex post facto*), survey, and correlation.

Causal Comparative

Causal comparative studies do not permit the researcher to control for extraneous variables. Changes in the independent variable have already occurred before the study is conducted; thus, these studies are also known as *ex post facto*, meaning “from after the fact.” Research questions of interest may be on differences in subjects on dependent variables when subjects have known differences on independent variables, or the extent to which subjects differ on independent variables when they have known differences on the dependent variables.

Survey

Sample surveys, unlike census surveys that query the entire population as in the U.S. Census, collect data from a sample of individuals thought to be representative of the larger (target) population to which the researcher wants to generalize. Surveys are used to collect data over a period of time (longitudinal) or to collect data at one point in time. Responses are aggregated and summarized, and participant identity should be confidential or anonymous. Statistical procedures for reporting survey data include frequencies, percent, cross-tabulations (cross-tabs), chi-square statistic, phi coefficient, Kendall coefficient, and the gamma statistic.

Correlation

Correlation research is used to explore relationships between or among two or more variables. Correlation studies are useful for establishing predictive validity, establishing test reliability, and describing relationships. Simple correlation procedures involve ascertaining the relationship between two variables, whereas partial correlation procedures are used to control for a variable that may influence the correlation between two other variables. A multiple correlation coefficient (multiple regression) indicates the relationship between the best combination of independent variables and a single dependent variable. Canonical correlation indicates the relationship between a set of independent variables and a set of dependent variables. The kind of correlation

coefficient computed depends on the type of measurement scale used and the number of variables.

QUASI-EXPERIMENTAL DESIGN

A scientific experiment is a controlled set of observations aimed at testing whether two or more variables are causally related. William Shadish, Thomas Cook, and Donald Campbell describe two broad types of experiments: (a) randomized experiments, in which study units are randomly assigned to observational conditions; and (b) quasi-experiments, in which study units are not randomly assigned to observational conditions because of ethical or practical constraints. Although it is more difficult to draw causal inferences from quasi-experiments than from randomized experiments, careful planning of quasi-experiments can lead to designs that allow for strong causal inferences.

In order to infer a relationship between cause and effect, three requirements must be met: Cause must precede effect; cause must be related to effect; and, aside from the cause, no alternative explanation for the effect must be plausible. Randomized and quasi-experiments do not differ with respect to the first two requirements. However, with respect to the third requirement, randomized experiments have an advantage over quasi-experiments. Because study units are randomly assigned to conditions in randomized experiments, alternative explanations (e.g., confounding

variables) are equally likely across these conditions and can be ruled out. But because quasi-experiments lack random assignment between conditions, alternative explanations are difficult to rule out. This entry focuses on the validity of, common designs of, and inferences drawn from quasi-experiments.

Validity

Inferences based on an experiment are only as good as the evidence that supports them. The term *validity* is used to refer to the relation between the conclusion of an inference and its supporting evidence. In experimentation, inferences (i.e., conclusions) are valid if they are plausible.

A number of conditions must be met in order to draw a valid inference based on an experiment. These conditions fall into four categories. First, the *internal validity* of an inference refers to whether the covariation between the experimental manipulation and the experimental outcome does indeed reflect a causal relationship between the manipulation and outcome. Second, *external validity* refers to the generalizability of an inference (i.e., do the results of the experiment apply outside of the experimental setting?). Third, *statistical conclusion validity* refers to the validity of inferences about the covariation between manipulation and outcome. Fourth, *construct validity* refers to the validity of inferences about the higher order construct(s) that the experimental manipulation operationalizes.

Threats to Internal Validity

Factors that influence the nature and strength of inferences are referred to as threats to validity. Of particular relevance to quasi-experimental designs are threats to internal validity as they increase the likelihood that a plausible alternative explanation for the experimental outcome exists. Shadish and colleagues identify the following threats to internal validity:

Ambiguous temporal precedence: Lack of clarity about which variable occurred first may yield confusion about which variable is the cause and which is the effect.

Selection: Systematic differences over conditions in respondent characteristics that could also cause the observed effect.

History: Events occurring concurrently with treatment could cause the observed effect.

Maturation: Naturally occurring changes over time could be confused with a treatment effect.

Regression: When units are selected for their extreme scores, they will often have less extreme scores on other variables, an occurrence that can be confused with a treatment effect.

Attrition: Loss of respondents to treatment or to measurement can produce artificial effects if that loss is systematically correlated with conditions.

Testing: Exposure to a test can affect scores on subsequent exposures to that test, an occurrence that can be confused with a treatment effect.

Instrumentation: The nature of a measure may change over time or conditions in a way that could be confused with a treatment effect.

Additive and interactive effects of threats to internal validity: The impact of a threat can be added to that of another threat or may depend on the level of another threat.

Common Designs

Because threats to internal validity are prominent in quasi-experiments, care must be taken to ensure that the influence of these threats to validity is minimized. Shadish and colleagues discuss three principles useful in this respect: identification and study of plausible threats to internal validity; design controls that limit threats to internal validity (e.g., control groups, pretest/posttest designs); and specific hypotheses that limit the number of viable alternative explanations (e.g., predicted interactions or inclusion of *nonequivalent dependent variables*, that is, a dependent variable that is predicted not to change because of the manipulation but is expected to respond to threats to internal validity the same way as the dependent variable being studied). Four types of common quasi-experimental designs are discussed, each of which has its own advantages and disadvantages concerning threats to internal validity. This discussion and examples of quasi-experimental designs draw on the work of Shadish and colleagues.

Designs Without a Control Group

One-Group Posttest-Only Design

This is a simple design involving a posttest on participants (O_1) following a manipulation (X).

$$X \quad O_1$$

For example, suppose knowledge of the causes of sudden infant death syndrome (SIDS) is low and stable within a community. Public health officials create a media campaign to raise awareness regarding factors affecting SIDS. Following the campaign, a sample of

citizens is surveyed concerning their knowledge of these factors. If the citizens are aware of factors affecting SIDS (O_1), one may infer that this is due to the media campaign (X).

Nonetheless, the one-group posttest-only design is a very weak design. It is impossible to guarantee temporal precedence, and furthermore, nearly all other threats to internal validity may apply. One way to improve this design, although it will remain weak, is to use multiple, unique posttests (O_{1A} through O_{1N}).

$$X \quad \{O_{1A} \ O_{1B} \ \dots \ O_{1N}\}$$

Results of the several posttests can be assessed individually and compared to the hypothesized outcomes for each individual posttest and the manipulation. This decreases the likelihood of an invalid inference based on just a single prediction.

One-Group Pretest–Posttest Design

Instead of having a single observation, as in the previous design, the one-group pretest–posttest design has a pretest measure (O_1) before manipulation (X) as well as a posttest measure (O_2) following treatment.

$$O_1 \quad X \quad O_2$$

For example, Jonathan Duckhart studied the effects of a program to reduce environmental lead in low-income urban housing units in Baltimore. Lead levels in each home were measured at pretest and following the intervention. Lead levels decreased between pretest and posttest, supporting the conclusion that the program was effective.

Because of the pre- and posttest, temporal precedence is more easily established, although the effect could still have been caused by history or maturation. Possible improvements involve using a double pretest,

$$O_1 \quad O_2 \quad X \quad O_3$$

or a nonequivalent dependent variable.

$$\{O_{1A} \ O_{1B}\} \quad X \quad \{O_{2A} \ O_{2B}\}$$

A double pretest can give an estimate of biases that may exist in the observed effect of the manipulation at posttest. Differences between the posttest and the second pretest that are similar to differences between the two pretests are likely due to factors other than the manipulation. Using a nonequivalent dependent variable reduces many threats to internal validity because any changes from pretest to posttest not due to the manipulation should affect the original dependent variable as well as the nonequivalent dependent variable.

Control Group Designs

Nonequivalent Groups Posttest-Only Design

The nonequivalent groups posttest-only design is similar to the one-group posttest-only design with a control group added (where NR indicates nonrandom assignment).

$$\begin{array}{ccc} \text{NR} & X & O_1 \\ \text{NR} & & O_2 \end{array}$$

For example, suppose psychotherapy researchers obtained two samples of individuals with depression: those who have attended psychotherapy and those who have not. If those who attend psychotherapy have fewer depressive symptoms than those who did not, the researchers may conclude that psychotherapy reduced the symptoms.

The added control group is a definite improvement over the design lacking a control group as it indicates which effects occur without the manipulation. However, the design is still rather weak because the experimental and control groups may have differed on many nonmanipulated variables related to outcome. This situation is often referred as *selection bias*. To estimate selection bias, this design can include an independent pretest sample that does not receive the experimental manipulation.

$$\begin{array}{ccc} \text{NR} & O_1 | X & O_2 \\ \text{NR} & O_1 | & O_2 \end{array}$$

Here, the pretest and posttest samples are independent across time (i.e., they may be sampled at the same moment in time, and thus on different study units).

Further improvements include matching (where study units with similar scores are matched across experimental and control groups), using internal controls (where the control group consists of a sample drawn from a population similar to that of the experimental group), using multiple nonequivalent control groups, and using a predicted interaction (a highly differentiated causal hypothesis that predicts one particular interaction but excludes others).

Nonequivalent Groups Pretest–Posttest Design

The nonequivalent groups pretest–posttest design is similar to the one-group pretest–posttest design with a control group added.

$$\begin{array}{ccc} \text{NR} & O_1 & X \quad O_2 \\ \text{NR} & O_1 & O_2 \end{array}$$

Note that although similar to the nonequivalent groups posttest-only design with a pretest, the current design includes a dependent pretest, that is, pretest and posttest data are gathered on the same study units. For example, Grace Carter, John Winkler, and Andrea Bidle compared scientists who had received a Research Career Development Award from the National Institutes of Health in order to improve their research careers to those who did not. They found that at posttest, scientists who had received such an award did better than those who did not. However, the former also exceeded the latter at pretest, thus calling into the question the effectiveness of the research awards.

Because pretest and posttest data are gathered on both experimental and control groups, only one of which receives the experimental manipulation, the existence of a possible selection bias may be estimated. Insofar as selection is present, it may magnify the effects of other threats to internal validity (e.g., maturation).

Improvements of this design include a double pretest that allows for the assessment of the selection-maturation threat to internal validity,

$$\frac{\text{NR} \quad \text{O}_1 \quad \text{O}_2 \quad \text{X} \quad \text{O}_3}{\text{NR} \quad \text{O}_1 \quad \text{O}_2 \quad \quad \text{O}_3};$$

switching replications, which entails delivering the manipulation to control group at a later date,

$$\frac{\text{NR} \quad \text{O}_1 | \text{X} \quad \text{O}_2 \quad \quad \text{O}_3}{\text{NR} \quad \text{O}_1 | \quad \text{O}_2 \quad \text{X} \quad \text{O}_3};$$

using a reversed treatment control group, in which two manipulations are delivered that are opposite in direction of effect,

$$\frac{\text{NR} \quad \text{O}_1 \quad \text{X}_+ \quad \text{O}_2}{\text{NR} \quad \text{O}_1 \quad \text{X}_- \quad \text{O}_2};$$

or direct measurement of threats to validity and incorporating these estimates into statistical analysis of the outcomes.

In addition to these modifications, cohort (successive, comparable groups) controls may also be used to improve the nonequivalent groups pretest-posttest design:

$$\frac{\text{NR} \quad \text{O}_1}{\text{NR} \quad \quad \text{X} \quad \text{O}_2}.$$

The first group, which is similar to the second group in relevant aspects, does not receive the experimental manipulation, whereas the second group does. Because of the similarity of the two groups, any differences

between them are assumed to be related to the manipulation.

This simple cohort control design may be further improved by adding pretests.

$$\frac{\text{NR} \quad \text{O}_1 \quad \text{O}_2}{\text{NR} \quad \quad \text{O}_3 \quad \text{X} \quad \text{O}_4}$$

Interrupted Time-Series Designs

In an interrupted time series design, the same variable is measured repeatedly over time.

$$\text{O}_1 \text{ O}_2 \text{ O}_3 \text{ O}_4 \text{ O}_5 \text{ X O}_6 \text{ O}_7 \text{ O}_8 \text{ O}_9 \text{ O}_{10}$$

A change in intercept or slope of the time series is expected at the point in time where the manipulation was delivered. For example, A. John McSweeney studied the effects of the Cincinnati Bell phone company instituting a charge of 20 cents per call for local directory assistance. At the point in time when this charge was added, a significant and immediate drop in the number of local directory assistance calls is visible in the data. This illustrates how a change in intercept of a time series can be used to judge the effect of a manipulation. A change in slope can also be used to judge the effect of a manipulation. For example, Julian Roberts and Robert Geboyts studied the impact of the reform of Canadian sexual assault law instituted in order to increase reporting of sexual assault crimes. They found a relatively flat slope in the years before the reform (that is, the reported number of assaults remained fairly constant), whereas in the years following the reform, a steady increase in the reported number of assaults was observed.

A major threat to this type of design is history—that is, other factors occurring at the same time as the manipulation that may cause the outcome under investigation. Several improvements can be made to this design. A nonequivalent control group may be added:

$$\frac{\text{O}_1 \text{ O}_2 \text{ O}_3 \text{ O}_4 \text{ O}_5 \text{ X O}_6 \text{ O}_7 \text{ O}_8 \text{ O}_9 \text{ O}_{10}}{\text{O}_1 \text{ O}_2 \text{ O}_3 \text{ O}_4 \text{ O}_5 \quad \text{O}_6 \text{ O}_7 \text{ O}_8 \text{ O}_9 \text{ O}_{10}}$$

A nonequivalent dependent variable may be added:

$$\frac{\text{O}_{A1} \text{ O}_{A2} \text{ O}_{A3} \text{ O}_{A4} \text{ O}_{A5} \text{ X O}_{A6} \text{ O}_{A7} \text{ O}_{A8} \text{ O}_{A9} \text{ O}_{A10}}{\text{O}_{B1} \text{ O}_{B2} \text{ O}_{A3} \text{ O}_{B4} \text{ O}_{B5} \quad \text{O}_{B6} \text{ O}_{B7} \text{ O}_{B8} \text{ O}_{A9} \text{ O}_{A10}}$$

The manipulation may be implemented and subsequently removed at a known time:

$$\text{O}_1 \text{ O}_2 \text{ O}_3 \text{ O}_4 \text{ O}_5 \text{ X O}_6 \text{ O}_7 \text{ O}_8 \text{ O}_9 \text{ ✕ O}_{10} \text{ O}_{11} \text{ O}_{12} \text{ O}_{13}$$

This may also be done multiple times, resulting in a multiple replications design:

$O_1 O_2 X O_3 O_4 \times O_5 O_6 X O_7 O_8 \times O_9 O_{10} X O_{11} O_{12} \times O_{13} O_{14}$

Delivering the manipulation to two nonequivalent groups at different times results in a switching replications design:

$$\frac{O_1 O_2 O_3 X O_4 O_5 O_6 O_7 O_8 \quad O_9 O_{10} O_{11}}{O_1 O_2 O_3 \quad O_4 O_5 O_6 O_7 O_8 X O_9 O_{10} O_{11}}$$

Regression Discontinuity Design

In regression discontinuity designs, experimental manipulation is based on a cutoff score (C) on an assignment variable (O_A) measured before manipulation.

$$\begin{array}{cccc} O_A & C & X & O_2 \\ O_A & C & & O_2 \end{array}$$

If the manipulation has an effect, then regression analysis of the data obtained from this design should reveal a discontinuity at the cutoff score corresponding to the size of the manipulation effect. If the manipulation has no effect, the regression line should be continuous. For example, Charles Wilder studied how the institution of the Medicaid program affected medical visits and found, perhaps unsurprisingly, that household income was positively correlated with medical visits. More importantly, however, the data also showed a dramatic increase in medical visits at the cutoff score for Medicaid eligibility, which supports the inference that the Medicaid program does indeed stimulate medical visits.

Differential attrition may cause a discontinuity in the regression line that resembles an effect of the manipulation and thus is a threat to internal validity. History is a plausible threat to validity if factors affecting the outcome occur only for study units on one side of the cutoff.

Inferences

Randomized experiments allow for solid inferences about a proposed causal relation of two variables. However, randomization is often not practically or ethically possible, making a quasi-experimental design necessary. Although threats to internal validity are often highly plausible in quasi-experimental designs, researchers can still draw valid causal inferences if they identify plausible threats to internal validity and select quasi-experimental designs that address those threats.

Often, the design adjustments require elaborate changes, such as administering and removing the intervention multiple times. However, a small, simple change often can make a large difference, such as adding a nonequivalent dependent variable. In either case, causal inferences are strengthened, which is the primary purpose of experimentation.

QUETELET'S INDEX

Quetelet's Index, more commonly known as the body mass index (BMI), is a measure of weight relative to height. Originally developed by 19th-century mathematician Lambert Adolphe Jacques Quetelet, it is a standard measurement that is widely used by health professionals and researchers as an index of body fat. The formula used to calculate this index is weight (in kilograms) divided by height (in meters squared). Height in meters can be calculated by dividing height in centimeters by 100. For example, a person who weighs 71 kilograms and is 165 centimeters tall has a BMI of 26 [(71 kg)/(1.65 m)² = 26]. Alternatively, BMI can be calculated by dividing weight (in pounds) by height (in inches squared) multiplied by a conversion factor of

703. For example, a person who weighs 145 pounds and is 65 inches (or 5' 5") tall has a BMI of 24 $\{[(145 \text{ lbs.})/(65 \text{ in.})^2] \times 703 = 24\}$.

Although the body mass index is not a direct measure of adiposity (body fat), it is correlated with direct measures of body fat, such as dual energy x-ray absorptiometry and underwater (hydrostatic) weighing. The advantages of using BMI as a proxy for adiposity are that it is inexpensive, it is easy to obtain, it does not require extensive training, and it is simple to calculate relative to other methods.

Interpretation for Adults

BMI is often used to classify overweight and obesity, but can be interpreted for the entire weight spectrum. Typically, a person is considered underweight if he or she has a BMI of 18.5 or less and normal weight between 18.5 and 24.9. A BMI of 25.0 to 29.9 is classified as overweight, and 30 or above is considered obese. The obese category can be further subdivided into Class I obesity (30.0 to 34.9), Class II obesity (35.0 to 39.9), and Class III or extreme obesity (40 or above). Recent estimates suggest that two thirds of the U.S. adult population are classified as overweight according to these categories, and nearly one third are obese.

Interpretation for Children and Adolescents

Although the calculation for BMI is the same for adults and children, the interpretation differs. For adults (aged 20 years and older), BMI is interpreted the same for both men and women using the categories listed above. However, for children and adolescents (aged 2 through 19 years), the interpretation is based on age- and sex-specific percentiles, which reflects the fact that adiposity changes with age and differs among boys and girls. Therefore, it is not appropriate to use the BMI categories for adults to interpret BMI and determine the weight category for children and adolescents. BMI can be used to identify children and adolescents who are either currently overweight or at risk of becoming overweight, based on BMI-for-age growth charts provided by the Centers for Disease Control and Prevention. After obtaining the BMI using the method described above, this number is plotted on the BMI-for-age growth charts for the appropriate sex to yield a percentile ranking, which indicates how the child's BMI compares to children of the same age and sex. Although children are usually not classified as obese, the current

recommendation is that BMI values that meet or exceed the 95th percentile of the BMI growth charts for their age and sex should be categorized as overweight, and those who are in the 85th percentile to the 95th percentile are classified as at risk of overweight. These growth curves are J-shaped and were constructed to identify BMI scores that show a trajectory toward overweight (BMI ≥ 25) or obesity (BMI ≥ 30) in adulthood. Childhood overweight is of particular concern because research suggests that it frequently tracks into adulthood, with the vast majority of obese adolescents going on to become obese adults.

Applications

BMI is often used to identify individuals who are at risk for developing weight-related diseases, such as hypertension, high cholesterol, Type 2 diabetes, and coronary heart disease, with increased risk as BMI class increases. Epidemiological research indicates that a BMI equal to or greater than 30 (in adults) is strongly correlated with both morbidity and mortality. Therefore, BMI provides a systematic and efficient method of evaluating risk for adverse health consequences, identifying individuals who may benefit from weight management interventions, as well as tracking changes in body mass over time. However, it should be noted that the BMI categories of overweight and obese identify *relative risk*, rather than *absolute risk*, and therefore must take into consideration other existing risk factors for disease. A high BMI alone does not necessarily indicate health risk; therefore, additional assessments such as family history, dietary and physical activity habits, waist circumference, cholesterol level, and blood pressure are necessary to determine risk status.

Reliability

Generally, BMI has been found to be a reliable indicator of body fatness, with a moderate to strong correlation. However, some have argued that although BMI is a valuable tool, it does have limitations that must also be taken into consideration. For example, BMI does not distinguish between lean and fat body mass, nor does it take into account the regional distribution of body fat (central vs. peripheral adiposity), both of which are important factors in assessing disease risk. Additionally, one assumption of the BMI is that adiposity can be adequately represented by adjusting weight for height regardless of age, race, or sex. Yet there is evidence that this association varies among different

populations. For example, it may overestimate body fat in athletes or those with a muscular build, and may be misleading for certain ethnic groups. Moreover, an increase in the ratio of fat to lean body mass is observed as individuals age, even among those who maintain a consistent BMI. Although BMI remains a widely used and useful tool, these considerations are important because the health risks associated with overweight and obesity are related to excess body fat, rather than weight per se.

QUOTA SAMPLING

The target population in a sampling survey can often be divided into several subpopulations based on certain characteristics of the population units. Some common variables used to categorize population include gender, age, location, education level, and so forth. It is also common in a sampling survey situation that investigators might require certain propositions or numbers for each type of sampling unit included in the sample for various reasons. For instance, a *representative sample* is often considered one of the most important criteria when evaluating the quality of a sampling survey, and a sample is considered to be representative if the sample structure is the same or close to the population structure; if one is to conduct a survey where gender is considered an influential factor of the response, the investigator needs to draw a sample where the proportion of each gender is as close to the target population as possible. Nevertheless, there are also cases when investigators' subjective judgments play an important role; for example, in a marketing survey of the acceptance level of a new perfume product, the investigator may likely consider a sample with a majority of female interviewees over males appropriate. Bear in mind, other motives or objectives are also possible.

All that being said, in reality, it has never been an easy task to randomly select a sample where the number of units belonging to each subpopulation are fixed; yet many sampling designs developed in the past were targeted toward that end. Several of these designs include stratified sampling designs, proportional allocation of sample sizes, proportional sampling, and quota sampling. Among all, quota sampling is one of the most commonly used sampling selection methods in opinion and marketing survey. The sampling method could be viewed as a different class of sampling designs that shares similar sampling principles. The practical popularity portioned to quota sampling is due mainly to its ability to provide samples with the desired numbers or proportions of each subpopulation at a limited sampling cost. Such an advantage is often compromised by the lack of legitimate statistical inference, as often criticized by statisticians. In the following sections, the general sampling principle of quota sampling and the usual methods used to construct the inference for the population quantity of interest, along with a short review of the advantages and disadvantages, are discussed. A possible manner to reach a balanced solution between sampling convenience and proper inference is also introduced.

Principle of Quota Sampling

In quota sampling, the quotas of each type of sampling unit are determined in advance, whereby investigators would look to fill in each quota. The quotas are fixed numbers for each type of unit that investigators would like to include in the sample. For instance, an investigator would like to have a sample in which the proportions of each gender by different age levels are the same as the population, and the sample size is 1,000. Suppose that the population proportion is given as shown in Table 1.

The *quota* of each type of sampling unit is the sample size multiplied by the population proportion, and the results are shown in Table 2.

Up until now, quota sampling appears very similar to stratified sampling (i.e., the proportional allocation of sample size emanated). If the within-subpopulation samples were selected by some probability sampling design, the quota sampling in this case can be viewed the same as stratified sampling. However, there is no specific rule as to how the quotas should be filled in quota sampling. As mentioned previously, quotas are sometimes determined based on subjective judgments, or whatever the investigators consider appropriate; as long as the sampling method is one with a fixed number of different types of sampling, it can be considered a type of quota sampling. Having said that, the term *quota sampling* is often used when the within-subpopulation sample is selected by some relatively nonrandomized designs, such as certain judgmental sampling or convenient sampling designs.

Inference

Consider a population with population size N is partitioned into H subpopulations, and the sizes of each subpopulation are $N_b, b = 1, \dots, H$ such that

$$N = \sum_{b=1}^H N_b.$$

Let y_{hi} be the value of the population variable of interest associated with the i th units in the b th subpopulation. Usually, the population quantities of primary interest in a survey sampling case would include the overall population total τ , population mean μ , subpopulation totals τ_b , and subpopulation mean μ_b . The population proportion is a special case of the population mean. The definition of the overall population τ is

$$\tau = \sum_{b=1}^H \sum_{i=1}^{N_b} y_{bi} = \sum_{b=1}^H \tau_b, \quad (1)$$

where $\tau_b = \sum_{i=1}^{N_b} y_{bi}$. The population mean μ is

$$\mu = \frac{1}{N} \tau = \frac{1}{N} \sum_{b=1}^H \tau_b = \sum_{b=1}^H \frac{N_b}{N} \mu_b, \quad (2)$$

where $\mu_b = \tau_b / N_b$. The population variance of the b th subpopulation is defined as

$$\sigma_b^2 = \frac{1}{N_b - 1} \sum_{i=1}^{N_b} (y_{bi} - \mu_b)^2 \quad (3)$$

In addition, let s_b be the within-subpopulation sample of the b th subpopulation, that is, s_b is an index set that is a subset of $\{1, 2, \dots, N_b\}$ and contains the labels of units selected. The sample mean $\bar{y}_b$ and the sample variance S_b^2 for the within-subpopulation samples are

$$\bar{y}_b = \frac{1}{n_b} \sum_{i \in s_b} y_{bi} \quad (4)$$

and

Table 1 Population Proportions

Gender	Age				
	20–29	30–39	40–49	50–59	60 and Above
Female	0.10	0.10	0.09	0.11	0.12
Male	0.10	0.08	0.1	0.11	0.09

Table 2 Quotas

Gender	Age				
	20–29	30–39	40–49	50–59	60 and Above
Female	100	100	90	110	120
Male	100	80	100	110	90

$$S_b^2 = \frac{1}{n_b - 1} \sum_{i \in s_b} (y_{bi} - \bar{y}_b)^2, \quad (5)$$

respectively. n_b is the within-subpopulation sample size (quota) of the b th subpopulation and $\sum_{b=1}^H n_b = n$ is the total sample size.

Because there is no specific regulation regarding how the quotas are filled in quota sampling, the inferences of the subpopulation and population totals/means vary depending on the within-subpopulation sampling selection. Usually, $\bar{y}_b$ and $N_b \bar{y}_b$ would be used to estimate μ_b and τ_b , respectively. Consequently,

$$\hat{\tau} = \sum_{b=1}^H N \bar{y}_b \quad (6)$$

and

$$\hat{\mu} = \frac{1}{N} \sum_{b=1}^H N \bar{y}_b \quad (7)$$

would be used to estimate the overall population total τ and mean μ .

If the quota sampling proceeds as the stratified random sampling, that is, the quotas are filled with within-subpopulation simple random sampling without replacement design and the selections are independent from one subpopulation to another, then Equations 6 and 7 are unbiased estimators and the associated confidence intervals based on Central Limit Theorem can be constructed accordingly. If the quotas are filled as general stratified sampling, the associated inferences of τ , μ , τ_b , and μ_b can be constructed as described in Steven K. Thompson's *Sampling*.

Following the above, the quotas are usually filled with certain nonrandomized designs for sampling convenience; for example, interviewers tend to interview qualified interviewees who are more readily accessible. That said, Equations 6 and 7 can be applied to estimate τ and μ . Under such circumstances, it is vital to remember that these estimators are no longer design-based. In fact, one would not be able to evaluate the property or performance of these estimators from a design-based perspective because one would lose the ability to appreciate the accuracy and precision of the estimators by bias and mean-squared error. One possible solution to establish the design-based inference under quota sampling is advised by Mohammad Salehi and Kuang-Cho Chang. Salehi and Chang describe a multiple inverse sampling scheme and the associated inferences to compromise the sampling convenience and a legitimate inference. If a quota sampling can proceed according to the principle of inverse sampling

instead of a judgmental design, it is possible to obtain a reasonable statistical inference.

On the other hand, the lack of design-based inference is often considered a major drawback of quota sampling; different authors have thus suggested a model-based inference. With such an approach, the population vector $\mathbf{y} = (y_1, \dots, y_N)$ is regarded as a constant vector in the design-based approach. The distribution of $\mathbf{Y}$ can be specified by a density function $f(\mathbf{y}; \boldsymbol{\theta})$, and the randomness used to construct the related inference will be introduced accordingly with the sampling design. Nevertheless, the employment of a model-based approach does not mean that the sampling design is always condonable; such degree depends on the types of inference method and the manner in which the sample is selected.

There are usually two approaches with t model-based inferences—sample-based and data-based. The most well-known example of a sample-based inference, where the inference depends on the conditional distribution given the sample, could be the best linear unbiased estimator, usually referred as BLUE. On the other hand, with the data-based approach, the inference depends on the conditional distribution given the data, such as the likelihood-based inference. If the sampling units are selected independently from $\mathbf{y}$ and other unknown parameters, the sampling design in general can be ignored from both the sample-based and data-based inferences. If the sampling selection $\mathbf{y}$ depends solely on observations, the design can be ignored from the data-based inference, but not the sample-based inference. By the same token, if the sampling selection depends on the unobserved part of $\mathbf{y}$ and/or other unknown parameters, then even the model-based inference needs to take the randomness as introduced by the sampling design into account. Nevertheless, if the quota sample is selected based on subjective judgment, it could be problematic to ignore the design regardless of whether a sample-based or data-based inference is used.

Advantages and Disadvantages

Quota sampling appears to be a reasonable sampling selection method because of its ability to provide a sample with structure as the investigator would ask, and at a lower sampling cost. As previously mentioned, investigators usually prefer to have a representative sample similar to the population structure; thus, quota sampling seems like a natural choice to draw such samples in a cost-efficient manner. What is often overlooked, nonetheless, is the true representation of the samples, and quite frequently, their representing intensity is low. This can be due to the investigator's inability

to include all the influential factors when he or she decides on the factors to categorize the population. For instance, the usual factors used to stratify the population for a political opinion survey might include gender, age, race, and location. However, depending on different issues of interest, other factors can play an important role as well, such as socioeconomic status and educational level. Hence, a sample that appears to be representative could be biased in some ways. Furthermore, with the usual judgment or convenient sampling selection that is used to fill in the quotas, it is known that the interviewees who are easy (or difficult) to reach have certain systematic patterns, which explains the existence of significant yet immeasurable selection biases. Having said that, quota sampling still has its considerable advantage of less sampling effort, which sometimes might be the prime criterion in a survey sampling case. Moreover, it is possible that quota sampling can outperform probability sampling. It is also viewed as a useful sampling design for marketing research. Rather than the possible poor outcome, the real disadvantage of quota sampling points to the challenges faced when trying to evaluate its performance. The model-based inference might be a possible solution. However, as already discussed, usage of model-based inference does not mean that the design can always be ignored. Additionally, one would always need to consider the validity of the assumed model. The inverse sampling strategy described in Salehi and

Chang is another potential solution to use quota sampling with a legitimate probability sampling scheme. Nevertheless, it is recommended that one should be cautious with the inference based on the data drawn by quota sampling.

R

R

R is a free, open-source programming language used by students, researchers, and industry experts worldwide to conduct statistical analyses and construct statistical graphics. Despite the rapid changes to data science over the years, one constant has been R. One reason for R's stability in use is that it has also evolved. In addition to the frequent improvements and updates the development team makes to the source code, users are regularly creating new packages and functions for others to use. In this entry, specific commands and packages in R are italicized in Courier font. For example, *mean()* is a command in R used to calculate the mean. The phrase *base R* will refer to any commands that are available upon downloading R (i.e., no additional packages need to be downloaded).

This entry first provides a brief description of the history of R before giving a general overview of the R interface. Then, various features of R and an environment it can be run in are discussed. Finally, R's strengths and weakness are examined.

History

R was started in the 1990s as an adaptation of another language: S. R is a play on words—or rather, a play on letter—of its predecessor and it has grown from a two-person effort consisting of Ross Ihaka and Robert Gentleman to a multiperson team that orchestrates an annual conference. The popularity of R has spawned the creation of books, workshops, and online tutorials for those looking to bolster their statistical skills. R began as a series of basic commands, but—because it is open source—users have contributed packages to allow

others to conduct nearly any analysis or construct any graph imaginable.

General Description

R is a command-driven language. This means to generate output, a command must be typed and executed. R primarily works with objects. An object in R is anything that contains a value (e.g., numbers, letters, model results). Values are assigned with `<-` or `=` (though `<-` is more common among R users). The command `x <- 4` assigns the value of 4 to `x`. If `y <- 3`, the command `x + y` will produce a value of 7. (These commands can be run on separate lines in the R console or on the same line if each command is separated by a semicolon.) Adding `x` and `y` will produce 7 because `x` and `y` are both objects stored in the *global environment*. The global environment is a collection of objects and their most recently assigned values in an active R session. The contents of `x` and `y` can be overwritten to contain new values or the objects can be removed from the global environment with the command `rm(object name)`. The global environment typically resets when a new R session is started.

Some have the illusion that R is not user-friendly because it involves coding or programming; however, many R commands are intuitive and there is a built-in help system. If one forgets that `sd()` calculates the standard deviation, for instance, typing `?sd` or `help(sd)` will produce a help window. The help window gives examples of the command and a description of its arguments. Arguments are specific requests in a command that can change its output. The help window for `sd` will show two arguments: `sd(x, na.rm=FALSE)`. The `x` is the data and the `na.rm=FALSE` is an argument that says missing values will not be removed before calculating

the standard deviation. The value after the argument (in this case, `FALSE`) is the default value. By default, R assumes all data are to be used in a calculation. Beyond R's built-in help system (and online help forums), there are many textbooks available for free online or at-cost in print.

Data Management and Entry

In R, data can be manually entered or external data can be inputted through a series of commands. To manually enter data into R, values can be concatenated with the `c()` function (e.g., `c(4,3,2,5,6,1,4)`). This creates a vector. With other commands, multiple vectors can be combined to create a matrix, or matrices can be combined to create multidimensional arrays for more complex analyses.

Commands in base R such as `read.table()` allow users to read in external data files or online databases. Reading in data requires a direct file path (e.g., `"C:/Users/Downloads/example.csv"`) or setting the *working directory*. If accessing multiple files from the same folder in an R session, the working directory can be set with `setwd("file path")`. Now, data can be inputted by typing the file name located in the working directory: `read.table("example.csv", sep=",")`. Data are read into a matrix or vector by default. Matrices must consist of the same data type. Numeric (e.g., 3, 4, 6, 1) or string (e.g., "a," "b," "d," "g") data types cannot be mixed in a matrix. R allows data sets to take multiple forms, however. Unlike a matrix, a data frame is a structure in R that allows multiple data types to be in the same set. For instance, there can be numeric variables for weight and characters such as "M" and "F" for biological sex in the same data frame. Although data manipulation and cleaning are possible in R, it is oftentimes simpler to do heavy data management (e.g., deleting and rearranging columns) in external programs like Microsoft Excel before reading the data into R.

Missing Data

There are two types of missing data: system and user-defined missing values. System missing data are when there is a blank cell in a data frame or matrix. These types of data will show up as `NA` in R. User-defined missing data are whatever value is typed in an empty cell to indicate missingness. Typically, these values are large and repetitive like "999." It is possible to assign `NA` values to any missing code or assign an existing missing code to `NA`. The latter is preferable in R as many packages and commands do not allow users to specify a code for missing data.

Graphics

R not only allows for rigorous statistical computations, but it also generates high-quality graphics with ease. Plots in R are constructed with a command such as `plot()` (for a scatterplot) or `hist()` (for a histogram). These plots can be further modified with subcommands. For instance, a line can be added to a plot with the command `abline()`. It is also possible to create interactive graphs in R. The command `locator()` allows one to click on points on a graph with the resulting output displaying the coordinates of that point. With the various plot types available (e.g., scatterplots, histograms, boxplots) and subcommands that allow features to be added or removed (e.g., plot titles, axes labels), a publication-quality graph can be constructed for most popular style guides.

Packages

One of the main strengths of R is the ability to download user-created packages from an online database. This database or collection of sites is called the *Comprehensive R Archive Network*. To download R, packages, and other pertinent materials, one selects a Comprehensive R Archive Network server (there are various servers around the world). There is no limit to the scope of these packages: The functions in packages can range from a calculation of the mean to complex structural equation models. Typically, packages are designed to conduct analyses not possible in base R or to expand on the capabilities of existing commands. For example, a package like `ggplot2` allows users to easily construct more complicated graphics than base R (e.g., violin plots) and make them more visually appealing. Packages can be downloaded with the `install.packages("package name")` command and called into a session with the `library(package name)` command. To become familiar with a package's arguments and defaults, one should read the package's documentation before using it.

RStudio

Keeping track of objects in the global environment and seeing what objects or data frames contain can be tricky in R since it is command-driven and does not have a graphical user interface. Luckily, R can be run in environments that make it easier to stay organized and keep track of work done in a session. RStudio is an integrated data environment (IDE)—it allows users to run R commands, keeps track of the global environment, has a display panel for figures, and allows for packages to be easily installed and updated, among

many other features. RStudio is also free to use on a local machine (though other features exist at varying costs). Since RStudio is an integrated data environment for R, it cannot run without R being installed. In other words, R can run by itself, but RStudio cannot.

Strengths and Limitations

There are many reasons one may choose to analyze their data in R. As mentioned earlier, R is open source and free. There is no need to wait for a yearly update to run a new analysis and there are no subscription fees or one-time costs to receive updates when they do occur. Because of R's popularity, packages are constantly being created for cutting-edge statistical techniques. It is a platform equally useful for those looking to do simple analyses as well as for those looking to do complicated statistical work.

R also has many extensions (that are optimized in RStudio) that allow users to do more than just conduct analyses or make graphs. For example, through an external package called *shiny*, users can program user-friendly (e.g., point-and-click) web applications to demonstrate statistical concepts and conduct analyses. Presentation slides, PDFs, and other dynamic files can be created in an extension of R called *R Markdown*. In addition, R is integrated with many other languages (e.g., C) and software (e.g., LaTeX), further expanding R's capabilities. Taken together, these features can make R a one-stop shop for researchers. The results of a study can be analyzed, a presentation for a conference can be created, and a manuscript can be written in R Markdown and submitted to a journal. If the study involved progressing a statistical method, a package and/or web application could be created that would enable others to use the same analysis in their own research. Considering the increasing cost of data analysis programs and software like Microsoft Office, R may be a particularly appealing option.

No software is perfect. R also has a couple of drawbacks, too. A major limitation of R is its speed. There are ways to optimize the speed of R (e.g., parallel processing in packages like *simdesign* or using another language like C), but it is still slower than other popular programs used in the industry like Python. Although packages are rigorously tested before being allowed on the R server, quality assurance is not guaranteed to the same degree it is for paid software in a program like SAS. One needs to place trust in the package authors and keep packages up-to-date in case any errors were identified in a previous version. Finally, there is a learning curve with R (as there is with any new software or programming language). This curve can be steep, especially for those without a background in statistics or

computer programming. This may make programs with point-and-click graphical user interfaces like SPSS more attractive.

Final Thoughts

R is a popular programming language that will continue to grow through updates and user-contributed packages. Although learning a statistical programming language can be challenging, learning one language can make it easier to learn others. In addition, there is a built-in help function that makes looking up commands easier. Since the program itself is open source and free, so are many resources to further enhance one's knowledge of R.

R²

R-squared (R^2) is a statistic that explains the amount of variance accounted for in the relationship between two (or more) variables. Sometime R^2 is called the coefficient of determination, and it is given as the square of a correlation coefficient.

Given paired variables (X_i, Y_i) , a linear model that explains the relationship between the variables is given by

$$Y = \beta_0 + \beta_1 X + e,$$

where e is a mean zero error. The parameters of the linear model can be estimated using the least squares method and denoted by $\hat{\beta}_0$ and $\hat{\beta}_1$, respectively. The parameters are estimated by minimizing the sum of squared residuals between variable Y_i and the model $\beta_0 + \beta_1 X_i$, that is,

$$(\hat{\beta}_0, \hat{\beta}_1) = \underset{\beta_0, \beta_1}{\operatorname{argmin}} (Y_i - \beta_0 + \beta_1 X_i)^2.$$

It can be shown that the least squares estimations are

$$\hat{\beta}_0 = \bar{Y} - \bar{X} \frac{S_{xy}}{S_{xx}} \quad \text{and} \quad \hat{\beta}_1 = \frac{S_{xy}}{S_{xx}},$$

where the sample cross-covariance S_{xy} is defined as

$$S_{xy} = \frac{1}{n} \sum_{i=1}^n (X_i - \bar{X})(Y_i - \bar{Y}) = \overline{XY} - \bar{X}\bar{Y}.$$

Statistical packages such as SAS, SPLUS, and R provide a routine for obtaining the least squares estimation. The estimated model is denoted as

$$\hat{Y} = \hat{\beta}_0 + \hat{\beta}_1 X.$$

With the above notations, the sum of squared errors (SSE), or the sum of squared residuals, is given by

$$SSE = \sum_{i=1}^n (Y_i - \hat{Y}_i)^2.$$

SSE measures the amount of variability in Y that is not explained by the model. Then how does one measure the amount of variability in Y that is explained by the model? To answer this question, one needs to know the total variability present in the data. The total sum of squares (SST) is the measure of total variation in the Y variable and is defined as

$$SST = \sum_{i=1}^n (Y_i - \bar{Y})^2,$$

where $\bar{Y}$ is the sample mean of Y variables, that is,

$$\bar{Y} = \frac{1}{n} \sum_{i=1}^n Y_i.$$

Since SSE is the minimum of the sum of squared residuals of any linear model, SSE is always smaller than SST. Then the amount of variability explained by the model is $SST - SSE$, which is denoted as the regression sum of squares (SSR), that is,

$$SSR = SST - SSE.$$

The ratio $SSR/SST = (SST - SSE)/SST$ measures the proportion of variability explained by the model. The coefficient of determination (R^2) is defined as the ratio

$$R^2 = \frac{SSR}{SST} = \frac{SST - SSE}{SSE}.$$

The coefficient of determination is given as the ratio of variations explained by the model to the total variations present in Y . Note that the coefficient of determination ranges between 0 and 1. R^2 value is interpreted as the proportion of variation in Y that is explained by the model. $R^2 = 1$ indicates that the model exactly explains the variability in Y , and hence the model must pass through every measurement (X_i, Y_i) . On the other hand, $R^2 = 0$ indicates that the model does not explain any variability in Y . R^2 value larger than .5 is usually considered a significant relationship.

Case Study and Data

Consider the following paired measurements from Moore and McCabe (1989), based on occupational mortality records from 1970 to 1972 in England and Wales. The figures represent smoking rates and deaths from lung cancer for a number of occupational groups.

<i>Smoking index</i>	<i>Lung cancer mortality index</i>
77	84
137	116
117	123
94	128
116	155
102	101
111	118

For a set of occupational groups, the first variable is the smoking index (average 100), and the second variable is the lung cancer mortality index (average 100). Suppose we are interested in determining how much the lung cancer mortality index (Y variable) is influenced by the smoking index (X variable). Figure 1 shows the scatterplot of the smoking index versus the lung cancer mortality index. The straight line is the estimated linear model, and it is given by

$$Y = -2.8853 + 1.0875X.$$

SSE can be easily computed using the formula

$$SSE = \sum_{i=1}^n Y_i^2 - \hat{\beta}_0 \sum_{i=1}^n Y_i - \hat{\beta}_1 \sum_{i=1}^n X_i Y_i, \quad (1)$$

and SST can be computed using the formula

$$SST = \sum_{i=1}^n Y_i^2 - \frac{1}{n} \left(\sum_{i=1}^n Y_i \right)^2. \quad (2)$$

In this example the coefficient of determination is .5121, indicating that the smoking index can explain the lung cancer mortality index.

Figure 1 Scatterplot of Smoking Index Versus Lung Cancer Mortality Index

Notes: The straight line is the linear model fit obtained by the least squares estimation.

Relation to Correlation Coefficient

With the previous Equations 1 and 2, R^2 can also be written as a function of the sample cross-covariance:

$$SSE = nS_{yy} - n \frac{S_{xy}^2}{S_{xx}} \quad \text{and} \quad SST = nS_{yy}.$$

Then the coefficient of determination can be written as

$$R^2 = \frac{S_{xy}^2}{S_{xx}S_{yy}} = \frac{(\overline{XY} - \bar{X}\bar{Y})^2}{(X^2 - \bar{X}^2)(Y^2 - \bar{Y}^2)},$$

which is the square of the Pearson product-moment correlation coefficient.

$$R = \frac{S_{xy}}{\sqrt{S_{xx}}\sqrt{S_{yy}}} = \frac{\sum_{i=1}^n (X_i - \bar{X})(Y_i - \bar{Y})}{\sqrt{\sum_{i=1}^n (X_i - \bar{X})^2} \sqrt{\sum_{i=1}^n (Y_i - \bar{Y})^2}}.$$

In the above example, the correlation coefficient is .7162, so the correlation square is .5121, the R^2 value.

R^2 for General Cases

The definition of the coefficient of determination can be further expanded in the case of multiple regression. Consider the following multiple regression model:

$$Y = \beta_0 + \beta_1 X_1 + \cdots + \beta_p X_p + e,$$

where Y is the response variable and $X_1, X_2, \dots, X_p$ are p regressors, and e is a mean zero error. The unknown parameters $\beta_1, \beta_2, \dots, \beta_p$ are estimated by the least squares method. The sum of squared residuals is given by

$$\begin{aligned} SSE &= \sum_{i=1}^n (Y_i - \hat{Y}_i)^2 \\ &= \sum_{i=1}^n [Y_i - (\hat{\beta}_0 + \hat{\beta}_1 X_{i1} + \dots + \hat{\beta}_p X_{ip})]^2, \end{aligned}$$

while the total sum of squares is given by

$$SST = \sum_{i=1}^n (Y_i - \bar{Y})^2,$$

Then the coefficient of multiple determination is given by

$$R^2 = \frac{SST - SSE}{SST},$$

which is the square of the multiple correlation coefficient R . As the number of regressors increases, the R^2 value also increases, so R^2 cannot be a useful measure for the goodness of model fit. Therefore, R^2 is adjusted for the number of explanatory variables in the model. The adjusted R^2 is defined as

$$R_{\text{adj}}^2 = 1 - (1 - R^2) \frac{n-1}{n-p-1} = \frac{(n-1)R^2 - p}{n-p-1}.$$

It can be shown that $R_{\text{adj}}^2 \leq R^2$. The coefficient of determination can be further generalized in more general cases using the likelihood method.

RADIAL PLOT

The radial plot is a graphical method for displaying and comparing observations that have differing precisions. Standardized observations are plotted against the precisions, where precision is defined as the reciprocal of the standard error. The original observations are given by slopes of lines through the origin. A scale of slopes is sometimes drawn explicitly.

Suppose, for example, that data are available on the degree classes obtained by students graduating from a university and that we wish to compare, for different major subjects, the proportions of students who achieved upper second-class honors or higher. Typically, different numbers of students graduate in different subjects. A radial plot will display the data as proportions so that they may be compared easily, allowing for the different sample sizes. Similarly, a radial plot can be used to compare other summary statistics (such as means, regression coefficients, odds ratios) observed for different sized groups, or event rates observed for differing time periods.

Sometimes, particularly in the natural and physical sciences, measurements intrinsically have differing precisions because of natural variation in the source material and experimental procedure. For example, archaeological and geochronological dating methods usually produce an age estimate and its standard error for each of several crystal grains or rock samples, and the standard errors differ substantially. In this case, the age estimates may be displayed and compared using a radial plot in order to examine whether they agree or how they differ. A third type of application is in *meta-analysis*, such as in medicine, to compare estimated treatment effects from different studies. Here the precisions of the estimates can vary greatly because of the differing study sizes and designs. In this context the graph is often called a *Galbraith plot*. In general, a radial plot is applicable when one wants to compare a number of estimates of some parameter of interest, for which the estimates have different standard errors.

A basic question is, Do the estimates agree (within statistical variation) with a common value? If so, what value? A radial plot provides a visual assessment of the answer. Also, like many graphs, it allows other features of the data to be seen, such as whether the estimates differ systematically in some way, perhaps due to an underlying factor or mixture of populations, or whether there are anomalous values that need explanation. It is inherently not straightforward to compare individual estimates, either numerically or graphically, when their precisions vary. In particular, simply plotting estimates with error bars does not allow such questions to be assessed.

The term *radial plot* is also used for a display of *directional data*, such as wind directions and velocities or quantities observed at different times of day, via radial lines of different lengths emanating from a central point. This type of display is not discussed in this entry.

Mathematical Properties

Let $z_1, z_2, \dots, z_n$ denote n observations or estimates having standard errors $\sigma_1, \sigma_2, \dots, \sigma_n$, which are either known or well estimated. Then we plot the points (x_i, y_i) given by $x_i = 1/\sigma_i$ and $y_i = (z_i - z_0)/\sigma_i$, where z_0 is a convenient reference value. Each y_i has unit standard deviation, so each point has the same standard error with respect to the y scale, but estimates with higher precision plot farther from the origin on the x scale. The (centered) observation $(z_i - z_0)$ is equal to y_i/x_i , which is the slope of the line joining $(0, 0)$ and (x_i, y_i) , so that values of z can be shown on a scale of slopes. Figure 1 illustrates these principles.

Furthermore, if each z_i is an unbiased estimate of the same quantity μ , say, then the points will scatter with unit standard deviation about a line from $(0, 0)$ with slope $\mu - z_0$. In particular, points scattering with unit standard deviation about the *horizontal* radius agree with the reference value z_0 . This provides a simple visual assessment of how well several estimates agree with each other or with a reference value: points should scatter roughly equally about a radius and nearly all within a ± 2 band. This is illustrated in Figure 2 using some simulated data with $\mu = z_0 = 5$. Such assessment

Figure 1 The Geometry of a Radial Plot Showing Linear Scales for x , y , and z and Two Points With Different Precisions

Notes: All points have unit standard deviation on the y scale, but higher precision points generate shorter confidence intervals on the z scale.

Figure 2 A Radial Plot of $n = 40$ Random Values $z_1, z_2, \dots, z_n$, Where z_i Is From a Normal Distribution With Mean $\mu = 5$ and Standard Deviation σ_i , Where $1/\sigma_i$ Is Randomly Sampled Between 0.4 and 2.8

Notes: The points scatter homoscedastically, nearly all within ± 2 of the horizontal radius corresponding to $z_0 = \mu = 5$.

can be applied to all of the points or to specific subsets of them. To facilitate this, it is useful to highlight the range ± 2 on the y axis, or even to show just this range, so it acts as a “two-sigma” error bar applicable to any point.

For the specific purpose of assessing homogeneity, it is not necessary to draw the z scale, but doing so allows one to interpret the points in context. Also, it is easier to visualize radii if the scale is drawn as an arc of a circle, as in Figure 2. This is no longer a linear scale (i.e., equal divisions of z are not quite equal divisions of arc length), but this is of no disadvantage because we want to make position judgments on the z scale rather than difference judgments (the latter being complicated due to the differing precisions). In general, z_0 should be chosen so that the horizontal radius goes through the middle of the data—a common choice being the weighted average $z_0 = \sum w_i z_i / \sum w_i$ where $w_i = 1/\sigma_i^2$ —though sometimes other choices of z_0 may be appropriate. When each z_i has the same expectation μ_i , this weighted average is the optimal (minimum variance unbiased) estimate of μ .

There is a close connection with fitting a regression line through the origin to the (x_i, y_i) data. The ordinary (unweighted) least squares estimate of the slope is $\sum x_i y_i / \sum x_i^2$, which is the same as $\sum w_i (z_i - z_0) \sum w_i$. Furthermore, when $z_0 = \sum w_i z_i / \sum w_i$, this slope is zero, so all fitted values are zero, and plotting y_i against x_i is the same as plotting the residuals against x_i .

Transformations

Often it is appropriate to plot estimates (by whatever method) with respect to a transformed scale, particularly if on the original scale the precision is related to the size of the estimate. Sometimes the standard error of an estimate is approximately proportional to the size of the estimate (or of the quantity being estimated). Then one would use a log transformation—that is, take z_i to be the natural log of the i th estimate and σ_i to be the standard error of z_i , so that z_i and σ_i are approximately independent. In this case, σ_i approximately equals the *relative* standard error of the original estimate e^{z_i} . Nonlinear scales can be used to show the original measurements and their relative standard errors.

To compare *odds ratios* of binary event outcomes (e.g., for a given treatment compared to a control, for each of several studies), one would normally use a log scale (i.e., let z_i be the log odds ratio for the i th study). For the radial plot, one would choose $z_0 = 0$, so the horizontal radius indicates an odds ratio of 1, corresponding to equal risk for treatment and control, and a positive (negative) slope indicates a higher (lower) event probability for the treatment group. The same applies to *risk ratios* (or relative risks).

Other useful transformations include the *square root*, for comparing event rates estimated from Poisson counts, and the *angular* transformation for comparing binomial proportions. In the former case, suppose r_i events are counted in time t_i where r_i is from a Poisson distribution with mean $\lambda_i t_i$. Then the estimate r_i/t_i of λ_i has standard error $\sqrt{\lambda_i/t_i}$, but the transformed estimate, $z_i = \sqrt{r_i/t_i}$, has approximate standard error $\sigma_i = 1/\sqrt{4t_i}$, which does not depend on λ_i .

Likewise, suppose r_i is from a binomial distribution with index n_i and success probability θ_i . Then the standard error of r_i/n_i is $\sqrt{\theta_i(1-\theta_i)/n_i}$, which depends on θ_i , but the transformed estimate

$$z_i = \arcsin \sqrt{\frac{r_i + \frac{3}{8}}{n_i + \frac{3}{4}}}$$

has approximate standard error $\sigma_i = 1/\sqrt{4n}$, which does not depend on θ_i . The correction terms $3/8$ and $3/4$ make practically no difference for moderate or large counts but allow one to plot estimates sensibly when $r_i = 0$ or n_i . Of course, using a point estimate and standard error in such cases (rather than a confidence

interval) is necessarily rough. With the advent of generalized linear models, such transformations are not used much nowadays for statistical modeling, but they are still useful for graphical analysis.

Examples

Figure 3 illustrates a radial plot of proportions using the angular transformation. The data are, for each of 19 degree subjects, the number of students n_i graduating, along with the number r_i of these who achieved upper-second-class honors or better. The students all graduated from a particular UK university in a 6-year period, all were under 21 years of age on entry, and all had achieved the same entry qualification of 26 A-level points.

In Figure 3, the slope axis shows a nonlinear scale of proportions (rather than z), and the x axis shows numbers of students (in addition to $1/\sigma$). The overall proportion of successes is 0.73, and z_0 is chosen to equal $\arcsin \sqrt{0.73}$. The graph shows clear heterogeneity (with respect to binomial variation) in the success rates for different subjects—even though the students all had the same A-level score—with several points well outside the ± 2 horizontal band. This figure could be used as a basis for further discussion or analysis.

Figure 3 A Radial Plot of Proportions of Students Graduating With Upper-Second-Class Honors or Better for 19 Degree Subjects

Notes: The horizontal radius corresponds to the overall proportion for all students.

Figure 4 A Radial Plot of Estimated Risk Ratios From a Meta-Analysis of the Effect of Passive Smoking on Coronary Heart Disease

Source: Data from J. He et al., 1999, Passive smoking and the risk of coronary heart disease: A meta-analysis of epidemiologic studies. *New England Journal of Medicine*, 340, 920–926.

Notes: Filled circles denote cohort studies, and open circles denote case-control studies. The cross is from a rogue study omitted from the meta-analysis.

Figure 4 displays a summary of results from a meta-analysis of studies of the possible effect of passive smoking on coronary heart disease (CHD). There are 10 cohort studies, identified by filled circles, and 8 case-control studies, identified by open circles. The cross indicates the result from an 11th cohort study that was omitted from the original analysis. The outcome variable was death due to CHD (within a given time), and the risk ratio (or relative risk) comparing individuals exposed to passive smoking with those not so exposed was estimated for each study, adjusting for age, sex, and some medical factors that were not the same in all studies. The basic data for plotting are (z_i, σ_i) the estimate and standard error of the natural logarithm of the risk ratio.

Figure 4 shows the actual risk ratios on a logarithmic scale, centered at $z_0 = 0$ corresponding to a risk ratio of 1. The x scale shows, in addition to the precisions, some values of 100σ , which here indicate percentage relative standard errors of the risk ratios. These features are included for illustration and are of course not essential to the basic plot.

The graph reveals some interesting patterns. Except for the cross (the omitted study), all of the estimated risk

ratios are greater than 1, suggesting that exposure to passive smoking is associated with a higher risk of death from CHD. Five of the points are from large cohort studies and have fairly precise estimates, but the estimates for the remaining studies are rather imprecise. Some have very high estimated risk ratios (off the scale), with relative standard errors much greater than 20%. Nevertheless, *all* these estimates lie within the ± 2 shaded band, apparently agreeing with a common risk ratio of about 1.25. However, the filled points by themselves (i.e., results for the cohort studies) do not scatter randomly about this radius—those for the small studies are all above the line (corresponding to a higher risk ratio), and those for the larger studies are below it (corresponding to a lower risk ratio than 1.25). It has been suggested that this may be due to *publication bias*, resulting in a lack of small studies with risk ratios close to 1.

RANDOM ASSIGNMENT

Random assignment is the process by which researchers select individuals from their total sample to participate in a specific condition or group, such that each participant has a specifiable probability of being assigned to each of the groups or conditions. These different conditions or groups represent different levels of the independent variable. Random assignment is generally considered the most important criterion to qualify a research design as a truly *experimental* design. A well-known example of random assignment is the randomized clinical trial, such as the 2020 COVID-19 vaccine trials. In these randomized clinical trials, researchers randomly assigned some participants to receive either the real vaccine to be evaluated or a

placebo vaccine (a sterile saltwater substance that appears identical to the vaccine but is known to be inert). By using random assignment, along with certain assumptions described later in this entry, any differences that are observed in the outcome variable (e.g., the rate of testing positive for COVID-19) can be causally attributed to the independent variable (e.g., receiving the vaccine). Random assignment is not to be confused with *random selection*, a term that refers to the process by which researchers randomly select a smaller sample from the larger population.

This entry discusses issues of causality, specifically how random assignment is used to help ensure that the observed differences between groups are due to the manipulated independent variable and not to other preexisting differences between the groups. It also describes the different levels of randomization; for example, random assignment can be made at the school level as opposed to the individual level. Finally, it discusses some potential problems that can arise with random assignment, particularly when working with human participants.

Causality and Internal Validity

The most important tenet of establishing a causal connection between two variables is that there must be no other plausible explanation for the observed relationship between the variables. That is, to validly make the claim that (independent) variable A causes changes in outcome (or dependent variable or *effect*) variable B, all other potential causes of changes in B must be ruled out. The many other potential variables that may affect the outcome variable are referred to as *confounding variables* or *nuisance variables*. If one can effectively rule out every other explanation for the relationship between variables A and B, the study has good *internal validity*.

Randomly assigning participants to the various groups (or levels or values or conditions) of the independent variable increases internal validity and thus aids in establishing causation, because it helps to create the “everything else equal” condition: The randomization process roughly equates the groups on *every* potential confounding variable. Thus, any observed differences between the groups that are beyond what would be expected by chance can be attributed to the independent variable. The beauty of random assignment is that, if the sample size is sufficiently large, it assures that all determinants of B, even unknown and unspecified ones, are largely evenly distributed between the groups.

Consider the following example of a project to evaluate a smartphone-delivered mindfulness meditation (MM) program intended to help students’ critical

thinking skills as compared to a *sham* program. The sham program was also delivered by smartphone and was described as meditation, but it did not provide guidance on how to control awareness of body or breath, critical elements of MM. From a pool of 91 college students, the researchers randomly assigned about half to participate in the true MM program and the other half to receive the sham program. After 6 weeks, the researcher compared the levels of critical thinking in the two groups. The researcher randomly assigned participants to the two groups, using randomizing software (a variety of software packages or macros are available for this purpose, such as Excel, R, SPSS, and randomizer.org). Because of this randomization, any preexisting differences in the levels of critical thinking skills, or any other possible confounding variable, should be approximately equated in these two groups. So, if the difference in the levels of critical thinking skills following treatment exceeds the small amount to be expected after randomization, the researcher could validly claim the difference is due to MM.

An alternative to random assignment that is often used to control or equate for preexisting differences between groups is through *matching*. Generally, though, when it is possible, the use of random assignment is much preferable to matching because it is impossible to match participants on every possible confounding variable.

The ability of random assignment to allow unambiguous attribution of causality to the independent variable rests on a number of important assumptions that can be invalidated by various imperfections in the way the study is carried out. In particular, if the groups are treated differently in respects *other than* the independent variable, this can introduce confounds. One well-known example of this problem involves *expectancy effects*. These can occur if the participant—or even the researcher—knows which individuals were assigned to each treatment; the resultant expectancy of a particular treatment effect could itself be the true cause of any observed group differences. To avoid any such bias in the results, the placebo or sham should be fully believable, and to go even further, researchers often employ double-blind procedures, as in the COVID-19 vaccine trials. In these types of studies, the experimenters who administer the treatments (as well as the participants themselves) do not know which type of treatment each participant is assigned; they may also be naive even to the hypotheses being tested in the study. This helps to ensure equal expectancies among the participants in the different conditions as well as equal recording of results.

Levels of Randomization

Depending on the type of research question in which one is interested, random assignment may occur at a variety of levels. Thus far, this entry has provided examples of random assignment at the individual level, as when a researcher randomly assigns participants to either receive the vaccine or the placebo. However, in some fields within experimental psychology, such as cognitive psychology, the standard approach is to use within-subjects randomization. In this case, the same individual will be exposed to multiple different experimental conditions (i.e., a repeated-measures design) that are randomly intermixed; sometimes this intermixing can even occur at the level of individual trials.

Going in the other direction, it can also be of interest or necessity to assign participants at the group level rather than the individual level. For example, the vaccine researchers could have randomly assigned at the level of nursing home, such that all the residents of the home received the same treatment, either the vaccine or the placebo. Randomly assigning predefined groups, such as nursing homes or schools, can often be more practical and/or cost-effective than randomly assigning at the individual level. Randomly assigning at the group level does, however, introduce statistical issues, such as clustering effects, which need to be addressed through appropriate data analysis methods, such as multi-level modeling.

Potential Randomization Problems

Some problems can arise with random assignment. The following subsections discuss several such potential problems.

Unhappy Randomization

Although the process of randomly assigning participants to groups should approximately equate the groups on all potential confounding variables, this won't occur in a small proportion of studies and is more of a problem when sample sizes are small. Some inequality will always remain, but statistical tests are designed to take this error into account. However, a small proportion of studies may be subject to *unhappy* randomization: The groups are found to be statistically unequal before the treatment is administered, despite proper randomization procedures, on one or more confounding variables. Advanced statistical techniques, such as analysis of covariance, can help draw appropriate conclusions in this case.

Compromised Randomization

Program staff can compromise randomization by not strictly following its assignment rules. For example, in the Canadian National Breast Screening Study, it was found that nurses likely arranged for particular women to be enrolled in a condition other than the one randomization designated. Experienced evaluators recognize the danger that program staff may well prefer to use their own strategies for assigning conditions (e.g., first-come/first-served, or basing assignment on the participants' appearance of need or motivation) rather than assignment at random. Thus, the random assignment process needs to be implemented in a way that prevents any tampering, whether inadvertent or purposeful, by intake staff.

Treatment Noncompliance

Issues arise when participants do not fully participate in the group to which they were assigned. This occurs when, for a variety of reasons (e.g., the experience of side effects, the amount of effort or diligence required for compliance), participants choose not to actually follow the regimen to which they're assigned. This can be especially problematic when the conditions are unequal in their propensity to elicit noncompliance. For example, consider a mindfulness study in which the treatment group is assigned to an intensive and strenuous meditation retreat, while the control group is assigned to a relaxation and wellness retreat. Assume that more participants in the treatment group will fail to comply or even completely disengage from their assigned activities. A threat to internal validity would occur if participants essentially self-select out of their assigned group (and possibly into another). There are statistical procedures that address this issue, such as intent-to-treat analysis, as well as newer methods, such as propensity score analysis.

Randomizing the Invitation, not the Treatment

A related problem occurs when the researcher randomly decides which condition to *invite* participants to (rather than the one they will receive), and those who decline are simply left out of the analysis. When the considerations leading to the decision to participate are different between the conditions, serious bias can enter. Consider a study in which ill individuals are to receive either an inert placebo or a drug with formidable side effects and only those who are randomized to the drug condition get informed about the side effects. Assume a high proportion of these (but not the placebo control group) thus decline to participate. Such a procedure

would render the composition of the two conditions different and not comparable. To maintain internal validity, the pretreatment comparability of the groups must be preserved. In this case, a good solution would be to explain the requirements of both conditions, including the side effects, to all participants; only those who choose to commit to either condition, whichever arises randomly, will then be allowed to participate.

While internal validity is preserved in such a procedure, large numbers of ill people may exclude themselves from the study altogether. Thus, the study may have a sample that underrepresents individuals with the illness. This limits the group about whom the conclusions are applicable. This limit on the ability to generalize the results is known as *external validity*. It has been well recognized that rigorous attempts to secure high internal validity often threaten external validity; it is imperative to recognize that there are thus inherent trade-offs between the two.

Differential Attrition

There are other situations in which participants may just drop out of the study altogether. This is known as *attrition* and can be a threat to internal validity, particularly if the reason the participants drop out is due to the condition to which they were assigned, therefore leading to differential attrition. Depending on the type and extent of the attrition, researchers may use a variety of statistical methods to deal with this missing data and salvage causal interpretation of results.

Ethical Considerations

There are many instances in which random assignment cannot be employed for ethical reasons. For example, consider a situation in which a researcher would like to understand the role of room ventilation on COVID-19 risk, for unmasked individuals spending time in indoor spaces. Because there are already known risks of COVID-19, it would be unethical to assign the control group to a poorly ventilated indoor space.

When it becomes unethical to randomly assign human participants to groups, researchers often use animals as participants, if possible. Researchers might also resort to quasi-experimental designs, for example, observing outcomes over a period of time for groups of people subjected to a policy in place for a limited time, then withdrawn. The discordant twin design is another type of quasi-experimental design, such as examining the relative likelihood of COVID-19 diagnosis among identical twins, if one worked in a poorly ventilated indoor location and the other did not. Although inferences of causation are less confidently made than with

randomized designs, quasi-experiments that are carefully designed and analyzed may still yield results bearing on causal processes.

RANDOM ERROR

Random error, as with most error in research design is not “error” in the sense of being an obvious mistake. Rather, it is variability that occurs in data due simply to natural inconsistency that exists in the world. Random error does not alter the measured values of a variable in a consistent or systematic way, but it does contribute to an imperfect measure of a variable.

Effects on Data

Random error contributes variability in all data collection measures, such that according to *classical test theory*, the observed value of a variable (x_0) is not actually the “true” value of the variable, but instead it is the true value (x_t) of the variable *plus* the value of the error (e). This idea can be written as $x_0 = x_t + e$. The error term may be made up of both random error (e_r) and *systematic error* (e_s), which is error that alters the values of the data in a consistent manner. Thus,

$$\begin{aligned}x_0 &= x_t + e, \\e &= e_r + e_s, \\x_0 &= x_t + e_r + e_s.\end{aligned}$$

Random error is equally likely to make an observed value of a variable higher or lower than its true value. Although the random error can lead to erroneous conclusions about the values of individual data points, the impact of random error on the value of any one observed variable is generally canceled out by other imperfect observed values of those data. Thus when a sample of data is collected, it is assumed that the random variability will not consistently contribute to the values of the data in one direction. Even though the random error contributes variability to observed data, the overall mean of all the observed data is assumed to be the same as the mean of the true values of the measured variable. The random error simply creates more “noise” in the data; even so, the noise is centered on the true value of the variable.

Because data measures are never perfect, hypothesis testing consists of conducting statistical analyses to determine whether the variability that exists in data is simply due to random error or whether it is due to some other factor, such as systematic error, or the effect of an independent variable. In hypothesis testing, the variability in the samples is compared with the estimated variability in the population in order to determine whether it is probable that the sample variability is equivalent to the variability expected due to random error. If there is more variability than one would expect simply due to random error, then the variance is said to be “statistically significant.”

Expected Value

When multiple samples are taken from a population, the values of the statistics calculated from those samples are assumed to contain random error. However, the mean of random error in those samples is assumed to be zero. In addition, because the

random error is equally likely to increase or decrease the observed value of the true variable, and it is not expected to have a systematic impact, random error is generally assumed to have a normal distribution. If multiple samples are taken from a normal distribution with a mean of zero, then the mean of those samples will also be zero. Thus, given that the mean of the normally distributed random error distribution is zero, the expected value of random error is zero. Consequently, the mean value of the measured data is equal to the mean value of the true data plus the mean random error, which is zero. Thus even though random error contributes to data measures, the mean of the measured data is unaffected by the random error and can be expected to be equal to its true value.

Causes and Related Terms

Random error can be caused by numerous things, such as inconsistencies or imprecision in equipment used to measure data, in experimenter measurements, in individual differences between participants who are being measured, or in experimental procedures. Random error is sometimes incorrectly referred to as experimental error or measurement error. *Experimental error* or *measurement error* can be due to both random error and systematic error. If an experiment is repeatedly performed, the effects of random error will differ with repetitions, while the effects of systematic error will likely be consistent across repetitions.

Example

If researchers are conducting a study on the impact of caffeine on reaction times, they may collect reaction time data by having participants respond to a stimulus on a computer screen by pressing the space bar. Sometimes a participant may not be fully paying attention and will respond slightly slower than his or her normal reaction time. On other trials, the participant may anticipate the stimulus and respond more quickly than the normal reaction time. These variations in response times are considered random error. Likewise if some of the participants in the experiment were short on sleep the night before the experiment, their responses might be slower than if they were well rested. At the same time, the responses of well-rested participants might be faster than if they were not so well rested. These variations due to temporary differences in an individual's physical or emotional states are also considered random error. However, if all the participants in the experiment could not easily reach the space bar, causing all their responses to be recorded as slower than

their initial attempts to respond, then that error in measurement would be systematic error.

RANDOM SAMPLING

In random sampling, the sample is drawn according to prespecified chances from the population, and thus it is also called *probability sampling*. Since planned randomness is built into the sampling design according to the probabilities, one can use these probabilities to make inferences about the population. For example, if one uses the sample mean to estimate the population mean, it is important to know how the sample is being drawn since the inference procedures such as confidence intervals will depend on the sampling scheme. Similarly, hypothesis testing on the population mean also depends on the sampling scheme used.

One important purpose of random sampling is to draw inferences about the population. On the other hand, if the sampling scheme is nonrandom, that is, not all outcomes have a known chance of occurring, the sample is likely to be biased. It is difficult to draw inferences about the population on the basis of nonrandom sampling. Some common nonrandom sampling methods are *quota sampling*, *convenience sampling*, and *volunteer sampling*.

The following sections provide a brief outline of some of the most commonly used random sampling schemes: simple random sampling, systematic sampling, stratified sampling, and cluster sampling.

Simple Random Sampling

Simple random sampling is the simplest random sampling scheme. There are two types of simple

random sampling: with or without replacement. For simple random sampling without replacement, n distinct units are selected from a population of N units so that every possible sample has the same chance of being selected. Thus the probability of selecting any individual sample s of n units is

$$p(s) = \frac{1}{\binom{N}{n}} \quad \text{where} \quad \binom{N}{n} = \frac{n!(N-n)!}{N!}.$$

Sampling without replacement is often preferred because it provides an estimate with smaller variance. However, even though for a finite population, when a sample has been selected, it does not provide additional information to be included in the sample again. One practical advantage to sample with replacement is that there is no need to determine whether a unit has already been sampled. In addition, when sampling with replacement, each drawing of each sample is independent, and the probability formulas for the samples are usually easier to derive. For simple random sample with replacement, a unit may be selected more than once, and each draw of a unit is independent: Each unit in the population has the same probability of being included in the sample. When the sample size is much smaller than the population size, the two sampling schemes are about the same. Otherwise, it is important to distinguish whether the simple random sampling is with or without replacement since the variance for statistics using these two schemes is different, and thus most inference procedures for these two schemes will be different. For example, in estimating the population mean under simple random sampling without replacement, the estimated variance for the sample mean is

$$\hat{V}(\bar{y}) = \left(1 - \frac{n}{N}\right) \frac{s^2}{n}$$

where s^2 is the sample variance. Note that the factor

$$\left(1 - \frac{n}{N}\right)$$

is called the *finite population correction factor*. Under simple random sampling with replacement, there is no need for this factor, and the estimated variance for the sample mean is simply

$$\hat{V}(\bar{y}) = \frac{s^2}{n}.$$

In designing a survey, one important question is how many to sample. The answer depends on the inference question one wants to answer. If one wants to obtain a confidence interval for the parameter of interest, then one can specify the width and level of significance of the confidence interval. Thompson (2002), chapter 4, provides an excellent discussion for determining sample sizes when one is using a simple random sample.

One advantage of simple random sampling is that making inferences is simple and easy with this sampling scheme. It is easy to apply to small populations. With a large population, it is often difficult for researchers to list all items before they draw randomly from the list. This difficulty limits the use of simple random sampling with large populations.

Systematic Sampling

Systematic sampling is easier to perform in the field and provides a useful alternative to simple random sampling. The researcher starts at a random point and selects items that are a fixed distance apart. When no list of the population exists or if a list is in approximately random order, systematic sampling is often used as a proxy for simple random sampling. In cases in which the population is listed in a monotone order, systematic sampling usually results in estimators with smaller (though sometimes unestimable) variances than those of simple random sampling. Repeated systematic sampling consists of more than one systematic sample, each with a different random starting point. Using the variability in the subsample means one can get a measure of the variance of that estimate in the entire sample. When the population is in periodic order, then it is important to choose the period appropriately in order to get a representative sample.

One can classify systematic sampling as a special case of cluster sampling. The population is partitioned into clusters such that the clusters consist of units that are not contiguous. For systematic sampling to be effective, the ideal cluster should contain the full diversity of the population and thus be representative of the population. One simple example for systematic sampling is to interview subjects in a long queue about their political affiliation. If there are 700 people in the queue and one plans to take a sample of size 50, then to take a systematic sample, one chooses a number randomly between 1 and 14 and then every 14th element from that number on. If the people form the queue in a random order, then systematic sampling will produce the same result as a simple random sample. If people with similar political affiliation stay close together in the

queue, then systematic sampling will likely be more effective than simple random sampling.

Systematic sampling is often used in industry for quality control purposes. When there is a malfunction beginning with and continuing from a certain item, a systematic sample will provide a representative sample of the population whereas simple random sampling may over- or underrepresent the defective items.

Stratified Sampling

When the population is partitioned into strata and a sample is selected from each stratum, then the sampling scheme is called *stratified sampling*. One important characteristic of the strata is that the elements in the population belong to one and only one stratum. Stratified random sampling refers to the situation in which the sample selected from each stratum is selected by simple random sampling. Alternatively, one may select a sample from each stratum by systematic sampling or other schemes. When the stratum consists of units more similar in the variable of interest, stratified sampling usually results in estimates with smaller variances. One example of stratified sampling is a study to estimate the average number of hours per week that undergraduates from a large public university spend studying. One can stratify by department and conduct stratified sampling. If the time that students within a department spend studying is about the same whereas there is large variability between departments, then a stratified sample will have smaller variance than a random sample will. On the other hand, if one wants to estimate the average height of undergraduate students in that university, one may choose to use stratified random sampling by department for ease of administration. Note that the resulting estimate from stratified sampling may not have the benefit of smaller variances than simple random sampling would offer because students in the same department may be of very different height.

One important practical consideration in stratified sampling is how many samples to allocate to each stratum. When one has no prior information about the variances of the strata, then the optimal allocation is to assign sample sizes proportional to stratum size. If the sampling cost is the same for each stratum and the standard deviations of each stratum can be estimated, then the optimal allocation is to assign sample sizes proportional to the product of stratum size and stratum standard deviation. That is, the optimal allocation assigns larger sample sizes to larger or more variable strata.

Quite often, the characteristic that one wants to base the stratification on may not be known before the survey is carried out. For example, we may want to

stratify voters by gender, but gender information may be known only after the voter is contacted. *Double sampling* (also called *two-phase sampling*) may be used in such situations. In double sampling, a simple random sample is collected from the population for the purpose of classifying these items to the appropriate stratum. A second sample is then selected by stratified random sampling from the first sample. One important use of double sampling is to adjust for nonresponse in surveys. In addition to the responses they obtain, the researchers stratify the population into response and nonresponse groups according to a first sample of the population. To obtain responses, the researchers recall people from the nonresponse group and offer them more incentives to respond. See Scheaffer, Mendenhall, and Ott (1995), Chapter 11.5, for guidelines for determining the number of callbacks.

Cluster Sampling

Sometimes listing the elements of a population is costly or not available, but a listing of clusters is available. Also, the cost of sampling elements within a cluster is often less than the cost of other sampling methods. In such cases, cluster sampling is a good choice. Cluster sampling and stratified sampling differ in that in stratified sampling, a simple random sample is taken from every stratum, whereas in cluster sampling, a simple random sampling of the clusters is taken. The effectiveness of cluster sampling depends on the variances from using the sampled clusters and the costs of sampling these clusters and the units within the clusters. Quite often, cluster sampling has less precision than simple random sampling from the same universe because units within the same cluster are usually more similar and thus provide less information per unit. In cluster sampling (or *one-stage cluster sampling*), all units of a cluster are sampled if the cluster is a sample. If, after selecting a sample of clusters, a sample of units within the clusters is selected, the design is called *two-stage cluster sampling*. Similarly, *multistage cluster sampling* may be carried out. Suppose one wants to estimate the average number of hours per week undergraduates from a large public university spend studying. One can treat each university department as a cluster. To conduct one-stage cluster sampling, one randomly selects departments in that university, then samples all the undergraduate students in those departments. If instead one samples some individuals from the selected departments, one is using two-stage cluster sampling. An example for multistage sampling is to first select states, then universities within the states, then departments within the universities, and then students within the departments.

In two-stage cluster sampling, various designs exist for selecting the clusters in the first stage. Frequently one uses probability proportional to size, in which the probability of a cluster's being selected is proportional to the number of units it contains. Other sampling schemes commonly employed at each stage include simple random sampling and systematic sampling.

When designing a cluster sample, one decides what overall precision is needed, what size the clusters should be, and how many to sample from each cluster. Lohr (1999) Chapter 5 provides a detailed discussion.

Conclusion

For a complex survey, rarely will only one type of sampling scheme be used. Often many sampling schemes will be combined. For example, a population may be divided into strata, and multistage cluster sampling can be used to sample from each stratum. Simple random sampling may be used in one stage whereas systematic sampling be used in the next stage. The four basic random sampling schemes discussed here have important implications for the estimators to use and the inference procedure for each estimator.

RANDOM SELECTION

Random selection is a precise, scientific procedure whereby each unit in a population has an equal chance of selection for inclusion in a sample. This concept underlies the premise of probability sampling and is central to probability methodologies and generalizability. Random selection eliminates sampling selection bias but introduces random error in its place. Random selection is the only valid strategy for obtaining a representative sample in research.

Random Selection and Probability Sampling

Probability theory, which emerged in response to a desire to better understand card games and gambling, is the branch of mathematics dealing with how to estimate the chance that events will occur. In probability theory, the probability of something occurring is usually expressed as the ratio between the number of ways an event can happen and the total number of things that can happen. For example, the probability of picking a heart from a deck of cards is $13/52$. In other words, inferences are made about events based on knowledge of the population.

There are two types of sampling methodologies that can be used in research: *probability* and *nonprobability*. Each methodology emphasizes different sample selection procedures. Probability sampling methods all use a random selection procedure to ensure that no systematic bias occurs in the selection of elements. The term *random selection* is commonly used in the context of experimental research, while the term *random sampling* is more common to survey research; however, the underlying principle is the same. In probability methodologies, each unit of the population has a known nonzero chance of being selected. Probability sampling is typically used for quantitative research and large sample sizes and is considered to be representative of reality by statistical inference.

The most simple and common example of random selection is the tossing of a perfect coin. Each toss of the coin can result in two outcomes, heads or tails, with both outcomes having an equal probability of occurrence, that is, 50%. Moreover, each event is totally independent of previous selections and is also mutually exclusive, that is, a head and a tail cannot occur at the same time.

There are several types of probability sampling methods, namely, simple random sampling, systematic sampling, stratified random sampling, and cluster sampling.

Simple Random Sampling

In simple random sampling, every element in the population has an equal chance of being selected. This method is ideal for drawing a sample but would be quite time-consuming and difficult if a large population is involved. The basic procedure involves the following: identifying the research population, enumerating each element, and devising a selection method to ensure that each element has an equal chance of selection. For example, if a class has 100 students and the teacher wanted to take 10 students on a field trip, the teacher could write each student's name on a piece of paper, place all the names in

a bottle, and then randomly select 10 names. A more sophisticated alternative would be to use a random number table to select the 10 students. Using this technique, each student would be assigned a number from 1 to 100. An arbitrarily starting point on the random number table would then be selected. The teacher would then move down the columns searching for the first 10 numbers on the table that carry 1 to 100 as their first 3 digits.

Systematic Sampling

Systematic sampling is a variant of simple random sampling whereby every n th element is selected from the research population list or sampling frame. The procedure involves identifying the research population, determining the interval for every n th element (population divided by desired sample size, e.g., $1,000/100 = 10$), selecting the first element randomly (this element should fall within the sampling interval, e.g., 1 to 10), and finally selecting every n th element until the sample size is achieved. Thus, if the first element is 7, the sample would be comprised of the numbers 7, 17, 27, 37, 47, 57, 67, 77, 87, and 97.

Stratified Random Sampling

Stratified random sampling involves dividing the population into subgroups or strata and taking a random sample from each stratum through either simple random or systematic sampling. The advantage of this method is that key subgroups, as well as the overall population, are accurately represented. Populations can be stratified by gender, age, location, size, and so on. The criterion for stratification is determined by the research question or hypothesis. This method is suitable only for fairly large populations.

Cluster Sampling

Cluster sampling is a process in which a random selection of naturally occurring clusters (e.g., schools for sampling students, blocks for city residents, countries for general population) is first performed, followed by a random selection of elements within the clusters. This methodology is best suited for large populations scattered across a wide geographical area, where an exhaustive listing of all the elements would be an unreasonable proposition and prohibitively expensive.

Benefits

There are two primary benefits to random selection. First, random selection removes the danger of sample selection bias caused by drawing a nonrepresentative sample and

associated with nonprobability sampling methods. Second, random selection (a) allows the researcher to estimate sampling error that causes differences between the sample and the population and (b) permits *statistical inference*. Statistical inference refers to the statistical processes, namely, confidence intervals and significance tests, used to make inferences concerning some unknown aspect of a population. More specifically, statistical inference indicates the confidence researchers can attach to their findings when they declare that the findings represent good estimates of what exists in the population.

Random Selection and Sampling

Researchers are generally interested in learning something about large groups or things. Thus, the major questions driving sampling are, What do you want to know? To whom do you want to generalize? There are two types of populations that a researcher can sample—*theoretical* and *accessible*. In practice, researchers sample an accessible population because a sample of a theoretical population would be quite an arduous undertaking and the cost of such a sample would be quite prohibitive. In addition, trying to obtain a sample from a theoretical population would be quite difficult because no accurate listing of the population may exist. For example, for a study of homeless urban teenagers in the United States, the researcher might use an accessible population comprising five urban areas in the United States.

Samples therefore offer a practical solution to the study of populations. *Sampling* may thus be defined as the process of selecting units from a population of interest. It is a key component of sound research design because the manner in which a sample is selected will determine whether generalizations can be made from the sample to the research population. In other words, only probability methodologies are suitable for making generalizations because these are the only methodologies that are based on random selection.

Researchers who wish to generalize must follow very stringent rules for sampling and sample size. Generally, the larger the population, the smaller the sample ratio that is needed to obtain a representative sample. Doubling a sample size does not double accuracy; however, it does double cost. Standard sampling ratios are 500 (50%), 1,000 (30%), 10,000 (10%), 150,000 (1%), and 1,000,000 (.025%). Today, sample size calculators are available on the Web that can generate sample size calculations in mere seconds.

Sampling Frame

To facilitate probability sampling, researchers must work with a sampling *frame*, that is, an exhaustive list of all the units that comprise the research population.

The sampling frame is critical to probability sampling. In order to construct or select a sampling frame, a researcher must have a very clear idea of the kinds of data sources that will be required for the particular study. Common examples of sampling frames include telephone directories, college enrollment records, patient records, membership lists, business directories, universities, cities, academic journals, unions, and professional associations, to name a few.

Generalization

Generalization refers to the extent to which researchers can make statistical inferences from a sample to a population, based on information obtained from a sample. Generalizations should be made cautiously—generalizations from a particular study should be taken as representing only the sum of elements from the initial sampling frame. Moreover, in order to make generalizations, it is critical that the initial sampling frame be relatively complete, with all elements having equal representation. In addition, the sample size must meet the statistical requirements necessarily for generalizability. For example, if a study was being done on the qualifications and evaluation experience of members of the American Evaluation Association (AEA), which has a diverse international membership, but the list from which the random sample was extracted included only members of the association who reside in the United States, it would be incorrect to use this study to make a generalization about the qualifications or experience of all AEA members. Likewise, even if the list included every member, but a random sample of only 10 individuals was taken, these results could not be generalized because a sample of 10 is inadequate for making a generalization.

Computer Software for Generating Random Numbers

Prior to the technological era, random selection was a cumbersome, tedious, manual process, particularly where large samples were involved. Selection was generally accomplished by using a random number table, that is, a table containing lists of numbers ordered solely on the basis of chance. These tables are generally located at the back of most social science research texts. Techniques such as randomly picking 100 entries from a hat, or every *n*th item to obtain a sample of 100, were not at all uncommon.

Fortunately, with the advent of modern technology, this process is now remarkably simple. Modern computer programs (e.g., EXCEL; SAS; SPSS, an IBM company formerly called PASW (R) Statistics; SYSTAT; KWIKSTAT; STATMOST) now have built-in random number generators that can generate a random sample of any size in mere seconds. However, for the computer

to generate this list, all elements in the sampling frame must be numbered. This task can also be performed in mere seconds. In addition, techniques such as *random digit dialing* can greatly simplify the process of random selection when telephone surveys are being conducted. This process is facilitated by an automated procedure whereby a machine dials random numbers within designated phone prefixes. However, since only approximately 20% of the numbers turn out to be working residential numbers, many telephone calls are required with this procedure in order to obtain the desired sample. Notwithstanding, random digit dialing is still quite a popular procedure for conducting polls. It is used by many large media organizations such as the *New York Times* and CBS News. A commonly used and more reliable variant of random digit dialing is a technique referred to as the *Waksberg method*. With this technique, approximately two thirds of all calls are placed to working resident telephones.

Today, several firms (e.g., Survey Sampling, Inc., Genesys Sampling Systems) specialize in providing samples for telephone surveys. These firms provide telephone lists that are scientifically sound, with business numbers excluded. Such firms are in great demand by organizations who conduct survey research via telephone interviewing.

RANDOM VARIABLE

A random variable, as defined by J. Susan Milton and Jesse Arnold, is an assigned value, usually a real number, to all individual possible outcomes of an experiment. This mapping from outcome to value is a

one-to-one relationship, meaning that for every experimental outcome, only one numeric value is associated with it.

Take for example the tossing of two coins. The outcomes of such an experiment will have the following possibilities: heads, heads; heads, tails; tails, heads; and tails, tails. For this experiment, the random variable will map those categorical outcomes to numerical values, such as by letting the random variable X be the number of heads observed. Preserving the above order, the possible outcomes for X are 2, 1, 1, and 0. This particular set lists each element with an equal probability; in this case, the four outcomes each have a 25% chance of occurring.

The listing of all possible outcomes of an experiment is called the *sample space*. In the case of the random variable X , which counts the number of heads, the sample space can be simplified to the set (2, 1, 0) where the values 2 and 0 each have a 25% chance of occurring and the value 1 has a 50% chance, since the outcomes (heads, tails) and (tails, heads) both have a value of 1 in terms of X .

A random variable is the unpredictable occurrence of a subset of outcomes from the aforementioned sample space. There are two types of random variables, namely, *qualitative* and *quantitative*, with quantitative random variables being the more widely used version in both applied and theoretical settings.

Qualitative random variables' defining characteristic is that they can be categorized into specific groups. The focus of the variable is on a "quality" that cannot be mathematically measured. Some examples of qualitative variables are characteristics such as hair color, eye color, or agreeability toward statistics. These variables contain outcomes that are not arithmetically comparable to one another, and they are also referred to as *nominal variables*.

Quantitative random variables are assigned an actual numeric value for each element that occurs in the sample space, as in the coin-tossing example above. A prerequisite for quantitative variables is that the numeric values will have a mathematical relationship with other values. This relationship may be as rudimentary as one value's being greater than another. Examples of quantitative variables include a person's height, age, or the position in which they finished a race. Quantitative variables can be further classified into *interval*, *ratio*, and *ordinal* scales.

In an interval scale, the key principle is that the distance between any value and its neighboring value will be the same distance found between any other two adjacent values on the scale. This scale does not contain an absolute zero point, so it does not make sense to construct a ratio of interval values. For example, the temperature scale of Fahrenheit is an interval scale, and

it is not proper to say that a 100-degree day is twice as hot as a day with a high of 50 degrees Fahrenheit.

In contrast to the interval scale, the ratio scale contains a true zero point. The existence of an absolute zero allows for an understandable ratio of any two values on the scale. A corollary to the previous statement is that a distance between any two points anywhere along the scale continuum has the same meaning. An example of a ratio scale is a measurement made in centimeters. The difference between 10 and 20 centimeters is the same as that found between 132 and 142 centimeters. Also, it is an obvious assumption that an object that is 10 centimeters long is twice as long as an object 5 centimeters in length.

The ordinal scale provides information about subjects relative to one another. The difference between any two subjects is indeterminable because the values assigned in the ordinal scale are not based on magnitude of an attribute. A 5-point Likert-type satisfaction scale, in which 5 is *very satisfied* and 1 is *very dissatisfied*, is an example of an ordinal scale. That is, an answer of 4 indicates that a respondent is more satisfied than a person who answered 2. Yet, the person answering 4 is not twice as satisfied as the person who answered with a satisfaction score of 2.

Within statistics, random variables are involved in three fundamental areas, namely *cumulative distributions*, *probability distributions*, and *expected values*, under the condition that the random variable in question, whether it is discrete or continuous, can be modeled by some formula with respect to probability.

The *cumulative probability* is the chance of finding some value, a , or any other value in the sample space that is less than a . The value of a must be greater than the smallest value, or the lower bound, of the sample space.

For the discrete case where $b < x < c$,

$$P(X \leq a) = \sum_b^a x_i.$$

For the continuous case where $b < x < c$,

$$P(X \leq a) = \int_b^a f(x)dx.$$

A probability distribution defines the probability of a random variable's being observed within a set of given values for either the discrete or continuous case. In particular, the probability distribution is the first-order derivative of the cumulative probability

distribution. A side note is that the probability of a single random variable in the discrete case exists, but not in the continuous case.

For the discrete case of a probability for the d th and e th values and in between,

$$P(d \leq x \leq e) = \sum_d^e x_i.$$

For the continuous case of a probability between the d th and e th values,

$$P(d \leq x \leq e) = \int_d^e f(x)dx.$$

The expected value is the mathematical expectation of the random variable. This value is sometimes called the mean. The expected value may or may not actually be an observable value in the sample space. Theoretically, the expected value is the value that would be observed if an infinite number of experiments were conducted and the outcomes were all averaged. The expected value is denoted as $E(x)$ and is found by multiplying each element in the sample space by its associated probability and either summing or integrating those products across the entire range for which the random variable is defined.

For the discrete case where $b < x < c$,

$$P(X \leq a) = \sum_b^a x_i p(x_i).$$

For the continuous case where $b < x < c$,

$$P(X \leq a) = \int_b^a xf(x)dx.$$

RANDOM-EFFECTS MODELS

Random-effects models are statistical models in which some of the parameters (effects) that define systematic components of the model exhibit some form of random variation. Statistical models always describe variation in observed variables in terms of systematic and unsystematic components. In *fixed-effects models*, the systematic effects are considered fixed or nonrandom. In random-effects models, some of these systematic effects are considered random. Models that include both fixed and random effects may be called *mixed-effects models* or just *mixed models*.

Randomness in statistical models usually arises as a result of random sampling of units in data collection. When effects can have different values for each unit that is sampled, it is natural to think of them as random effects. For example, consider observations on a variable Y that arise from a simple random sample from a population. We might write the model

$$Y_i = \mu + \varepsilon_i,$$

where μ is the population mean and ε_i is a residual term to decompose the random observation into a systematic part (a fixed effect) μ , which is the same for all samples, and an unsystematic part ε_i , which in principle is different for every observation that could have been sampled. Because the i th individual in the sample is a random draw from the population, the value Y_i associated with that individual is random and so is ε_i . Thus in this simple model, μ is a fixed effect and ε_i is a random effect.

More complex sampling designs typically lead to more complex statistical models. For example, two-stage (or multistage) sampling designs are quite common. In such designs, the sample is obtained by first sampling intact aggregate units such as schools or communities (generically called clusters in the sampling literature), then sampling individuals within those aggregate units. If our observations on Y arise from a two-stage sample, then a natural model might decompose the variation in Y into systematic parameters associated with the overall population mean (μ), and the effect of the aggregate unit (ξ), in addition to the residual (ε). Because there are now two aspects of the data to keep track of (aggregate units and individuals within those units), we might use two subscripts, denoting the j th observation in the i th aggregate unit (the i th cluster) by Y_{ij} and write the model as

$$Y_{ij} = \mu + \xi_i + \varepsilon_{ij}.$$

Here ξ_i , the effect of the i th aggregate unit, is a random effect because the aggregate units were chosen at random as the first stage of the sample. Similarly, the ε_{ij} s are also random effects because the individuals within the aggregate units were chosen at random in the second stage of the sample.

In most research designs, the values of the outcome variable associated with particular individuals (or residuals associated with particular individuals) are of little interest in themselves, because the individuals are sampled only as a means of estimating parameters describing the population. Similarly, in research designs that use multistage sampling, the specific values of the cluster-level random effects are of little interest (because inferences of interest are about the larger population). However, in both cases, the variances associated with individual-level or cluster-level random effects are of interest. These variances, often called *variance components*, have an impact on significance tests and precision of estimates of fixed effects, and they play a key role in determining the sensitivity and statistical power of research designs involving random effects. Consequently, random-effects models in some areas (such as analysis of variance) are often called *variance component models*.

To illustrate the role of the variance components on precision, consider our example of sampling from a population with mean μ and variance σ_T^2 , which can

be decomposed into a between-cluster variance σ_B^2 and a within-cluster variance σ_W^2 , so that $\sigma_T^2 = \sigma_B^2 + \sigma_W^2$. If we estimate the population mean μ from the mean of a simple random sample of $N = mn$ individuals, the variance of that estimate (the sample mean) would be μ . If we estimate the population mean μ using a sample of the same size $N = mn$, but using a two-stage cluster sample of m clusters of n individuals each, the variance would be

$$\left(\sigma_T^2 / N \right) \left[1 + (n-1) \left(\sigma_B^2 / \sigma_T^2 \right) \right],$$

so that the variance of the estimate is larger by a fraction (the quantity in square brackets) that depends on the between-cluster variance component.

This discussion refers to formal sampling designs (such as simple random sampling and two-stage sampling) for precision, but the principle that effects that are specific to sampled units (and may be different for each unit that might have been sampled) must be random effects applies whether or not formal sampling designs are used.

Several common random effects models are illustrated below, with an emphasis on the models, as opposed to data analysis procedures.

Analysis of Variance Models for Experimental Designs

For many researchers, the most familiar examples of random-effects models are analysis of variance models that arise in conjunction with experimental designs involving random effects. This is illustrated with three simple designs that are frequently used in themselves and are often the foundation for more complex designs: the completely randomized design, the hierarchical design, and the randomized blocks design.

Completely Randomized Design

In the completely randomized design, individuals are randomly assigned to treatments. The inferential question is whether all the treatments in a population of treatments have the same effect. For example, consider a population of stimuli generated by a computer according to a particular algorithm. One might want to test whether the average response to all the stimuli is the same. An experiment might select the treatments to be tested by taking a random sample of A treatments from a population of possible treatments, then assigning n individuals at random to each of the A treatments and observing the outcome. The model for the outcome of the j th individual assigned to the i th treatment might be

$$Y_{ij} = \mu + \alpha_i + \varepsilon_{ij},$$

where μ is the grand mean, α_i is the effect of the i th treatment, and ε_{ij} is a residual for the j th individual assigned to the i th treatment. Because we think of the treatments as being a random sample from a population of treatments, we would think of the α_i s (the treatment effects) as being a random sample from a population of treatment effects; in other words, the α_i are random effects in this model.

The particular treatments that happen to be in the sample to be evaluated in this experiment are of little interest in themselves. The object of inference is the population of treatments. Consequently, the hypothesis we wish to test is not about the particular α_i associated with this sample of A treatments but rather about the population from which they are sampled. That is, we wish to know whether all the α_i s in the population (not just the experimental sample) of treatment effects are identical. That is, the variance of the population of α_i s, σ_α^2 ,

is zero. Thus the null hypothesis in this random effects model is

$$H_0: \sigma_\alpha^2 = 0.$$

This illustrates how variance components are used in formulating hypotheses in random-effects models.

Hierarchical Design

In a hierarchical design, individuals belong to preexisting aggregate units (*blocks* in experimental design terminology or *clusters* in sampling terminology). In the hierarchical design, entire aggregate units (blocks) are assigned to the same treatment. Because entire blocks or clusters are randomized to treatments, this design is sometimes called a *cluster-randomized* or *group-randomized design*. In experimental design terminology, the blocks are *nested* within treatments. In this design, blocks are taken to be random, that is, sampled from a population of blocks. Treatments may be fixed (as in the case of a small set of treatments of interest) or random (as in the case of the completely randomized design discussed above).

For example, consider an experiment designed to compare two mathematics curricula. In this case, the treatment (curriculum) is a fixed effect. However suppose that the experiment involved sampling $2m$ schools with n students in each school and assigned m schools to use each curriculum. The model for Y_{ijk} , the outcome of the k th student in the j th school receiving the i th treatment, might be

$$Y_{ijk} = \mu + \alpha_i + \beta_{ji} + \varepsilon_{ijk},$$

where μ is the grand mean, α_i is the effect of the i th treatment, β_{ji} is the effect of the j th school nested within the i th treatment, and ε_{ijk} is a residual for the k th individual in the j th school assigned to the i th treatment. Because we think of the schools as being a random sample from a population of schools, we would think of the β_{ji} (the school effects) as being a random sample from a population of school effects; in other words, the β_{ji} s are random effects in this model.

Randomized Blocks Design

In the randomized blocks design, as in the hierarchical design, individuals belong to preexisting aggregate units (blocks or clusters). In the randomized blocks design, individuals within aggregate units (blocks) are assigned to the different treatments so that every treatment occurs within each block. Because the individuals

within each block are matched by virtue of being in the same block, this design is sometimes called a *matched design*. In experimental design terminology, the blocks are *crossed* with treatments. In this design, blocks are usually taken to be random, that is, sampled from a population of blocks, but in some circumstances blocks may be taken to be fixed (when the blocks included in the experiment constitute the entire population of blocks that are of interest). Treatments may be fixed (as in the case of a small set of treatments of interest) or random (as in the case of the completely randomized design discussed above).

Consider the example of an experiment designed to compare two mathematics curricula. In this case, the treatment (curriculum) is a fixed effect. However, suppose that the experiment involved sampling m schools with $2n$ students in each school and assigning n students within each school to use each curriculum. The model for Y_{ijk} , the outcome of the k th student in the j th school receiving the i th treatment, might be

$$Y_{ijk} = \mu + \alpha_i + \beta_j + \alpha\beta_{ij} + \varepsilon_{ijk},$$

where μ is the grand mean, α_i is the effect of the i th treatment, β_j is the effect of the j th school, $\alpha\beta_{ij}$ is the interaction of the i th treatment with the j th school, and ε_{ijk} is a residual for the k th individual in the j th school assigned to the i th treatment. Because we think of the schools as being a random sample from a population of schools, we would think of the β_j (the school effects) as being a random sample from a population of school effects; in other words, the β_j s are random effects in this model. Similarly, we would think of the $\alpha\beta_{ij}$ (the Treatment $\times$ School interaction effects) as being a random sample from a population of Treatment-School interaction effects; in other words, the $\alpha\beta_{ij}$ s are random effects in this model.

Hierarchical Linear Models

Hierarchical linear models (also called *multilevel models*) can be used to analyze a very wide range of data, including survey data that arise from multistage samples, and longitudinal data, and even as an alternative to analysis of variance for experiments with hierarchical or randomized blocks designs. Hierarchical linear models specify the overall model via separate models for the data at each stage of sampling. In principle, these models can have any number of levels, although two- and three-level models are the most common. Two-level models are used to illustrate hierarchical linear models here.

Hierarchical Linear Models for Survey Data

Consider a survey with a two-stage sample, such as sampling of students by first obtaining a sample of schools, then obtaining a sample of students within each of the schools. The Level-1 (within-school) model specifies the model for individual observations within each school. The Level-2 (between-school) model specifies the model for variation of school-specific parameters across schools. Because the Level-2 model describes parameters that depend on the particular schools sampled and the sample is random, these parameters are random effects.

The Level-1 model for Y_{ij} , the outcome of the j th student in the i th school, might say that Y_{ij} depends on a linear model including one or more individual-level covariates (here we use only one covariate, X):

$$Y_{ijk} = \beta_{0i} + \beta_{1i}X_{ij} + \varepsilon_{ij},$$

so that β_{0i} is the intercept in school i and β_{1i} is the slope of Y on X in school i . Because β_{0i} and β_{1i} are both specific to school i , and the particular schools observed arise from sampling schools at random, it is natural to think of β_{0i} and β_{1i} as random effects. The student level residual, ε_{ij} is also random because it depends of the particular student within a school, which is also sampled at random.

The Level-2 model includes two equations, one for β_{0i} and the other for β_{1i} , which may include one or more school-level covariates (here we include one covariate, W):

$$\beta_{0i} = \gamma_{00} + \gamma_{01}W_i + \eta_{0i}$$

and

$$\beta_{1i} = \gamma_{10} + \gamma_{11}W_i + \eta_{1i},$$

where η_{0i} and η_{1i} are school-level residuals that describe how different a particular school's intercept (in the case of η_{0i}) or slope (in the case of η_{1i}) is from the value that would be predicted based on W . Note that the covariate W has only a single subscript (here i , referring to the school) because its value is specific to the Level-2 unit. In the Level-2 model, the regression coefficients γ_{00} , γ_{01} , γ_{10} , and γ_{11} are all fixed effects. Because β_{0i} and β_{1i} are random effects, the residuals η_{0i} and η_{1i} must be random effects.

In some circumstances, one or more of the Level-1 parameters (e.g., β_{1i}) might be assumed to be constant across all Level-2 units (all schools). This is functionally the same as declaring that the Level-2 residuals associated with that coefficient (e.g., the η_{1i} s) are identically zero or, equivalently, that the residual has zero variance.

Hierarchical Linear Models for Longitudinal Data

Hierarchical models can also be applied to the analysis of longitudinal data. In this situation, the Level-2 units are individuals and the Level-1 units are observations within individuals. Let Y_{ij} be the measurement at the j th time of the i th person. Then the Level-1 model describes the growth trajectory of the outcome over time for each person individually. For example, a quadratic growth trajectory might lead to a Level-1 (within-individual) model such as

$$Y_{ij} = \beta_{0i} + \beta_{1i}X_{ij} + \beta_{2i}X_{ij}^2 + \varepsilon_{ij},$$

where here X_{ij} is the time of the j th measurement of the i th person. In this Level-1 model, the coefficients β_{0i} , β_{1i} , and β_{2i} describe the growth trajectory for the i th person and, in principle, can take different values for each individual. Because individuals are sampled at random, β_{0i} , β_{1i} , and β_{2i} are random effects.

The Level-2 model in longitudinal studies might reflect the impact of individual characteristics (such as family background, gender, or treatments received) on their growth trajectories. Because three coefficients are used to describe the individual growth trajectories at Level 1, there are three Level-2 equations. With one Level-2 covariate, the Level-2 (between-individual) model could be

$$\beta_{0i} = \gamma_{00} + \gamma_{01}W_i + \eta_{0i},$$

$$\beta_{1i} = \gamma_{10} + \gamma_{11}W_i + \eta_{1i},$$

and

$$\beta_{2i} = \gamma_{20} + \gamma_{21}W_i + \eta_{2i},$$

where η_{0i} , η_{1i} , and η_{2i} are individual-level residuals that describe how different a particular individual's intercept (in the case of η_{0i}), linear trend (in the case of η_{1i}), or quadratic trend (in the case of η_{2i}) are from the value that would be predicted based on W . In the Level-2 model, W and the regression coefficients γ_{00} , γ_{01} , γ_{10} , γ_{11} , γ_{20} , and γ_{21} are all fixed effects. Because β_{0i} , β_{1i} , and β_{2i} are random effects, the residuals η_{0i} , η_{1i} , and η_{2i} must be random effects.

In some circumstances, one or more of the Level-1 parameters (e.g., β_{2i}) might be assumed to be constant across all Level-2 units (all individuals), or modeled as such if the data contain too little information to obtain precise estimates of all the fixed effects. This is functionally the same as declaring that the Level-2 residuals associated with that coefficient (e.g., the η_{2i} s) are identically zero or, equivalently, that the residual has zero variance.

Random Effects Models for Meta-Analysis

Meta-analysis involves the combination of information across independent research studies by representing the results of each study via a quantitative index of effect size (such as a standardized mean difference, correlation coefficient, or odds ratio) and combining these estimates. Let θ_i be the effect size parameter associated with the i th study and let T_i be a sample estimate of θ_i , so that

$$T_i = \theta_i + \varepsilon_i,$$

where $\varepsilon_i = T_i - \theta_i$ is a residual reflecting error of estimation of θ_i by T_i . Fixed-effects models for meta-analysis treat the θ_i as fixed constants. In a formal sense, this is equivalent to limiting the statistical inference to studies that are identical to those observed, but with different samples of individuals drawn from the same populations.

In contrast, random-effects models treat the sample of studies observed as a random sample from a larger population of studies, so the effect-size parameters are therefore random effects. For example, a random effects model might posit that the θ_i s are a sample from a population of effect size parameters with mean θ_* and variance τ^2 , so that

$$T_i = \theta_* + \xi_i + \varepsilon_i,$$

where $\xi_i = \theta_i - \theta_*$ is a study-specific random effect with mean zero and variance τ^2 . The object of the statistical analysis is to estimate the mean (and possibly the variance) of the population of effect sizes, or in other words, to estimate the fixed effect θ_* (and possibly τ^2).

RANDOMIZATION TESTS

Randomization tests use a large number of random permutations of given data to determine the probability that the actual empirical test result might have occurred by chance. Contrary to traditional parametric tests, they do not rely on the properties of known distribution, such as the Gaussian, for determining error probability, but they construct the probability according to the actual distribution of the data. In parametric statistics, it is assumed that all potential sampled scores follow a theoretical distribution that is mathematically describable and well known. By transforming and locating an empirical score on the respective distribution, one can calculate a density function, which then gives the position of this score within this density function. This position can be interpreted as a p value. Most researchers know that some restrictions apply for such parametric tests, so they may seek refuge in nonparametric statistics. However, nonparametrical tests are also normally approximated to a parametrical distribution, which is then used to calculate probabilities. In such a situation, strictly speaking, randomization tests apply.

Moreover, there are several situations in which parametric tests cannot be used. For instance, if a situation is so special that it is not reasonable to assume a particular underlying distribution, or if a single case research is done, other approaches are needed. In those, and in many more other cases, randomization tests are a good alternative.

General Procedure

The basic reasoning behind randomization tests is quite simple and straightforward. Randomization tests assume that a researcher has done a controlled experiment, obtaining values for the experimental condition and values for the control condition, and in which an element of chance is involved as to either when the intervention started or which treatment a person was assigned to. Randomization tests also assume that a researcher has a range of possible values that could

have popped up simply by chance. The researcher calculates test statistics, such as the difference between the experimental and control scores. The researcher then has the computer calculate all possible other differences (or does it by hand, in simple cases), obtaining a little universe of all possible scores. The researcher then counts the number of cases in which the empirically calculated difference is equal to or lesser or greater than all possible ones. This figure, divided by all possible scores, gives the researcher the true probability that the score obtained can be achieved just by chance.

The benefits of this procedure are as follows: It can be related directly to an empirical situation. It does not make any assumptions about distributions. It gives a true probability. It does not necessitate the sampling of many cases to reach a valid estimate of a sampling statistic, such as a mean or a variance (i.e., it can also be done with single cases). Most randomization tests are also associated with certain designs, but the basic reasoning is always the same.

Practical Examples

Let us take an example for a single-case statistical approach, a randomized intervention design. The assumption of the intervention in this case is that a change in general level, say of depression or anxiety, is produced by the intervention. A researcher might want to think about such a design, if he or she has only a few patients with a particular problem and cannot wait until there are enough for a group study, or if he or she tailors interventions individually to patients, or if simply too little is known about an intervention.

In such a case, the researcher could do the following:

1. Decide on an outcome that can be measured daily or several times a day and that allows the researcher to draw conclusions about the state of the patient.
2. Think about how long it would take to decide whether the intervention was effective. This could be a week, a few days, or a month. This period determines the length of the baseline and follow-up observation period. During this period the researcher just measures to document the baseline condition and the condition after the intervention.
3. Between the baseline and the follow-up period, define a period of days within which the intervention can start. Also, consider how long the intervention should be applied and factor this into the planning. Let us

assume, for the sake of the example, a period of 30 days between the baseline and the follow-up period.

4. Have the patient, or someone else, measure the desired outcome each day, or more often if possible and useful.
5. Decide at random the day of the variable period the intervention will start, and stick to the decision.
6. After the treatment, average all the scores from the start of the baseline to the start of the intervention, because this was the “real” baseline. Also, average all the scores from the day the intervention began until the end of the follow-up period. Calculate the difference. This will be the real, empirical difference.
7. Now repeat this procedure for every possible partitioning of time, first assuming the intervention had started at Day 1, calculating the difference between the baseline and the rest of the scores averaged over the rest of the period, then assuming it had started at Day 2, and so forth, until all the possible differences (in this example, 30 possible differences) are calculated. Here one can see why it is important to define a baseline and a follow-up period that is long enough: Simply by chance, it is possible that the intervention is to start on Day 1 of the variable period, and the researchers want a stable enough baseline to estimate the effect. Or it is possible that the intervention will be randomized to start only on Day 30. In that case the researcher will want a stable enough follow-up. If a longer treatment, say half a year, is expected until the treatment shows effects, the researcher could stipulate such a period between the end of the variable period, when the intervention can start, and the follow-up period.
8. Calculate all potential (in this case, 30) differences between baseline and follow-up, which in this example will give the researcher 30 statistical scores, only one of which is the real one, the one that was obtained by the actual intervention.
9. Now count how many of the possible difference scores are equal to or larger than the one obtained in the real experiment. Divide this number by the number of possibilities, in this case 30.
10. This gives the true probability that the score obtained was obtainable by chance alone. If none of all the other potential differences is larger than the score obtained, the probability is $p = 1/30 = .033$. Should the researcher find another score just as large as the

empirically obtained one, the p value would be $p = 2/30 = .066$.

This also shows that the p value is related to two figures: One is the actual magnitude of the effect, that is, the effect size, or the power of the intervention to actually change the outcome parameter measured. This outcome is a matter of empirical reality. The other figure is the number of potential scores the researcher can calculate. In the example, this was 30, because of the assumption that the intervention can start by chance on any one of 30 days. With that setup, a strong intervention whereby the researcher can be sure that it shifts the outcome parameter sufficiently is needed. If the researcher is not quite sure how strong the intervention is, he or she might want to be on the safe side and increase the power of the test. This can be done either by increasing the measurement frequency to twice a day within the same time, yielding 60 potential differences, or by using a longer time. Similar to standard statistical testing, a researcher can manipulate the power of such a randomization test by increasing, in this case, not the number of participants, but the number of potential permutations, which in this design is related to the number of days or number of measurements.

Using such a design could potentially allow a researcher to make decisions on effectiveness of an intervention on an individual basis. It also allows the researcher to make decisions without having to withhold treatment, because there is no need for a control group. In this design, everyone is his or her own control, and the only restriction is that a participant might have to wait until the intervention begins. One could potentially also study a psychotherapeutic technique that takes longer to work. He or she would simply factor in the therapy time before the follow-up measurements.

Such an approach can also be used if one wants to study the short-term effects of interventions, similar to a crossover design in pharmacology. The same principle applies: The researcher defines possible periods, say days or weeks, within which the participant takes a substance or does something, perhaps watch a certain kind of video, and other days or weeks within which to take the control substance or watch other videos. The researcher measures the outcome of the intervention, and the time needed for measuring the outcome and for the effect to revert back to baseline is normally the time block. In the example case of pharmacology, this might be a week, or if the researcher wants to study the effect of funny versus violent movies, it might be a day. Here again, the kind

of intervention and theoretically expected duration of effect define the length of the time block. The procedure is the following:

1. The researcher defines a number of blocks in which to study the experimental intervention and a number of blocks in which to apply the control condition. Here, as in the previous case, the number of possible time blocks defines the power of the test. Let us assume five blocks are used for the intervention and five blocks for the control, each block consisting of 1 day, making the whole experiment 10 days long.
2. The researcher randomizes the blocks, that is, decides at random on which day which intervention is going to be applied. In the extreme, it could be the first 5 days treatment, the next 5 days control, or the other way round. It could be alternating each day and any possible combination in between. In fact, there are then $10!/5!*5! = 252$ possibilities to permute $2*5$ days at random.
3. The researcher applies the interventions according to the design that has come out of the random choice.
4. The researcher measures the outcome after each intervention, depending on the intervention and the measure, perhaps even multiple times. Note that the length of the time blocks should be determined by such factual and operational criteria and define the design accordingly, not the other way a round.
5. The researcher averages the outcomes for the control conditions and for the intervention conditions. Note that these could be averaged pre-post measurements per period, slopes of time curves in a continuous measurement of some physiological variable, or simply post measurements. This will yield one empirical difference between experimental conditions and control conditions.
6. The researcher now permutes the empirical results, under the assumption that some of the real experimental interventions had been controls, and the other way a round. This means all possible differences between experimental and control conditions are calculated. Here is a simplified example:

Let us assume a researcher had only three conditions each, the real sequence being a b b a a b, with “a” meaning treatment and “b” meaning control. Let the values of the outcome measurements associated with this design be 12 5 7 13 14 6. This would yield an average for the treatment of 13 and for the control of 6, with an empirical difference between the two

conditions of 7. Now recalculate the values, permuting the design through all possible arrangements, which are $6!/3!*3! = 20$, assuming that the design had been a a b a b b. This would yield an average of 10 for the treatment and 9 for the controls. The sequences are permuted and the averages and the differences recalculated accordingly:

$$\begin{aligned}
 a a a b b b & 8 - 11 = -3 \\
 b b b a a a & 11 - 8 = 3 \\
 b a b a b a & 8 - 11 = -3 \\
 b b a b a a & 9 - 10 = -1 \\
 b a b b a a & 8.3 - 10.7 = -2.4 \\
 b a a b b a & 6 - 13 = -7 \\
 b a a a b b & 8.3 - 10.7 = -2.4 \\
 b b a a a b & 11.3 - 7.7 = 3.6 \\
 b b a a b a & 8.6 - 10.3 = -1.6 \\
 b a b a a b & 10.7 - 7.7 = 3 \\
 b a a b a b & 8.7 - 10.3 = -1.6 \\
 a a b b a b & 10.3 - 8.7 = 1.6 \\
 a b b b a a & 10.7 - 8.1 = 2.6 \\
 a b a a b b & 10.7 - 8.1 = 2.6 \\
 a b b a b a & 10.3 - 8.7 = 1.6 \\
 a a b a b b & 10 - 9 = 1 \\
 a a b b b a & 7.8 - 11.1 = -3.3 \\
 a b a b a b & 11 - 8 = 3
 \end{aligned}$$

One can see immediately that none of the permuted values is larger than the empirically obtained one of 7.

7. Now the researcher divides 1 by 20 (i.e., the number of potential permutations), which yields $p = .05$, conventional significance. This is the true probability of having obtained such a result purely by chance. One can also see that, had there been more possible permutations and only one value larger than every other possible one, the p value would be smaller. To be able to obtain a value comparable to conventional significance, the minimum number of permutations possible has to be 20, yielding $p = 1/20 = .05$

Randomization tests can be employed whenever a researcher has single case designs in which some control is compared with some experimental intervention and an element of random shuffling can be introduced. All possible permutations of data have to be done and the calculation of the target statistics repeated for each

possible permutation. If the effect is reasonably sized and the number of permutations is large enough, statistical decisions can be made on the basis of individual cases.

These individual p values being independent can be agglutinated across independent cases using the Fisher-Pearson chi-square omnibus test $\chi^2 = -2 * \sum \ln(p)$, with degrees of freedom $= 2 * k$, where k is the number of p values to agglutinate, $\ln$ the natural logarithm, and p the actual p values. This yields a chi-square score that can be used to find the appropriate omnibus p value.

In complex cases, randomization statistics can be combined with Monte Carlo techniques. This would apply, for instance, if in an EEG experiment one would not want to fall back on parametric tests. Then a distribution can be generated out of the given data by random sampling of time points or time sequences. The general procedure is the same: The empirically found values are compared with the ones obtained by random sampling. The number of values equal to or larger than the empirically obtained ones is divided by the number of all possible values, yielding the true probability of having received the empirical result just by chance.

Limitations

Randomization statistics are very robust because they do not depend on any assumptions. Their result is normally influenced by only two parameters: the real, empirically given effect and the number of possible permutations. The larger these possible permutations, the more powerful the test. However, increasing the number of possible permutations would have to be done at the cost of prolonging an experiment and increasing the number of measurements, making the experiment less feasible from a practical point of view.

However, where the expectation of finding a strong effect is realistic, such a design can produce a reliable result with very little effort. It is particularly feasible for single-case experiments, or in instances in which a large number of data sets have been acquired in comparatively few cases, such as in psychophysiological or psychological monitoring. In all these cases, randomization tests might be the only feasible way of reaching a scientifically sound conclusion.

Some caveats are in order: Randomization tests require certain conditions, such as a minimum number of possible, randomly permuted blocks across time or a minimum number of possible times when an intervention might begin. Such formal requirements might, in certain cases, conflict with clinical necessities. For

instance, the effect of a repeated intervention of, say, funny videos or stimulating pharmacological agents might taper off, creating a habituation and thus thinning out the effect. Or the assumption of a steady level of change of an intervention might not be warranted, or the measurement parameter used might suffer from a response shift, such that, over time, the inner standards of rating something changes. Thus, randomization tests and the corresponding designs have to be used with due care that the design be adapted to the research situation and question, and not the other way around.

Some also think that parametric statistics should be dumped altogether because the conditions under which they operate are violated more often than not, and it is rarely known how such a violation will affect the outcome of the test. Although this is probably true, the pragmatism of statistical testing has settled for the most part on using parametric tests because they are simple and straightforward to calculate and probably also because they have been incorporated in many computer programs and thus are user friendly. This should not prevent researchers, though, from using more adequate approaches, especially in conjunction with single-case designs.

RANDOMIZED BLOCK DESIGN

As enunciated by Ronald A. Fisher, a randomized block design (RBD) is the simplest design for a comparative experiment using all three basic principles of experimental designs: randomization, replication, and local control. In this design, the treatments are allocated to

the experimental units or plots in a random manner within homogeneous blocks or replications. It is appropriate only when the experimental material is heterogeneous. It may be used in single- or multifactor experiments. This entry considers the application, advantages and disadvantages, layout, randomization methods, and statistical analysis of randomized block designs.

Applications

Randomized block design is most useful in situations in which the experimental material is heterogeneous and it is possible to divide the experimental material into homogeneous groups of *units* or *plots*, called *blocks* or *replications*.

It is mostly used in agricultural field experiments, where soil heterogeneity may be present due to soil fertility gradient, and in clinical trials on animals, where the animals (experimental units) vary in age, breed, initial body weight, and so on. A randomized block design can eliminate effects of heterogeneity in one direction only.

Advantages and Disadvantages

The design is very flexible as no restrictions are placed on the number of treatments or replications. The statistical analysis is simple, and if some observations are missing or lost accidentally, one has recourse to the *missing plot technique*. The design is more efficient than a completely randomized design as error variance is reduced as a result of blocking (assigning to blocks or replications), which increases the precision of the experiment. The design is not suitable if a large number of treatments are used or the experimental material is reasonably homogeneous.

Layout of the Design

The plan of allocation of the treatments to the experimental material is called *layout of the design*. Let the i th ($i = 1, 2, \dots, v$) treatment be replicated r times. Therefore, $N = vr$ is the total number of required experimental units. Blocks or replications are formed perpendicular to the soil fertility gradient in field experiments, or age, breed, initial body weight, and so on, in the clinical trials on animals, or education, age, religion, and so on, in social science experiments. Then, the treatments are allocated to the experimental units or plots in a random manner within each replication (or block). Each treatment has equal probability of allocation to an experimental unit within a replication or block.

Table 1 Layout of Randomized Block Design in the Field

T1	T5	T2	T4	T3
T5	T4	T3	T2	T1
T3	T2	T1	T5	T4

Given in Table 1 is the layout plan of RBD in a field experiment with five treatments denoted by T1, T2, T3, T4, and T5, each replicated three times and allocated to 15 experimental units (rows are replications).

Randomization

Some common methods of random allocation of treatments to the experimental units are illustrated in the following examples:

- For an experiment that has no more than 10 treatments, each treatment is allotted a number, using a 1-digit random number table. The researcher picks random numbers without replacement (i.e., a random number may not be repeated) from the random number table until the number of replications of that treatment is exhausted.
- For more than 10 treatments, researchers may use a 2-digit random number table or combine two rows or columns of 1-digit random numbers. Here each 2-digit random number is divided by the number of treatments, and the residual number is selected. The digit 00 is discarded.
- On small pieces of paper identical in shape and size, the numbers 1, 2, . . . , N are marked. These are thoroughly mixed in a box, and the papers are drawn one by one. The numbers on selected papers are random numbers.
- The random numbers may also be generated by computational algorithms.

Statistical Analysis

The data from RBD are treated by the method of analysis of variance for two-way classification. The analysis of data from RBD is performed using the linear fixed-effects model given as

$$y_{ij} = \mu + t_i + b_j + \varepsilon_{ij}, i = 1, 2, \dots, v; j = 1, 2, \dots, r,$$

where y_{ij} is the yield or response from the i th treatment in the j th replication, t_i is the fixed effect of the i th treatment, and ε_{ij} is the random error effect. Suppose one is interested in knowing whether wheat can be grown in a particular agroclimatic situation. One would randomly select some varieties of wheat from all possible varieties for testing in an experiment. Here the effect of treatment is random. When the varieties are the only ones to be tested in an experiment, the effect of varieties (treatments) is fixed.

The experimental error is a random variable with mean zero and constant variance (σ^2). These errors are assumed to be normally and independently distributed, with mean zero and constant variance for every treatment.

Let $N = vr$ be the total number of experimental units,

$$\sum_{i=1}^v \sum_{j=1}^r y_{ij} = N\bar{y}_{..} = G =$$

grand total of all the observations,

$$\sum_{j=1}^r y_{ij} = r\bar{y}_{i.} = T_{i.} =$$

total response from the experimental units receiving the i th treatment; and

$$\sum_{i=1}^v y_{ij} = v\bar{y}_{.j} = T_{.j} =$$

total response from the experimental units in the j th block then

$$\sum_{i=1}^v \sum_{j=1}^r (y_{ij} - \bar{y}_{..})^2 = r \sum_{i=1}^v (\bar{y}_{i.} - \bar{y}_{..})^2.$$

$$+v \sum_{j=1}^r (\bar{y}_{.j} - \bar{y}_{..})^2 + \sum_{i=1}^v \sum_{j=1}^r (y_{ij} - \bar{y}_{i.} - \bar{y}_{.j} + \bar{y}_{..})^2.$$

That is, $TSS = TrSS + RSS + ErSS$ where TSS , $TrSS$, RSS , and $ErSS$ stand for total, treatments, block, and error sum of squares. This implies that the total variation can be partitioned into three components: variation due to treatments, blocks, and experimental error. Table 2 shows an analysis of variance table for randomized block design.

Under the null hypothesis, $H_0 = t_1 = t_2 = \dots = t_v$, that is, all treatment means are equal, the statistic $F_t = s_t^2 / s_e^2$ follows the F distribution with $(v-1)$ and $(v-1)(r-1)$ degrees of freedom.

If F_t (observed) $\geq F$ (expected) for the same degrees of freedom and at a specified level of significance, say $\alpha\%$, then the null hypothesis of equality of treatment means is rejected at $\alpha\%$ level of significance, and F_t is said to be significant at $\alpha\%$ level of significance.

If H_0 is rejected, then the pairwise comparison between the treatment means is made by using the critical difference test statistic,

$$t = \frac{\bar{y}_{i.} - \bar{y}_{j.}}{s_e \sqrt{\frac{2}{r}}}.$$

The critical point for the two-tailed test at α level of significance is $t_{(v-1)(r-1), 1-\alpha/2}$. If the test statistic is more than or equal to the critical point, the treatment means i and j are said to differ significantly.

Under the null hypothesis, $H_0 = b_1 = b_2 = \dots = b_r$, that is, all block means are equal, the statistic $F_b = s_b^2 / s_e^2$ follows the F distribution with $(r-1)$ and $(v-1)(r-1)$ degrees of freedom.

Table 2 Analysis of Variance (ANOVA) for Randomized Block Design

Source of Variation	Degrees of Freedom	Sum of Squares (SS)	Mean Sum of Squares	Variance Ratio (F)
Treatments	$v - 1$	$TrSS$	$s_t^2 = TrSS / (v - 1)$	$F_t = s_t^2 / s_e^2$
Blocks	$r - 1$	RSS	$s_b^2 = RSS / (r - 1)$	$F_b = s_b^2 / s_e^2$
Error	$(v - 1)(r - 1)$	$ErSS$	$s_e^2 = ErSS / (N - v)$	
Total	$N - 1$	TSS		

Note: TSS = total sum of squares; $TrSS$ = treatments sum of squares; RSS = block sum of squares; $ErSS$ = error sum of squares.

If F_b (observed) $\geq F$ (expected) for the same degrees of freedom and at a specified level of significance, say $\alpha\%$, then the null hypothesis of equality of block means is rejected at $\alpha\%$ level of significance.

If H_0 is rejected, then the pairwise comparison between the block means is made by using the critical difference test statistic,

$$t = \frac{\bar{y}_{.i} - \bar{y}_{.j}}{s_e \sqrt{\frac{2}{v}}}$$

The critical point for the two-tailed test at α level of significance is $t_{(v-1)(r-1), 1-\alpha/2}$. If the test statistic is more than or equal to the critical point, the block means i and j are said to differ significantly.

If the null hypothesis, that is, equality of means for blocks, is not rejected, then one may infer that either the blocking has not been done properly or it is not feasible or the experimental material is reasonably homogeneous. The critical difference is also called *least significant difference*.

Coefficient of Variation

The coefficient of variation (CV) is a relative measure of experimental error. It is given by $CV\% = (s_e / GM) \times 100$, where s_e^2 and GM stand for error variance and grand mean, respectively. The coefficient of variation empirically lies between 10% and 20% for yields from field experiments. However, it may be even less than 5% for characters showing little variability, such as oil content, protein content, and so on. The researcher has prior information about the CV% from similar experiments. If the CV% is very high, the researcher may suspect that the uniform application of agronomical practices and statistical methods has not been carried out properly and may reject the experimental findings. If the CV% is very low, the genuineness of the data is suspect and suggests proper examination of the data.

Missing Plot Technique

Sometimes a treatment value may be missing for accidental reasons and not as a result of the effect of treatment. In such cases, these values can be estimated and statistical analysis carried out after substituting the estimated value. The formula for one missing value is given by

$$X = (Tv - Rr - G) / (v - 1)(r - 1),$$

where X is the estimated value for the missing plot, v is number of treatments, r is number of replications, T is total of the treatment that contains the missing value, R is total of the block in which the missing value occurs, and G is total of all observations excluding the missing value.

The estimated value is substituted, and then the analysis is done as usual. Since one observation is lost, the error degrees of freedom and total degrees of freedom should be reduced by one. The standard error of difference between the mean of the treatment with a missing value and the mean of any other treatment is given by

$$SE_d = \sqrt{s_e^2 \{(2/r) + v / (r - 1)(v - 1)\}},$$

where s_e^2 is error variance in the analysis of variance.

RANGE

The range of a distribution of values is the difference between the highest and lowest values of a variable or score. In other words, it is a single value obtained by subtracting the lowest (minimum) from the highest (maximum) value. Range provides an indication of statistical dispersion around the central tendency or the degree of spread in the data. There are several methods to indicate range, but most often it is reported as a single number, a difference score. However, in some contexts, the minimum and maximum are both presented to reflect the range as a pair of values. For example, if the data included values from 10 through 42, the range may be noted as either 32 (the difference between the highest and lowest value; i.e., 42–10) or the pair of numbers reflecting the lowest and highest values (10, 42).

Examples of Range

The range is the smallest number subtracted from the largest number.

Example 1: What is the range of the following data set (1, 2, 3, 4, 2, 3, 4, 5, 5, 5)?

Range is $5 - 1 = 4$; otherwise noted as (1, 5).

Example 2: What is the range of the following data set (1, 1, 1, 1, 1, 1, 1, 1, 5)?

Range is $5 - 1 = 4$.

Example 3: What is the range of the following data set (1, 1, 1, 2, 2, 2, 2, 2, 10)?

Range is $10 - 1 = 9$.

Range is typically used to characterize data spread. However, since it uses only two observations from the data, it is a poor measure of data dispersion, except when the sample size is large. Note that the range of Examples 1 and 2 earlier are both equal to 4. However, the two data sets contain different frequencies of each value. It is an unstable marker of variability because it can be highly influenced by a single outlier value, such as the value 10 in Example 3. One way to account for outliers is to artificially restrict the data range. A common method is to adjust the ends or extremes of the distribution curve. Typically, *interquartile range* (i.e., the distance between the 25th and 75th percentiles) is used. By definition, this contains 50% of the data points in a normally distributed data set. In some contexts, it may be appropriate to use the *semi-interquartile range*, which covers 25% of the data points and is even less subject to variation due to scatter. Likewise, *interdecile range* evaluates only the 1st and 9th deciles or spread between 10th and 90th percentiles. This is similar to the median concept.

Examples of Range Restriction

In correlational studies (examining how one variable relates to another), the sampling procedure, or the measuring instrument itself, sometimes leads to a restriction in the range of either or both of the variables being compared. The following examples illustrate the point.

1. The height of professional basketball players is more restricted than height in the general population.

2. The IQ scores of college seniors are more restricted than the IQ scores of the general population.
3. The vocabulary test scores of fifth graders are more restricted than the vocabulary test scores of all grade school children.
4. Tests that are extremely easy or difficult will restrict the range of scores relative to a test of intermediate difficulty. For example, if the test is so easy that everyone scores above 75%, the range of scores will obviously be less than a test of moderate difficulty in which the scores range from 30% to 95%.

Statistical Implications

Data that are restricted in range may produce a threat to interpretation of outcomes because they artificially reduce the size of the correlation coefficient. This is because restriction of range would be reflected in a smaller variance and standard deviation of one or both marginal distributions. For example, consider the use of height of basketball players to predict performance, as measured by points scored. Who is likely to score more, a person 62 inches (157.5 cm) tall or a person 82 inches (208.3 cm) tall? Nothing is certain, but a person who is 82 inches tall seems a better bet than someone 62 inches tall. Compare this situation with the question, Who is likely to score more, a person 81 inches (205.7 cm) tall or a person 82 inches tall? Here the prediction is much less certain. Predicting from the narrow range of 1 inch (2.54 cm) is extremely difficult compared with predicting from a range of 20 inches (50.8 cm). In sum, range restriction likely results in smaller variance, which in turn reduces the correlation coefficient.

Other References to Range

Other references to range include the following:

Crude range: the difference between the highest and lowest score, another term commonly used for range.

Potential crude range: a potential maximum or minimum that will emanate from a measurement scale.

Observed crude range: the actual smallest and greatest observation that resulted from a measurement scale.

Midrange: the point halfway between the two extremes. It is an indicator of the central tendency of the data. Much like the range, it is not robust with small sample size.

Studentized range distribution: range has been adjusted by dividing it by an estimate of a population standard deviation.

RATING

Ratings are summaries of behaviors or attitudes that have been organized according to a set of rules. Although the general use of the term in research can refer to written data, such as an anecdotal report, a *rating* usually refers to a number assigned according to a defined scale.

Ratings can be *quantified*, as numbers or scores chosen to identify the position on a scale, or they can be *graphic indicators*. Likert-type scales, for example, provide a balanced list of alternatives from which raters may choose to indicate a response to a statement or question. The response chosen is attached to a quantity that becomes a score for use in data analysis. A rating item designed in this way might appear as shown below:

The instructor for this course was prepared for each class.

1. *strongly disagree*
2. *disagree*
3. *neither agree nor disagree*
4. *agree*
5. *strongly agree*

This type of rating is so common that it appears intuitive, but it is not without its disadvantages.

Concerns about this method can arise when the data are analyzed statistically. Most researchers are comfortable treating these responses, and especially summed or averaged total scores across many ratings, such as *interval*-level measurement and apply parametric statistical methods, which assume that high level of measurement. Some critics point out that the psychological processes that lead to a rater choosing a particular rating may not reflect an underlying interval-level scale (e.g., is the meaningful *distance* between *strongly agree* and *agree* ratings equal to the distance between *disagree* and *strongly disagree*?). So the use of parametric statistics may be inappropriate. The consensus of studies over the past several decades, however, suggests that the use of parametric statistical methods to analyze ratings of this type produces fairly accurate results, especially when a total summed score of several ratings is used, and the concern may be primarily academic.

Examples of graphic indicators as ratings include visual analog scales, which can be used to indicate with a high degree of precision a respondent's subjective impression. This method allows for a greater variability in responses and, theoretically, allows for the score to more closely estimate a true or accurate response. Pain scales, for example, ask patients to mark an *x* somewhere along a line to indicate the level of pain they are currently experiencing:

No pain—————x—————Most pain I can imagine

The score for a graphic rating scale is determined by literally measuring the location of the mark along the line, in millimeters, for example, that length becomes the rating. Beyond the potential for greater precision, an advantage of this rating method is that the measurement approach is more clearly interval- or ratio-level, and parametric statistical methods seem a clearly appropriate method of analysis. Concerns for this method center on the absence of many anchors, verbal description of scale points, and logistical measurement difficulties when forms are reproduced at different sizes, such as in different online contexts.

A third type of rating, the *checklist*, is sometimes quantified and sometimes represented as a set of independent observations. Checklists are lists of characteristics or components that may be present or absent in a person, object, or environment. A scale for depression, for example, or alcoholism, may ask people to place a check mark next to, or circle, each characteristic that is true of them. The number of checks may be summed, and if a *cut score*, or critical total, is reached, then the

raters may be categorized as, for example, being depressed or having a drinking problem.

The term *rating* is sometimes misused by researchers to describe a *ranking*. A rating is criterion-referenced, which means the score has meaning when compared to the researcher-chosen definitions of different scale points; all elements or items may receive the same rating. A ranking is norm-referenced: a score is defined as the rank order of the element or item when compared to other elements or items. With rankings, all elements, usually, must receive a different score. An advantage of ranking is that respondents may find it easier to rank order than to apply a rating to each element. A disadvantage of rankings is that less information is provided, and generally speaking, less powerful methods of statistical analysis are available for ordinal-level data. Researchers who wish to ultimately report rankings with their data can always measure their variables using ratings and determine the rankings if they wish at a later time, using the same data.

RATIO SCALE

Ratio scale refers to the level of measurement in which the attributes composing variables are measured on specific numerical scores or values that have equal distances between attributes or points along the scale and are based on a “true zero” point. Among four levels of measurement, including nominal, ordinal, interval, and ratio scales, the ratio scale is the most precise.

Because attributes in a ratio scale have equal distances and a true zero point, statements about the ratio of attributes can be made. The score of zero in a ratio scale is not arbitrary, and it indicates the absence of whatever is being measured. Most variables in experimental sciences, particularly in behavioral sciences and natural sciences, are ratio-scale variables. One advantage of the ratio scale is that all mathematical operations are permitted for ratio-scale data.

True Zero Point

Variables measured at the ratio-scale level have equal distances between attributes and a true zero point. The score of zero in ratio-scale variables indicates the absence or complete lack of an attribute. The variable *number of vehicles owned in the past 5 years* is an example of a ratio-scale variable. A score of zero for this variable means the respondent owned no vehicles in the past 5 years.

Similarly, it is possible for respondents to have zero years of work experience, no children, a score of zero on a midterm exam, zero dollars in a savings account, or zero people living below the poverty line. These are all examples of ratio-scale variables.

The true zero point also makes a ratio-scale variable more precise than an interval-scale variable. The true zero point allows ratio scale variables to make statements about the ratio of attributes. It is possible to multiply and divide the attributes of a ratio-scale variable. For example, it is possible to say that four vehicles are twice as many as two vehicles in the variable *number of vehicles owned in the past 5 years*.

Similarly, for the variable *number of years of work experience*, those who have 3 years of work experience have half as many years of work experience as those who have 6 years of work experience. For the variable *amount in a savings account*, \$1,500 is 3 times as much savings as \$500 or one third as much savings as \$4,500. In the variable *proportion of people living below the poverty line*, areas that have 3,000 people living below the poverty line have twice as many people living below the poverty line as areas that have 1,500 people living below the poverty line.

Mathematical Operations

One advantage, and perhaps the most important advantage, of the ratio scale is suitability for all mathematical operations. Data measurement on the ratio scale permits all mathematical operations to be used, including addition, subtraction, multiplication, division, and square roots. The use of all mathematical operations in turn permits the use of most statistical techniques for data measured on the ratio scale. There are many statistical techniques that are not appropriate for data measured at the nominal-, ordinal-, or interval-scale level but that are appropriate for the ratio-scale level, such as correlation, regression, factor analysis, and time-series analysis.

The statistics for ratio-scale variables are more powerful and produce more information than statistics for nominal-, ordinal-, and interval-scale variables. For

example, statistics for measuring dispersion are available for nominal-scale data (index of qualitative variation), ordinal-scale data (range and the interquartile range), and interval- and ratio-scale data (standard deviation). Among the statistics for measuring dispersion, standard deviation is the most powerful statistic for measuring data dispersion.

Dummy Variables

It is a common practice in statistics to convert nominal- or ordinal-scale variables to what are called *dummy* variables so that they can be analyzed as if they were ratio-scale variables. In the simplest case, a dummy variable has two attributes, including 0 and 1. In experimental research design, a dummy variable is used to distinguish different treatment groups. A person is given a value of 0 if he or she is in the control group or a value of 1 if he or she is in the treatment group.

For example, the variable *gender* is a nominal-scale variable that has two attributes: female and male. Such a variable cannot be used in statistical techniques that are only appropriate for ratio-scale data unless the variable *gender* is converted into a dummy variable. In regression analysis, a nominal-scale variable such as *gender* can be used as an independent variable after being converted into a dummy variable. The attribute *female* could be coded as 1 and *male* could be coded as 0. After being converted into a dummy variable, the variable *gender* is no longer a nominal-scale variable and becomes the variable *femaleness*. The variable *femaleness* has a true zero point, and the attribute *male* has 0 *femaleness*. The variable *femaleness* could now be considered a ratio-scale variable and used as an independent variable in regression analysis.

RAW SCORES

Raw scores are simply the total sum of a respondent's selections before any statistical conversions are made. While serving as a rudimentary level of statistical measurement, raw scores are functionally limited. In application, raw scores are used to arrive at a set of standardized scores (i.e., *T* scores, *z* scores) that can be used to compare individuals to a reference group. Researchers use raw scores to perform statistical analyses or to norm measures. Applied practitioners use raw scores to communicate performance or measurement results.

Although not universally true, raw scores typically are the sum of correct responses out of the total possible correct responses. For example, on a scale containing 10 questions, a respondent may correctly answer 8. Therefore the respondent would achieve a raw score of 8. Of course, this raw score converts rather easily to the percentage correct on the scale, in this case 80%. In this example, 80% is a representation of the respondent's raw score; however, only the number 8 is considered the actual raw score.

Educational measurement is a common application of raw score usage. Take for instance a student who achieves a raw score of 17 on an assessment. This score provides limited information without an indicator of the total possible score. If the total score was 20, one would have a better indicator of the student's performance, yet this assessment provides no information about the student's performance relative to peers (i.e., normative) or to the student's past performance (i.e., growth modeling). However, if these other scores are part of the student's ongoing classroom assessment, one would have enough information to tally the student's current performance level. Even if this particular assessment weighs more or less heavily than other assessments with a total of only 20 possible points, these scores provide enough information to allow us to create a total of points that go into the student's overall performance file.

Applications of raw scores do not always require a measure with correct or incorrect responses. Measures of interest, personality, or motivation, for example, do not contain right or wrong answers, but responses that reflect the participant's response preferences. In this example, these inventories measure a number of domains, usually through a Likert-type scale; scores on these domains are summed but do not represent a ratio of correct to incorrect responses.

Although in most cases raw scores provide enough information for typical educational purposes, they remain limited in measurement applications. Consider for a moment that we want to examine how this

student performed in comparison to peers. In a class with a small number of students, it might be tempting to simply order the performance of peers from lowest to highest and perform a count of the scores until we arrive at our student's score. However, if the scores were taken from a class of five and those additional four scores were 19, 16, 14, and 17, simply ordering those scores and then counting until we arrive at our student's score becomes inadequate. If one is interested in the student's score in comparison with peers, one would consider the group's highest and lowest score on this assessment and remove the full range of possible scores from consideration. Through the use of a selected statistical metric, we are able to convert the student's raw score into a standard score and determine how it compares to the scores of peers.

As another example, imagine a student who has taken a standardized computer adaptive assessment as part of graduate school application requirements. The test has been constructed and normed by the use of stringent testing standards. Under computer adaptive testing conditions, test item difficulty for the subsequent question depends on the student's previous performance. As the student answers questions correctly, the difficulty of test items increases. Conversely, when the student misses a question, the testing program responds by selecting an easier item. This type of testing design allows efficient administration while obtaining a valid measure of the student's ability. However, for two students who both responded to 60 questions of varying difficulty, it becomes impossible to use raw scores alone to determine how the students rank in comparison with each other. Assume that these students both correctly respond to 45 questions out of 60, but due to differences in the two students' abilities, Student A correctly answers the first few questions before missing an item, whereas Student B incorrectly answers the initial questions. In this situation, Student A will continue to face increasingly difficult questions while Student B receives increasingly easier questions. Although both students correctly answer 45 questions out of 60, Student A correctly answers more questions at a higher difficulty level. Because of the differing levels of item difficulty, the raw scores of correctly answered questions does not provide an accurate reflection of the two students' performance.

One could argue that once those scores are correctly weighted, the raw scores resulting from those exams provide enough information to determine which student performed better. However, this assumption applies only in tests in which each item contains clear weighting. Let us now imagine that Student A has applied to a competitive program and is now competing for admission with other students who took tests from the same testing company, measuring the same

domain; however, the test is frequently reconstructed to maintain test security, and each test reconstruction is an essentially different test. Because these tests used different questions in their item pools, it becomes impossible using raw scores alone to determine how those scores compare with each other. In this example, Student A is now competing with students who achieved scores ranging from 15 points higher to 15 points lower than A's score of 45. Even assuming the total possible correct score for all students is 60, information on which to weight the tests is still lacking. Comparing student scores more accurately requires further statistical information, including the mean and the standard deviation scores. As previously mentioned, Student A has correctly responded to 45 questions and is now competing for admission with Student C, who has obtained 50 out of 60 points on the exam. For convenience, let us assume that all items are weighted equally. Based on these scores alone, it is tempting to assume Student A performed inferiorly compared with Student C. However, on further examination, we learn that the mean score (i.e., arithmetic average) from the test our student took was 40, and the standard deviation score is 5 points. With this information, we now understand that Student A scored 1 standard deviation above the mean and higher than or equal to approximately 84% of the students who took the same exam. An analysis of Student C's scores reveals the mean score from Student C's test is 55 and the standard deviation score is 2 points. Now it becomes clear that even though Student C has a raw score that is 5 points higher than Student A's score, Student C actually scored 2.5 standard deviations below the mean. Assuming there were no biases in the assessment, we can conclude that even though Student A has a lower raw score, Student A is likely a significantly better candidate than Student C in this particular domain.

REACHABILITY

The concept of reachability is gaining importance as universities experience funding decisions based not only on the number and quality of their research

publications but also on how widely their research work is disseminated to a variety of third parties. Being published is no longer considered to be sufficient. The discoveries from research need to *reach* those parties, both individuals and organizations, who can then apply the research in a manner that has a real *impact* on the world. Research that does not lead to positive change and/or that does not solve pressing problems represents a missed opportunity.

Researchers expend considerable effort at each of the stages of the research process: posing a well-stated research question, choosing an appropriate research design, recruiting appropriate participants, collecting and analyzing relevant data, and then using that analysis to provide an answer to the research question that was posed. By this point in the research process, many researchers have run out of steam and neglect the final, and arguably most important, stage of dissemination. Thus, many research discoveries suffer the fate of the proverbial tree that falls in the forest and is not heard.

But even dissemination is not enough. Traditionally, researchers were expected to produce a well-argued dissertation or thesis document, which was examined by experts and, once passed, held a place of honor on the shelves of the researcher's university library. The researcher earned their relevant research degree and went on to either further research or to an academic or industry position. In more recent decades, at least one publication in a peer-reviewed journal was expected from research students, and in some cases was even included in the dissertation itself, using the increasingly popular and recommended pathway of *thesis by publication*. Research students could understandably be proud of both their thesis and their publication arising from it and could point to both as tangible outcomes of their research project.

But it is the pointing process that often fell by the wayside. Only someone dedicated to finding research on a topic, by undertaking the arduous process of searching library literature databases to discover a digital dissertation, or a journal publication, would be motivated to *go hunting* for these scholarly documents. Scholars were primarily only talking to other scholars. Such conversations were useful for building and advancing the body of evidence in a particular field, as scholars built upon each other's work when designing future research projects. But getting research off campus and *out there* to the rest of the world is not a migration that has been done well in previous scholarly traditions.

As tempting as it may be for a researcher to "rest on their laurels" once their thesis has been examined and passed, their degree conferred, and possibly even their journal article published, stopping at this point is a lost

opportunity for further visibility and impact of the research. Researchers need to reach out to various relevant parties, in numerous disparate ways, to ensure the people who can take their work forward, know that it even exists.

The first step is to consider the who, and the second step is to consider the how. The who consists of anyone who might benefit from knowing the discoveries found by the researcher, and many of these parties have already had some involvement, and thus investment, in the research project as it unfolded. Often organizations have been involved in enabling the researcher to access participants, who are their employees, patients, or clients. Both the organizations and the participants need to be advised of the discoveries they helped to cocreate when they enabled access or provided data to the researcher. These communications need to be tailored to these audiences and not be relegated to simply telling them to "read my dissertation" or "here's my journal article"—neither of which actions are likely to occur. Providing a lay language abstract, seminar, or town hall forum is all more likely to be well received, especially when people have the chance to ask the researcher specific questions that are relevant in their own work contexts or lived experiences. Researchers need to be as visible at the dissemination and impact phases as they were at the recruitment stage.

Reaching the public is now an obligation for all researchers, and learning to communicate complex research findings in short, simple, and contextually based language is also an ethical obligation. Human research ethics committees and/or funding bodies often now include such lay or public dissemination as a requirement to receive their approval or funds, and a clear plan to accomplish it may need to be included in the ethics or funding applications. Even in the absence of stipulations from others, academics advising research students often insist that a detailed dissemination plan be included in the project design from its conception.

Besides the public, all relevant stakeholders and beneficiaries should be considered and tailored communication strategies developed for each of these identified parties. Other relevant people could include professional organizations; patient support group organizations; disease-specific nongovernment organizations; charitable organizations; policymakers at local, state, national, and international levels; educational institutions; and public-facing institutions that provide services to particular populations. Recommendations in the discussion section of a dissertation or a journal publication are often organized according to the four main areas of recommendations for practice, policy, research, and education. This same framework can be used early in the planning process to identify which stakeholders or beneficiaries would

benefit from learning the discoveries arising from the research project related to the aforementioned four types of recommendations.

Once the who has been clearly identified, the how also needs attention. Lay language directed to the public through various media outlets is an often-overlooked method of dissemination. Interviews by radio, television, traditional print media, and numerous online media outlets are all viable means to let the world know about these discoveries. Presentations to community groups are another way to reach the lay public. Targeted contact with government officials who hold relevant portfolios can also be an important way to ensure research findings are translated into evidence-informed new policies. Social media can also play a vital role, with researchers holding accounts in such platforms as Research Gate, Google Scholar, LinkedIn, Facebook, and Twitter. These methods can help a researcher connect to other professionals with common interests.

Deciding the who and the how for dissemination of research findings is a critical phase in research planning and can substantially increase the impact of new discoveries. Research is an exciting way to create positive change, but only if the world *hears* that tree that each dedicated researcher has nurtured and tended, when it does fall in the forest.

REACTIVE ARRANGEMENTS

Reactive arrangements are an example of a threat to the internal validity of a research design. *Reactivity* occurs when the results of an experiment are due, at least in part, to behaviors of participants that artificially result from their participation in the experiment. Thomas D. Cook and Donald T. Campbell and colleagues, in their works defining threats to validity in research design, distinguish between artifacts due to the use of measures in a study and other reactions that occur because participants are aware that they are in a study. When these reactions become a functional part of the treatment or independent variable, then reactive arrangements are present.

Reactivity has occurred when the “meaning” of a treatment includes the human reactions to being in a study. Reactions to the study procedures themselves may occur in several different ways:

- Participants may respond favorably after receiving a nonactive drug used as a control (the placebo effect).
- Study subjects may guess or ascertain the expected outcome of an experiment and behave in ways they feel will please the researcher.
- Participants may perform higher or lower on skill or achievement measures because of increased motivation or anxiety-induced interference.
- Apprehension of being evaluated by a “scientist” may encourage some subjects to produce expected responses.

Protections against the threat of reactive arrangements center on hiding the true purpose of a study by making all control treatments appear to be authentic, measuring the outcome surreptitiously, and designing pretest measures so as not to give cues for expected outcomes. A researcher examining the effectiveness of a psychological therapeutic intervention, for example, may replace a no-treatment group with a group that receives another approach to therapy that is believed to be weaker or ineffective. Many studies use this approach with their treatment-as-usual group. Another approach is for researchers to make the measurement of outcomes less obvious by not assessing the outcome at the immediate conclusion of the treatment or procedures but, if possible and still theoretically meaningful, assessing outcomes on some delayed basis.

Participants will almost always make their own hypotheses as to the purpose of a study, however, so

complete protection against this threat may not be possible. There are also ethical requirements to give enough information about the purpose of a proposed study so that recruits can give free and informed consent to take part. Some extreme ethical positions might even require that the researcher share the study hypotheses with all recruits. Most researchers, however, control for the threat of reactive arrangements through design choices or, at the least, measure variables in ways that allow for a determination of the presence of reactive arrangements.

Reactive arrangements are a particularly tough threat to compensate for, because they are among those threats to validity that are not eliminated or lessened by random assignment to different groups. Random assignment can control for preexisting differences between members of different groups, but in the case of reactive arrangements, the differences between groups do not exist until the study begins. While group comparison is the basis of modern experimental research, one consequence of this analytic technique is the possibility of reactive arrangements.

RECIPROCITY

Reciprocity, a dimension of research ethics, is an exchange between two or more parties in which both mutual effort is given and mutual benefit is received. Although reciprocity is a means to supporting equitable researcher-participant relationships, the extent to which reciprocity is attempted and actualized varies in practice. Across paradigms, researchers minimally rely on relationships with people, groups, institutions, and organizations as sources of data. Participants who are providing or coconstructing data may expect, want, or need something in return for their efforts.

Researchers most effectively address reciprocity when they align its implementation with their theoretical and philosophical frameworks throughout study design, data collection, analysis, and dissemination. Reciprocity can be implemented with a single strategy, such as monetary compensation in exchange for participants' time in survey research. Alternatively, reciprocity can be enacted as a stance that informs a collaborative relationship over multiple stages of research, as in participatory action research. This entry offers a list of common examples of strategies and stances illustrating reciprocity, followed by the identification of key ethical questions that can emerge during implementation.

Examples of Reciprocity Strategies and Stances

There are multiple ways to approach reciprocity in research. Effective approaches demonstrate alignment between researchers' philosophy, theory, and methodology.

Quid Pro Quo Strategy

At a most basic, transactional level, researchers may elect to use incentives to reciprocate participants' effort and time when, for example, they participate in surveys or interviews. This approach, as its nickname suggests, is an exchange of something desired by participants that is similar in material or symbolic value to the effort and risk incurred through research participation. Institutional review boards have generally been responsible for approving the use of research incentives provided to human participants, seeking to reduce coercion and promote transparent distribution. The use of monetary incentives is common across disciplines in medical and social science research; however, the strategy may have dual purposes—a way to both thank and recruit them.

Shared Recognition Strategy

While fame, recognition, and professional accomplishment can hold different meanings and weight for people based on their identities, group membership, roles, and responsibilities, mutual recognition of research-based knowledge can reconfigure the gaze of the researcher and center the voices of those typically pushed to the margins of society. This strategy can also lend credibility to researchers' work, recognizing the importance of honoring differing perspectives in the

research design and study, while simultaneously boosting the clout of the participants in formalized educational spaces. The use of shared recognition can take the form of publication coauthorship of researchers and participants, think tanks, and organizations.

Relational Stance

Some research methodologies rely heavily on interdependent relationships established over time. These relationships reflect the situated power and status of researchers and participants. Reciprocity grounded in researcher–participant relationships exceeds the use of a single strategy and is enacted across stages of the research process. For example, participants may introduce researchers to other potential participants (i.e., snowball sampling) and participate by responding to emergent themes following data analysis (i.e., member checking). In return, researchers might make resources relevant to the study and to participants' community accessible. A relational stance of reciprocity requires researchers to grapple with positionality intentionally, giving consideration to all parties' valuation of both processes and results. Researchers who adopt a relational stance to reciprocity acknowledge how power differs across researchers and participants; however, researchers' commitment to sharing power equally or systematically varies.

Collaborative Stance

Reciprocity is not always an exchange of material gains. Symbolic exchanges can result when researchers focus on expanding their collaboration with participants who have proximity to cultural knowledge and who act as brokers of cultural information. Because collaboration represents effort, a collaborative stance facilitates reciprocity through shared knowledge when researchers acknowledge participants' expertise. Sometimes what is being shared is an explanation of cultural or context-specific norms, which strengthens research and amplifies its usability. Some collaborative research methodologies, such as participatory action research, emphasize the equal contributions of researchers and participants throughout all stages of research as the basis of reciprocity. Adopting a participatory cocreation stance to reciprocity elevates mutual decision-making in design, implementation, and the sharing of results. Here, reciprocity is not so much about mutual gain as a result of the research endeavor as it is about balanced voice, perspective, and power in the research process. In this stance, researchers do not begin with a research question or outlined methods but meet continuously with participants to codevelop research

questions, study protocol, data collection, and data analysis; no step is taken without consultation of all parties involved. This stance disrupts the typical binary of researcher and participant, as it positions all participants as coresearchers.

Social Justice Stance

The purpose of a social justice stance to reciprocity accepts that making society more equitable is a key purpose of research. Social justice research addresses decolonization and democratization writ large. For example, the examination of the inclusion of children with disabilities in general education settings would establish reciprocity with researchers and participants in ways that support inclusion, such as having people with disabilities lead or consult during the implementation of research. For this work, the equal exchange of power and compensation would be paramount to achieving the goals of reciprocity.

Emergent Ethical Questions

Approaches to reciprocity—be they strategies, stances, or a combination of the two—are informed by paradigm and associated methods. Questions about the effective and ethical implementation of reciprocity are questions of alignment. For example, *Does reciprocity in this study fit within the research method and its guiding philosophy and/or theory?* Relatedly, while some definitions consider reciprocity in terms of balanced research's efforts and affordances, such can be difficult to determine. Reciprocity is seen through multiple lenses, two of which—researchers and participants—are central to its conceptualization. Other lenses include those of readers and consumers of research. One emergent question is about perspective and perceptions of balance. *Who decides when what is given and what is taken is balanced?* Additionally, implementing studies and the publication of results can occur over lengthy periods of time, so the valuation of reciprocity may be fluid and change with shifting cultural and historical events. Thus, another emergent question is, *How is reciprocity measured and how does this occur over time?* Research as a relational and interdependent endeavor perhaps negates only one question: Is there a need for reciprocity?

RECRUITMENT

The success of any human subject research project is usually only as good as the researcher's ability to recruit the proper participants. Common limitations of empirical research studies usually include small sample sizes and/or samples that are not representative of the population. Small and/or nonrepresentative samples could result for a number of reasons (e.g., limited funding, time, access to the population of interest); however, effective recruitment is often a factor. Recruitment is the act of enlisting people for a certain cause, in this case, participation in a research experiment. This entry discusses different methods of recruitment and strategies to improve recruitment methods.

Recruitment Methods

Considerations and planning for recruitment should occur during the early stages of project development. A methodology section often needs to be tailored to accommodate the needs of recruitment and retention (keeping individuals in the study). The ability to attract and maintain participants is crucial to most studies, and some methodologies can lead to problems with participation and recruitment. Methodological problems may include length of time of the study, number of surveys, location, and language and literacy barriers. In addition, partnerships formed with community

agencies, which will increase recruitment, may have restrictions that require alterations to the methods. For this reason in particular, designing recruitment strategies needs to occur at the beginning of the study design to allow for any necessary adjustments.

There are several ways to recruit participants for research studies. One common method used at universities is department subject pools. In several undergraduate classes, students are often mandated to participate in research studies for course credit, and students are provided a list of research projects available for participation.

Online research advertisements are also very popular. There are several options for posting online research. For example, popular social networking sites such as MySpace or Facebook are often used. Researchers can also contact website owners of relevant topics and ask for permission to advertise. Depending on the site, an advertising fee may be required. There are also several websites dedicated to posting research studies. If a study is posted online but requires in-person contact, it is advisable to make sure that the advertisements are located on a website frequented by individuals within the geographical area.

Other common recruitment strategies include advertisements in newspapers, community magazines, television or radio announcements, flyers posted at community centers, stores, related businesses, or available at related community events. Some of these forms of advertisement may be costly; however, companies may be willing to donate space, especially if the researcher is affiliated with a nonprofit organization such as a public university. It is important that before materials are posted in public places, permission for posting is obtained.

Another form of recruitment includes the use of a preexisting database of individuals who have consented to be contacted to participate in research studies. University departments or community agencies can be contacted to inquire about requirements to access these databases. Examples include a registry established at the Center for Cognitive Neuroscience at the University of Pennsylvania and the Cognitive Neuroscience Research Registry at McGill University, which provide a structure for recruitment and retention and serve as a data management system for cognitive neuroscience researchers. However, as with these examples, some of the participant lists may be specific to one topic.

Many studies use multiple methods of recruitment to ensure that the study consists of the target population and the desired sample size. However, it is not necessary to use all forms of recruitment in every study to be successful. There are limitations, such as time and funding, that dictate whether some recruitment

methods are feasible for a study. What is most important is that the recruitment methods used are tailored specifically to the target population in order to maximize enrollment in the research study.

Strategies for Improving Recruitment

There are several strategies that researchers can employ to encourage participation in a study. Each of these strategies can be used alone or in conjunction with one another, depending on the circumstances of the researcher.

Tailoring Recruitment to the Population and Type of Study

Two key factors of a study that have a major influence on recruitment strategies are the target population (e.g., children, older adults, ethnic minorities, abused women) and the specific methods involved in the study (e.g., survey instruments, treatment, longitudinal design). Recruitment has been known to be challenging for certain target populations, one being minority populations. Common reasons for lack of participation often include inappropriate methodology used to reach the target community; recruitment materials that are not understood by the target population; a perception by the target population that the research is not relevant; lack of community involvement by researchers, leading to lack of community trust; no minority representation on research teams; and few incentives provided for participation. Issues such as these must be addressed and their solutions built into the research design to ensure ample recruitment. With regard to recruitment challenges due to unavoidable research methodology, such as longitudinal studies or physically invasive medical research, challenges could be due to higher demands that are placed on the participants.

Judith McFarlane in 2007 conducted a longitudinal study on abused women and found that retention rates were between 89% and 100% when efforts were made to establish a strong working relationship with the community agencies, incremental monetary incentives were offered, contact was made with the participants on a constant basis, and safety factors were taken into consideration. This study had two complications: working with a vulnerable population and the requirement of a long-term commitment. Each research study may require special accommodations to entice and retain participants. For this particular study, it was crucial to ensure safety for participants, and team members had to have consistent personal contact in an effort to decrease drop-out rates.

Community and/or Organizational Involvement

One barrier to recruitment is often mistrust, especially in vulnerable populations (children, minorities, abused women, etc.). If a partnership is established with a respected community member, agency, and/or organization, individuals within that community may be more likely to participate. Recruitment can also be easier for the researcher when a connection is formed with a group that is willing to perform some of the recruitment activities. Some common community connections could be through community leaders, local agencies or community centers, churches, or local schools. One example is forming a relationship with a target community school whose principal would endorse the research and encourage staff to pass out flyers, speak to parents, and so on. In this example, the recruitment occurs through a source in which the individuals may already have an established relationship.

Collaboration with an agency (a company or an organization) for recruitment purposes can have a significant impact on the success of the study. It is important to learn about the agency and the community the agency serves in order to build a good working relationship and determine goodness of fit for the research study. Building this relationship may include spending a day at the agency and speaking with staff and current clients. It is important to keep the agency informed and to offer something to the agency in return for its assistance. This can be a monetary payment or an exchange of services, depending on the agency's need and the resources of the researcher. For example, researchers can offer to teach classes or assist with problems in the researchers' area of expertise. One potential problem with agency collaboration is the possibility that agency policies and procedures could affect the research study. Offering to have a member of the agency on the research team may allow the agency to feel more invested in the project and to maintain consistent contact regarding progress or problems with the research study, and it may result in fewer problems when determining adjustments to the research design to comply with agency rules. If having a member of the agency on the research team is not possible, then a member of the research team must connect with the agency on a regular basis. Often-times in research, several research team members and assistants may need to interact with agency workers, which can cause confusion and frustration for the agency. It may be beneficial to have as assigned agency contacts a small number of researchers who are willing to work with the agency's schedule.

Personalized Recruitment

Recruitment methods that are personal elicit better responses than impersonal methods do. Strategies include having research assistants phone individuals, walk door to door in target neighborhoods, set up information tables at community events or centers, or speak to individuals at target community centers, shopping malls, or agencies. It is always important to obtain permission from the property owner if advertising will be conducted on private property. Another important task in personalized recruitment is accurate tracking logs that list the date, time, person making the contact, and person contacted. This will avoid a single participant's receiving multiple telephone calls or visits, which may discourage participation. Even though these methods may be time-consuming, personalized strategies may increase trust, acceptance, and the likelihood that certain populations are aware of the research study.

Language

Language can serve as a barrier for many different populations for different reasons. Some populations may not speak the language used in the recruitment strategy, the language may be too complex to fully explain the study, the print may not be legible, or the advertisement design may be too distracting. Overall, terminology should always be as simple as possible, and researchers may want to avoid the use of certain words that might offend potential participants. For example, advertisements should have a title using general, familiar terminology in addition to a more detailed description of the actual study. The use of nonthreatening words and words that carry no stigmas may make potential participants more comfortable. It is important that these adjustments do not deceive participants but rather provide a clear explanation of the study. This same idea can be used when introducing consent forms. In some studies, consent forms are sent home as part of the recruitment process. These forms can be very formal, hard to understand, and intimidating. Even though a consent form may not allow for alteration of language, a cover letter can often be added that is written for the target audience and can explain the technicalities in simpler terms.

Transportation and Child Care

In many families, participation is difficult because of lack of transportation or child care. Using available funding to provide these resources or conducting the study at a convenient time for the participant or at the

participant's home, when possible, could significantly increase participation in certain populations.

Incentives

Providing compensation can be a great recruitment method. It is the ethical responsibility of the researcher to ensure that the compensation is not coercive. Incentives can come in the form of gift cards, cash, or other materials (i.e., food, clothes). Researchers could use local or national wage standards to determine dollars per hour for participation. It has been previously suggested that monetary incentives used for longitudinal studies be provided in an incremental way, whereby each time a participant completes a part, the amount increases. It is very important to pick incentives that match the goals or needs of the population; for example, if a study is being conducted on the homeless population, it may be appropriate to provide food or clothing. Including incentives on advertisement materials can enhance recruitment efforts.

Retaining Participants

An effective recruitment plan will be responsive to the needs of the target population and the specifics of the research design. If the above suggestions are taken into consideration as the methods are designed, recruitment should prove to be less of a challenge and a realistic understanding of the ability to obtain certain samples will be reached in advance. The recruitment process does not end once an individual has agreed to participate. Recruitment strategies need to be maintained throughout the study in order to retain participants.

REGRESSION ARTIFACTS

The term *regression artifacts* refers to pseudoeffects from a regression type of analysis. These incorrect causal estimates are due to biases from causes other than the cause of interest. Note that such artifacts are problems only when making causal inferences, not when merely predicting some future outcome. A famous regression artifact, for example, was that the first major evaluation of Head Start concluded that the summer program actually caused children to do worse in school. If this were merely a prediction, it would have been correct that having attended Head Start would predict poorer performance in school. These children did poorly in school because of their disadvantaged status, which Head Start could not completely compensate for. This correct prediction becomes an artifact only when someone makes a *causal* conclusion that Head Start is responsible for their below-average academic performance later.

The most general reason for regression artifacts is that the statistical analysis reflects an incomplete picture of reality, which is called a *specification error*. Specification errors include the omission of relevant variables and other mismatches between statistical assumptions and reality. A *relevant variable* is any variable that is associated with the cause of interest but that also causally influences the outcome variable directly. In the Head Start case, being from a disadvantaged background was associated with attendance at Head Start, but it also caused poor academic performance. Mismatches between reality and linear statistical assumptions include a curvilinear relationship and an interaction effect, in which the effect of one causal variable depends on another variable. Another common mismatch is that unbiased causal evidence usually requires that other relevant variables (potential confounds) be measured

without error. Socioeconomic status (SES) was controlled for statistically in the first major evaluation of Head Start, but measurement error in SES reduced its ability to fully correct for disadvantage. Regression estimates of causal influences are unbiased only if statistical analyses include perfectly valid and reliable measures of all relevant variables and correctly reflect any complexities among their interrelationships. To the extent a regression type of analysis falls short of that ideal, there is potential for regression artifacts, that is, pseudoeffects masquerading as causal evidence.

Types of Regression Artifacts

Regression Toward the Mean

There are several major types of regression artifacts. The most common is regression toward the mean, which is summarized in another entry in this encyclopedia, as well as in an important book by Donald Campbell and David Kenny, titled *A Primer on Regression Artifacts*. Regression toward the mean occurs when the participants are selected on the basis of their extreme scores (e.g., deciding to start therapy because of a bad day). Such people usually move toward the mean spontaneously, which could be incorrectly interpreted as a causal effect, such as improvement due to therapy.

Underadjustment Bias

Another example of regression artifacts is underadjustment bias, the systematic error remaining after typical statistical adjustments for potential confounds. Campbell and Kenny have shown that several kinds of statistical adjustments reduce the bias but do not eliminate it. They called this one of the most serious difficulties in data analysis. In the Head Start example, statistical adjustments for differences in SES gave the illusion that the effects of disadvantage were removed, even though they were only reduced. This is why Head Start appeared to be hindering students' subsequent success in school, even when that was not the case. It was the residual (remaining) influence of being disadvantaged, and not Head Start, that was hindering students' success in school.

Attenuation

A third type of artifact is attenuation, which is the reduced magnitude of regression coefficients due to measurement error or restricted range in the variables. Attenuation can be corrected by dividing the correlation by the square root of the product of the two variables' reliabilities. The accuracy of the correction requires the correct estimate of reliability. When regression analyses

include multiple predictor variables, measurement error and restriction of range in one predictor can cause inflation as well as attenuation in coefficients for other predictor variables (e.g., the underadjustment bias).

Suppression Effect

The final example of a regression artifact is a suppression effect. The main concern for most other regression artifacts is that a significant association might falsely suggest a causal effect. In contrast, a suppression effect occurs when a causal variable appears to be unrelated to an outcome, whereas in fact, its causal effect has been suppressed by other causal influences that are not represented in the regression analysis. A classic example is that paper-and-pencil aptitude tests might fail to predict a practical ability, such as potential ability to be a competent airplane pilot. In this hypothetical example, doing well on the aptitude test might reflect verbal ability as well as potential piloting ability. In a suppression effect, adjusting statistically for verbal ability would then show the aptitude test to predict future piloting ability, even though there was no association between those two variables before the statistical adjustment.

Adjustments

Overall, regression artifacts are possible from regression types of analyses unless groups have been equated successfully on all characteristics except the causal variable being investigated. Random assignment is the best way to equate the groups. When that cannot be done, there are several ways to adjust statistically for potential confounds or causes, but most adjustments reduce the bias without eliminating it. Therefore, studies that rely solely on statistical adjustments need to consider other plausible explanations of their results in order to alert themselves and their readers to the possibility that their causal evidence might be misleading due to a regression artifact.

REGRESSION COEFFICIENT

The regression coefficient expresses the functional relationship among the response (explained, dependent) variable and one or more explanatory (predictor, independent) variables. Denoting the response variable by Y and the set of explanatory variables by $X_1, X_2, \dots, X_k$, the regression model can generally be formulated as

$$Y = f(X_1, X_2, \dots, X_k) + \varepsilon,$$

where k denotes the number of predictor variables and ε denotes the random disturbance or error, representing the discrepancy between the observed response variable and the estimated regression line.

Following the commonly used notational convention in linear regression analysis, which uses Greek letters to denote the unknown parameters, the linear regression model can be written as

$$Y_{ij} = \beta_0 + \beta_1 X_1 + \beta_2 X_2 + \dots + \beta_k X_k + \varepsilon,$$

where β_0 denotes the intercept and $\beta_1, \beta_2, \dots, \beta_k$ denote the regression coefficients to be estimated from the data. More specifically, the regression coefficients indicate the dependence of the response variable on one or more explanatory variables, as shown in the linear regression model above. The parameter β_0 denotes the intercept, or where the regression line crosses the y -axis. As such, the intercept β_0 determines the mean value of the response variable Y , independent of any explanatory variable.

Estimating Regression Coefficients

Purposes of Estimating Regression Coefficients

The estimated regression coefficients or “estimators” $\hat{\beta}_1, \hat{\beta}_2, \dots, \hat{\beta}_k$ (the “hat” on the beta, i.e., $\hat{\cdot}$, refers to an estimated regression coefficient), calculated from the regression analysis, can then serve multiple purposes:

1. *Evaluating the importance of individual predictor variables.* A common approach here would be to use standardized response and predictor variables in the regression analysis. From the standardized variables, one can estimate standardized regression coefficients, which measure in standard deviations the change in the response variable that follows a standard unit change in a predictor variable. The standardization procedure

allows one to assess the importance of individual predictor variables in situations in which the predictor variables are measured in different units.

2. *Analyzing the changes in the response variable following a one-unit change in the corresponding explanatory variables $X_1, X_2, \dots, X_k$.* For instance, $\hat{\beta}_1$ indicates the change in the response variable following a one-unit change in the predictor variable X_1 , while holding all other predictor variables $X_2, X_3, \dots, X_k$ constant.
3. *Forecasting values of the response for selected sets of predictor variables.* In this case, using all the estimated regression coefficients, $\hat{\beta}_0, \hat{\beta}_1, \hat{\beta}_2, \dots, \hat{\beta}_k$, together with a given set of predictor variables $X_1, X_2, \dots, X_k$, one would be able to forecast the expected value of the response variable.

Besides the absolute magnitudes of the estimated regression coefficients, the signs of the estimators are of major importance because they indicate direct or inverse relationships between the response variable and the corresponding predictor variables. It is usual to have prior expectations of the expected outcomes of the signs of the estimators. In other words, it is conceptually predetermined whether the relationship between the response variable and a predictor variable should be of positive or negative nature.

Example of Use of Estimated Regression Coefficients

In real estate appraisal, an analyst might be interested in how building characteristics such as floor space in square feet (X_1), number of bedrooms (X_2), and the number of bathrooms (X_3) help in explaining the average market values (Y) of real estate properties. In this oversimplified example, the estimated regression coefficients may be used for several purposes. Using standardized regression coefficients, one could determine whether the floor space in square feet, the number of bedrooms, or the number of bathrooms is most important in determining market values of real estate properties. In addition, the unstandardized, estimated regression coefficient $\hat{\beta}_1$ would indicate the expected change in the average market value of real estate properties for a 1-square-foot change in floor space while the number of bedrooms and bathrooms remain constant. Analogously, $\hat{\beta}_2$ or $\hat{\beta}_3$ would indicate how much one more bedroom or one bathroom would potentially add to the expected market value of real estate properties. And finally, using $\hat{\beta}_0, \hat{\beta}_1, \hat{\beta}_2, \dots, \hat{\beta}_k$, one could estimate the market value of a hypothetical 2,200-square-foot real estate property with three

bedrooms and two bathrooms. Of course, one would expect all the estimated regression coefficients to have positive signs.

Method of Estimating Regression Coefficients

The regression coefficients $\beta_0, \beta_1, \beta_2, \dots, \beta_k$ are estimated from the available data. As a general rule, the number of observations (n) must be greater than the number of explanatory variables or regression coefficients (k) to be estimated, and the more the better. Note that the estimation procedure is stochastic—rather than deterministic—by nature. Thus, the inclusion of the random disturbance term is essential to account for the discrepancy between the observed response variable and its corresponding estimated value. Consequently, the assumptions embedded in the disturbance terms imply important and far-reaching properties to the estimated regression coefficients.

The most commonly used and conceptually most easily understood method of estimating the regression coefficients is the ordinary least squares (OLS) method. Accordingly, the estimated regression coefficients are often referred to as OLS regression coefficients, or $\hat{\beta}^{\text{OLS}}$.

The least squares regression coefficients are obtained by minimizing the sum of squares of vertical distances from each observation to the fitted line. These vertical distances, the differences between the actual and estimated Y values, or $Y_i - \hat{Y}_i$, represent the errors in the response variables, or the variation in the response variable that cannot be explained by the regression model.

Using the simple, one-predictor-variable regression model,

$$Y = \beta_0 + \beta_1 X_1 + \varepsilon,$$

and applying the process of differential calculus to minimize the squared vertical distances yields the following normal equations:

$$\sum Y_i = n \cdot \hat{\beta}_0 + \hat{\beta}_1 \cdot \sum X_i$$

$$\sum Y_i X_i = \hat{\beta}_0 \sum X_i + \hat{\beta}_1 \cdot \sum X_i^2$$

Solving these two normal equations simultaneously, we get the solutions for the two OLS regression coefficients for the simple regression model:

$$\hat{\beta}_1 = \frac{\sum (X_i - \bar{X})(Y_i - \bar{Y})}{\sum (X_i - \bar{X})^2} = \frac{\sum x_i \cdot y_i}{\sum x_i^2}$$

$$\hat{\beta}_0 = \bar{Y} - \hat{\beta}_1 \bar{X},$$

where n denotes the total number of observations, and i denotes an individual observation between 1 and n .

Properties of Estimated Regression Coefficients

Gauss–Markov Theorem

The properties of estimated regression coefficients, in return, depend on the assumptions embedded in the disturbance terms. The *Gauss–Markov theorem* states the following assumptions for the disturbance terms in a linear regression model: (a) the mean value of disturbance terms is zero, or $E(\varepsilon_i) = 0$; (b) all disturbances have the same variance, or $\text{Var}(\varepsilon_i) = \sigma^2$, which is also referred to as homoscedasticity; and (c) all disturbance terms are uncorrelated with one another, or $\text{Cov}(\varepsilon_i, \varepsilon_j) = 0$, for $i \neq j$. Following the Gauss–Markov assumptions of the disturbance terms, the estimated OLS regression coefficients for the simple regression model have the following properties:

The estimated OLS regression coefficients $\hat{\beta}_0$ and $\hat{\beta}_1$ are unbiased:

$$E(\hat{\beta}_0) = \beta_0$$

$$E(\hat{\beta}_1) = \beta_1.$$

The estimated OLS regression coefficients $\hat{\beta}_0$ and $\hat{\beta}_1$ have minimum variance:

$$\sigma_{\hat{\beta}_0}^2 = \frac{\sum X_i^2}{n \cdot \sum x_i^2} \cdot \sigma^2$$

$$\sigma_{\hat{\beta}_1}^2 = \frac{\sigma^2}{\sum x_i^2}.$$

Putting it together, the Gauss–Markov theorem implies that for a linear regression model—in which the disturbance terms are uncorrelated and have a mean value of zero and equal variances—the unbiased OLS estimators of β have minimum variance. In this case, the estimators $\hat{\beta}_0$ and $\hat{\beta}_1$ are said to be the *best linear unbiased estimators* of β_0 and β_1 .

Disturbance

So far, no assumptions have been made regarding the distribution of the disturbance terms. Assuming that, in addition to the Gauss–Markov theorem, the disturbance terms are normally and independently distributed (NID), or

$$\varepsilon_i \sim \text{NID}(0, \sigma^2),$$

adds the following properties of estimated regression coefficients to previous results:

1. The estimator $\hat{\beta}_0$ is normally distributed:

$$\hat{\beta}_0 \sim N(\beta_0, \sigma_{\hat{\beta}_0}^2).$$

2. The estimator $\hat{\beta}_1$ is normally distributed:

$$\hat{\beta}_1 \sim N(\beta_1, \sigma_{\hat{\beta}_1}^2).$$

3. The estimators $\hat{\beta}_0$ and $\hat{\beta}_1$ are distributed independently of $\hat{\sigma}^2$.

4. The estimators $\hat{\beta}_0$ and $\hat{\beta}_1$ are consistent estimators. With increasing sample size n , $\hat{\beta}_0$ and $\hat{\beta}_1$ converge to their true, but unknown, population parameters.

5. The quantity $\frac{(n-2) \cdot \hat{\sigma}^2}{\sigma^2}$ has a chi-square distribution with $(n-2)$ degrees of freedom.

6. $\hat{\beta}_0$ and $\hat{\beta}_1$ are now the *best unbiased estimators* of β_0 and β_1 . Relaxing the linearity assumption of the estimators, they have now minimum variance of all unbiased estimators.

Testing Estimated Regression Coefficients

The normality assumption of the random disturbance terms implies important and far-reaching properties to the OLS regression estimators. The most important is that $\hat{\beta}_0$ and $\hat{\beta}_1$ follow a normal probability distribution, and $\hat{\sigma}^2$ follows a chi-square distribution. The same regression coefficient properties, of course, hold for the multiple linear regression model.

With their sampling distributions, the estimated regression coefficients can then be tested for their statistical significance. For a predictor variable $X_1, X_2, \dots, X_k$, to be a statistically significant predictor of the response variable Y , it must be different from zero. For the simple regression model, the null hypotheses for testing the usefulness of the two estimators can be written as

$$H_0 : \beta_0 = 0 \text{ and}$$

$$H_0 : \beta_1 = 0.$$

The alternative hypotheses would then be $H_1 : \beta_0 \neq 0$ and $H_2 : \beta_1 \neq 0$. Given that in most cases the true population variance σ^2 is not known and is therefore replaced in practice by the unbiased estimator $\hat{\sigma}^2$, the Student's t distribution is the appropriate test distribution with $(n-2)$ degrees of freedom for the simple regression model. The test statistics are computed as

$$t_0 = \frac{\hat{\beta}_0}{se(\hat{\beta}_0)}$$

and

$$t_1 = \frac{\hat{\beta}_1}{se(\hat{\beta}_1)},$$

where $se(\hat{\beta}_0)$ and $se(\hat{\beta}_1)$ denote the standard errors of $\hat{\beta}_0$ and $\hat{\beta}_1$, respectively. The standard error is a measure on how precisely the regression coefficients have been estimated; the smaller the standard error, the better. The standard errors for the two estimators of $\hat{\beta}_0$ and $\hat{\beta}_1$ are calculated as

$$se(\hat{\beta}_0) = \hat{\sigma} \cdot \sqrt{\frac{\sum X_i^2}{n \cdot \sum x_i^2}}$$

$$se(\hat{\beta}_1) = \frac{\hat{\sigma}}{\sqrt{\sum x_i^2}}.$$

The hypothesis test for each estimator is carried out by comparing the calculated test statistics t_0 and t_1 with the appropriate critical value from the t table in a two-tailed test. The null hypothesis, which states that the estimated regression coefficients are zero, can be rejected at a selected level of significance of α if the test statistic falls in the critical rejection region in either of the two tails of the test distribution; that is, if the absolute value of the test statistic is larger than or equal to the appropriate critical value. For the estimator $\hat{\beta}_1$, for instance, the decision criterion is

$$|t_1| \geq t_{(n-2, \alpha/2)}.$$

Using the p -value approach, the criterion, which is equivalent to the t -test criterion above, to reject H_0 can be formulated as

$$p(|t_1|) \leq \alpha,$$

where p denotes the area left in the two tails that corresponds to the calculated test statistics.

Regression software packages provide tests of significance for each estimator as standard output.

Usually, each estimator is reported with its corresponding t statistic and standard error. In addition, an F test, which tests the overall statistical significance of the regression model, is usually provided. The null hypothesis for the F test states that all predictor variables (excluding the intercept) under consideration are simultaneously zero; in other words, they have no explanatory power. This is stated as

$$H_0 : \beta_1 + \beta_2 + \dots + \beta_k = 0.$$

The alternative hypothesis H_1 for this specific case then states that not all regression coefficients are simultaneously zero. Following the same logic as for the t test, H_0 can be rejected if the calculated F statistic is larger than the critical F value for the given level of significance, where the F statistic is calculated as

$$F = \frac{\text{explained sum of squares}/k}{\text{unexplained sum of squares}/(n - k - 1)},$$

where the explained sum of squares is due to regression and the unexplained sum of squares is due to error. The two sums of squares needed for the F test are reported in the analysis of variance table.

In practice, the most widely used approach to estimate the regression coefficients is the OLS approach. Alternative methods include the Bayesian method, the maximum likelihood approach, quantile regression, nonparametric regression, and nonlinear regression.

REGRESSION DISCONTINUITY

Regression discontinuity (RD) is a two-group, pre-post, quasi-experimental method for evaluating the effect of an intervention. Assignment to the experimental or comparison group is based on the value of some variable. That variable can be either the baseline value of the outcome itself or some other variable. The effect of the intervention is assessed by looking at the discontinuity of the regression lines between the groups at the cutoff point.

History

The RD design was introduced in 1960 by Donald Thistlewaite and Donald Campbell to evaluate the effects of compensatory educational interventions. Since that time, it has been used in areas such as criminal justice, social welfare, economics, and pharmaceutical health services research, although it is still a relatively rarely used design. Indeed, a recent search of the psychological and medical literature since 1960 turned up only 59 references, of which 34 were about the technique and only 25 actually used it. Of the latter, about one third were dissertations, and nearly three quarters were in the field of education.

Method

The unit of assignment can be individuals or groups, such as classes within a school, entire schools, or even school districts. The units are assigned to the treatment or control conditions on the basis of their score on some measure. The cutoff score can be determined in one of two ways: either on the basis of knowledge of the properties of the score (e.g., a failing grade, the proportion of high school students not graduating, or blood pressure above some threshold for hypertension) or on the basis of the resources that are available (e.g., the program is able to handle only 25% of the people). In the simplest case, the grouping variable is the outcome variable itself, which is measured before and after the intervention for the experimental group and at equivalent times for the comparison group. Hence, the basic design looks like

Experimental group : Pretest Intervention Posttest

Comparison group : Pretest Posttest

and the results are plotted with the pretest on the x -axis and the posttest on the y -axis.

For example, people can be chosen for a weight-loss program if their body mass index (BMI) is more than 30, which is regarded as the cut point for obesity. At the end of a 6-month intervention, the BMIs for all people are measured again, and the hypothetical results are shown in Figure 1.

If the intervention has no effect, then the regression lines will be continuous at the cut point. The discontinuity at the cutoff, seen in Figure 1, indicates that the program was effective in that the postintervention scores for the experimental group tend to be lower than the prescores, whereas the before and after BMIs for those in the comparison group are about the same.

It is not necessary that the pre- and posttreatment variables be the same or that the cut point be based on the pretest. For example, the pretreatment and cutoff scores could be the BMI, and the posttest score could be caloric intake. Similarly, caloric consumption could be measured before and after the intervention, but the cutoff could be based on the BMI; or caloric intake could be measured at Time 1, weight measured at Time 2, and BMI used to determine the cut point.

Advantages

The gold-standard design for evaluating the effectiveness or efficacy of an intervention is the randomized controlled trial (RCT). However, there is an ethical problem with RCTs. If the intervention works, then half the participants will have been denied it (at least until the study ends). In contrast, all eligible people (or groups) in an RD study receive the treatment, to the degree that resources permit.

A second advantage is that if an RD design is correctly implemented and analyzed, the results are an unbiased estimate of the treatment effect. Moreover,

Figure 1 Pre- Versus Postintervention Body Mass Indexes (BMIs) for Treated and Control Participants in a Weight-Loss Program

the inclusion of a comparison group is protection against many of the threats to internal validity found in many other quasi-experimental techniques. For example, if there were external factors that could modify the relationship between the pre- and postmeasures, then these should act in a similar fashion in both groups (except for the highly unlikely circumstance that the factors operate only at the exact cutoff point). Indeed, the internal validity of an RD study is as strong as that of an RCT.

Third, because the groups are compared only at the cut point, the RD design is not susceptible to the biases affecting other pre-post designs, such as maturational effects or regression to the mean; and it is not necessary to assume that the data are interval, which is the case when difference scores are used.

Disadvantages

There are a number of disadvantages with the RD design. First, it tends to be less powerful than an RCT. This means that more participants must be enrolled in order to demonstrate a statistically significant effect for a given effect size. Some estimates are that 2.75 times as many people are needed in an RD design than in an equivalent RCT. If the unit of allocation is the group rather than the individual (e.g., a classroom or hospital), then the sample size determination must be adjusted to account for the correlation of scores within the group (i.e., clustering effects).

A second problem is a direct consequence of the lack of random assignment of people to groups. In an RCT, randomization tends to minimize group differences, so that any result can be attributed to the intervention. Because this is not the case in an RD design, there is an assumption that there is no discontinuity between the groups in terms of the relationship between the two measures that, just by accident, happens to coincide with the cutoff.

A third potential problem is that the validity of the results is dependent on the form of the relationship between the pre- and postmeasures. For example, if there is a quadratic (i.e., curvilinear) relationship, then fitting a straight line may lead to the erroneous conclusion that there is a discontinuity at the cutoff point, when in fact there is none.

REGRESSION TO THE MEAN

Regression to the mean (RTM) is a widespread statistical phenomenon that occurs when a nonrandom sample is selected from a population and the two variables of interest measured are imperfectly correlated. The smaller the correlation between these two variables, the more extreme the obtained value is from the population mean, and the larger the effect of RTM (that is, there is more opportunity or room for RTM).

If variables X and Y have standard deviations SD_x and SD_y , and correlation = r , the slope of the familiar least squares regression line can be written rSD_y/SD_x . Thus a change of one standard deviation in X is associated with a change of r standard deviations in Y . Unless X and Y are perfectly linearly related, so that all the points lie along a straight line, r is less than 1. For a given value of X , the predicted value of Y is always fewer standard deviations from its mean than is X from its mean. Because RTM will be in effect to some extent unless $r = 1$, it almost always occurs in practice.

As discussed by Donald Campbell and David Kenny, RTM does not depend on the assumption of linearity, the level of measurement of the variable (for example, the variable can be dichotomous), or measurement error. Given a less than perfect correlation between X and Y , RTM is a mathematical necessity. Although it is not inherent in either biological data or psychological data, RTM has important predictive implications for both. In situations in which one has little information to make a judgment, often the best advice is to use the mean value as the prediction.

History

An early example of RTM may be found in the work of Sir Francis Galton on heritability of height. He observed that tall parents tended to have somewhat shorter children than would be expected given their parents' extreme height. Seeking an empirical answer, Galton measured the height of 930 adult children and their parents and calculated the average height of the

parents. He noted that when the average height of the parents was greater than the mean of the population, the children were shorter than their parents. Likewise, when the average height of the parents was shorter than the population mean, the children were taller than their parents. Galton called this phenomenon regression toward mediocrity; we now call it RTM. This is a statistical, not a genetic, phenomenon.

Examples

Treatment Versus Nontreatment

In general, among ill individuals, certain characteristics, whether physical or mental, such as high blood pressure or depressed mood, have been observed to deviate from the population mean. Thus, a treatment would be deemed effective when those treated show improvement on such measured indicators of illness at posttreatment (e.g., a lowering of high blood pressure or remission of or reduced severity of depressed mood). However, given that such characteristics deviate more from the population mean in ill individuals than in well individuals, this could be attributable in part to RTM. Moreover, it is likely that on a second observation, untreated individuals with high blood pressure or depressed mood also will show some improvement owing to RTM. It also is probable that individuals designated as within the normal range of blood pressure or mood at first observation will be somewhat less normal at a second observation, also due in part to RTM. In order to identify true treatment effects, it is important to assess an untreated group of similar individuals or a group of similar individuals in an alternative treatment in order to adjust for the effect of RTM.

Variations Within Single Groups

Within groups of individuals with a specific illness or disorder, symptom levels may range from mild to severe. Clinicians sometimes yield to the temptation of treating or trying out new treatments on patients who are the most ill. Such patients, whose symptoms are indicative of characteristics farthest from the population mean or normality, often respond more strongly to treatment than do patients with milder or moderate levels of the disorder. Caution should be exercised before interpreting the degree of treatment effectiveness for severely ill patients (who are, in effect, a nonrandom group from the population of ill individuals) because of the probability of RTM. It is important to separate genuine treatment effects from RTM effects; this is best done by employing randomized control groups that include individuals with varying levels of illness severity and normality.

How to Deal With Regression to the Mean

If subjects are randomly allocated to comparison groups, the responses from all groups should be equally affected by RTM. With placebo and treatment groups, the mean change in the placebo group provides an estimate of the change caused by RTM (plus any other placebo effect). The difference between the mean change in the treatment group and the mean change in the placebo group is then the estimate of the treatment effect after adjusting for RTM. C. E. Davis and others (e.g., P. L. Yudkin & I. M. Stratton) showed that RTM can be reduced by basing the selection of individuals on the average of several measurements instead of a single measurement. They also suggested selecting patients on the basis of one measurement but to use a second pretreatment measurement as the baseline from which to compute the change. It was noted that if the correlation coefficient between the posttreatment and the first pretreatment measurement is the same as that between the first and the second pretreatment measurement, then there will be no expected mean change due to RTM. Of course, understanding the phenomenon of RTM is the first step to overcoming the problems caused by RTM.

RELATIVE MEASURES OF DISPERSION

Dispersion refers to the spread or variation of a collection of data measurements around a center point (such as the mean, median, or mode). Measures of dispersion are differentiated based on their unit of measurement. Absolute measures of dispersion are expressed in the same unit as the original measurement. Relative

measures of dispersion are expressed as standardized measurement units, such as ratios or percentages. Absolute measures of dispersion do not allow analysts to directly compare dispersion between samples that have different means or that have different units of measurement. For example, income may be shown in dollars or euros; length as feet or meters; temperature as Celsius or Fahrenheit. This makes comparison among such groups difficult or impossible. In contrast, using relative measures of dispersion makes such comparisons possible, because ratios and percentages are dimensionless and not associated with a specific unit of measurement. In general, relative dispersion is defined as absolute dispersion divided by the average, and each absolute measure has a corresponding relative measure.

Relative measures of dispersion are usually defined in relation to their corresponding absolute measures (see Table 1). Larger coefficients indicate more dispersion.

Coefficient of Range

The range is the difference between the largest and the smallest values in a data set. If l is the largest value and s is the smallest value, then the range is calculated as $l - s$. The coefficient of range (CoR) is the relative measure of the dispersion of the range, a larger value indicating more

dispersion. As shown in Equation 1, CoR is the ratio of the range to the sum of the largest and smallest values:

$$\text{CoR} = \frac{l - s}{l + s} \quad (1)$$

For example, in the data set (48, 37, 53, 42, 57), the smallest value is 37 (s) and the largest value is 57 (l). The range is 20, which is calculated by subtracting 37 from 57. Then, as shown in Equation 2, to calculate the CoR, divide the range by the sum of the largest and smallest values:

$$\text{CoR} = \frac{57 - 37}{57 + 37} = \frac{20}{94} = 0.21 \quad (2)$$

Coefficient of Quartile Deviation

Quartiles divide a data set into four equal groups, with each group including 25% of the measurements. The value of the first quartile is called $Q1$ (25th percentile), of the second quartile is called $Q2$ (50th percentile), and of the third quartile is called $Q3$ (75th percentile). $Q4$ is the maximum value contained in the data.

The quartile deviation is the absolute measure of dispersion for the range between $Q3$ and $Q1$. It is calculated as one-half the distance between $Q3$ and $Q1$. The corresponding relative measure of dispersion is the coefficient of quartile deviation (CoQD). The CoQD is calculated using Equation 3.

$$\text{CoQD} = \frac{\frac{Q3 - Q1}{2}}{\frac{Q3 + Q1}{2}} = \frac{Q3 - Q1}{Q3 + Q1} \quad (3)$$

The CoQD can be used to compare dispersion across two or more data sets, with the larger CoQD indicating greater quartile dispersion. As demonstrated in Table 2, Data Set 1 has greater dispersion than Data Set 2: $0.60 > 0.25$.

Table 1 Correspondence Between Absolute Measures and Relative Measures of Dispersion

Absolute Measures	Relative Measures
Range	Coefficient of range
Quartile	Coefficient of quartile deviation
Standard deviation	Coefficient of variation
Mean/median/mode	Coefficient of mean deviation

Table 2 Comparison of CoQD of Two Data Sets

Dataset	Value	Q1	Q2	Q3	Q4	Q3-Q1	Q3+Q1	CoQD
1	8, 12, 13, 13, 17, 18, 30, 34, 40, 49, 50, 51, 58, 63, 70, 71, 86, 89, 90, 90	17.5	49.5	70.5	90	53	88	$53/88 = 0.60$
2	3, 8, 15, 65, 60, 67, 72, 78, 78, 88, 93, 97	48.5	69.5	80.5	97	32	129	$32/129 = 0.25$

Coefficient of Variation

The coefficient of variation (CoV), also called the *coefficient of standard deviation*, is probably the most important relative measure of dispersion. The standard deviation (SD) is the square root of the mean squared differences of a data set. The CoV is the SD divided by the mean. It is usually expressed as a percentage, so the ratio will be multiplied by 100 as shown in the following equation:

$$\text{CoV} = \frac{\text{SD}}{\text{Mean}} \times 100 \quad (4)$$

As seen in Table 3, the CoV for Data Set 2 (CoV = 5.1) is less than half of the CoV for Data Set 1 (CoV = 12.5). This indicates that the values in Data Set 1 are

more spread out around the mean as compared to the values in Data Set 2.

Coefficient of Mean Deviation

The coefficient of mean deviation (CoMD) is the standardized mean of average differences, defined as the ratio of average mean difference to the average raw score value. The CoMD may be calculated using any of the three measures of central tendency (mean, median, mode). In the example below, this measure is referred to as the *average*.

To calculate the CoMD, first, determine the appropriate measure of central tendency to use. Second, for a single data set, compute the mean deviation (MD) by subtracting the selected average from each data point, keeping the absolute value. Next, the CoMD can be

Table 3 Comparison of CoV of Two Data Sets

<i>Dataset</i>	<i>Value</i>	<i>SD</i>	<i>Mean</i>	<i>CoV</i>
1	58, 60, 64, 66, 69, 73, 73, 74, 76, 88	8.76	70.1	(8.76/70.1) * 100 = 12.5
2	64, 65, 68, 68, 69, 69, 72, 73, 74, 74	3.57	69.6	(3.57/69.6)*100 = 5.1

Table 4 Example of Calculating CoMD

<i>No.</i>	<i>Value</i>	<i>Absolute Difference</i>
1	58	58-70.1 = 12.1
2	60	60-70.1 = 10.1
3	64	64-70.1 = 6.1
4	66	66-70.1 = 4.1
5	69	69-70.1 = 1.1
6	73	73-70.1 = 2.9
7	73	73-70.1 = 2.9
8	74	74-70.1 = 3.9
9	76	76-70.1 = 5.9
10	88	88-70.1 = 17.9
Mean	Average = (58 + 60 + 64 + 66 + 69 + 73 + 73 + 74 + 76 + 88)/10 = 70.1	MD = (12.1 + 10.1 + 6.1 + 4.1 + 1.1 + 2.9 + 2.9 + 3.9 + 5.9 + 17.9)/10 = 6.7

calculated using Equation 5 (i.e., dividing mean deviation by the average). In the example illustrated in Table 4, $\text{CoMD} = 6.7/70.1 = 0.1$.

$$\text{CoMD} = \frac{\text{MD}}{\text{Average}} \quad (5)$$

RELIABILITY

This entry focuses on reliability, which is a desired property of the scores obtained from measurement instruments. Therefore, reliability is relevant in a variety of contexts, such as scores on multiple-choice questions on an achievement test and Likert-type scale responses on a survey questionnaire. The concept of reliability is premised on the idea that observed responses are imperfect representations of an unobserved, hypothesized latent variable. In the social sciences, it is typically this unobserved characteristic, rather than the observed responses themselves, that is of interest to researchers. Specifically, reliability serves to quantify the precision of measurement instruments over numerous consistent administration conditions or replications and, thus, the trustworthiness of the scores produced with the instrument. This entry discusses several frameworks for estimating reliability.

Reliability as Replication

While it is assumed that items (also called questions, tasks, prompts, or stimuli) on an instrument measure the same theoretical construct, this assumption always needs to be tested with empirical data. Reliability does not provide direct information about the meaningfulness of score interpretations, which is the concern of validation studies, but serves as an empirical prerequisite to validity.

Reliability provides information on the replicability of observed scores from instruments. Consequently, at least two sets of scores are required to obtain information about reliability. These can be multiple administrations of an instrument to the same group of respondents (*test-retest reliability* or *score stability*), the administration of two comparable versions of the instrument to the same group of respondents (*parallel-forms reliability*), or the comparison of scores from (at least) two random halves of an instrument (*split-half reliability* and *internal consistency*).

To estimate test-retest reliability, the original instrument has to be administered twice. The length of the time interval is not prespecified but should be chosen to allow variance in performance without the undue influence of developmental change; ideally, the time interval should be reported along with the reliability estimate. To estimate parallel-forms reliability, two forms of the instrument have to be developed according to the same set of test specifications and have to be administered to the same group of respondents. As with test-retest reliability, the time interval between administrations is important and should be reported.

To estimate the split-half reliability or internal consistency of an instrument, only one instrument needs to be administered to one group of respondents at one point in time. Technically, the instrument needs to be split into at least two randomly parallel halves. Of course, there are many ways to divide the items on the instrument into two halves. To overcome the limitation imposed by the arbitrariness of the split, coefficient alpha has been developed. It is theoretically equivalent to the average of all potential split-half reliability estimates and is easily computed. Estimating the internal consistency of an instrument effectively measures the homogeneity of the items on the instrument.

Reliability as a Theoretical Quantity

To understand the definitions of different reliability coefficients, it is necessary to understand the basic structure of the measurement framework of classical test theory (CTT). In CTT, observed scores (X) are decomposed into two unobserved components, true score (T) and error (E ; i.e., $X = T + E$). While true score is assumed to be stable across replications and observations, error represents a random component that is uncorrelated with true score. Additional restrictions can be placed on the means and variances of the individual components as well as their correlations in order to make them identified and estimable in practice.

In particular, using a few basic assumptions, true score variance can be defined as the sum of observed score variance and error variance (i.e.,

$Var(X) = Var(T) + Var(E)$. Reliability is simply the amount of variation in the observed scores that is due to true interindividual differences. Alternatively, the reliability coefficient can be viewed as the ratio of signal to signal-plus-noise. More technically, it is the ratio of true score variance to observed score variance. Using $\rho_{XX'}$ to denote the reliability coefficient, σ_X^2 to denote observed score variance, σ_T^2 to denote true score variance, and σ_E^2 to denote error variance, the reliability of scores for item X is defined as

$$\rho_{XX'} = \frac{\sigma_T^2}{\sigma_X^2} = \frac{\sigma_T^2}{\sigma_T^2 + \sigma_E^2}.$$

The value of this reliability coefficient tends to 0 when the variance of the true scores in the population goes to 0 (i.e., when there is little interindividual variation in the population). The reliability coefficient will approach 1 if the variance of the true scores in the population goes to infinity (i.e., if there is very little measurement error relative to the amount of interindividual differences in the population).

Estimates of Reliability

It is important to note that the reliability coefficient defined above is a theoretical quantity that is always positive because variance components are always positive. Moreover, it cannot be estimated directly, because true score variation is not directly observable from data. Instead, the true reliability of scores has to be estimated from data using suitable sample coefficients. Essentially, most of the sample coefficients that are used to estimate the true reliability of scores are *correlation coefficients*.

The most common coefficient in practice is the Pearson product-moment correlation coefficient (PPMCC). To estimate test-retest reliability, the scores on the same instrument from the two measurement occasions are correlated by means of the PPMCC; to estimate parallel-forms reliability, the scores from the two forms of the instrument from the two measurement occasions are correlated by means of the PPMCC; and to estimate split-half reliability, the scores from two randomly selected halves are correlated by means of the PPMCC.

The Spearman-Brown Formula

Generally speaking, reliability increases when homogeneous items are added to an existing instrument. Homogeneous items are items whose correlations with other items on the augmented form equal the average interitem correlation of the existing form. This

principle can be used in estimating the reliability of shortened or lengthened instruments by using what is known as the Spearman-Brown Prophecy formula. This formula is defined as

$$_{SB}\rho_{XX'} = \frac{n\rho_{XX'}}{1 + (n-1)\rho_{XX'}},$$

where n is an integer value representing the ratio of projected form length to original form length. To estimate the reliability of a full form via a split-half reliability coefficient, this simplifies to

$$_{SB}\rho_{XX'} = \frac{2\rho_{X_1X_2}}{1 + \rho_{X_1X_2}},$$

where $\rho_{X_1X_2}$ is the correlation between the observed scores on the two halves.

The Kuder-Richardson Formulas

Alternatively, for instruments comprising dichotomously scored items solely, two often cited reliability coefficients are the Kuder-Richardson (KR) coefficients KR-20 and KR-21. The KR-20 reliability coefficient is estimated as

$$_{20}\rho_{XX'} = \left(\frac{n}{n-1} \right) \left(1 - \frac{\sum_{all\ items} P(1-P)}{\sigma_X^2} \right),$$

where n is the number of items on the form, P is the proportion of respondents getting a dichotomously scored item correct, and $P(1-P)$ is simply the resulting variance of that item. KR-21 makes the additional restrictive assumption that all items have the same proportion correct, allowing the reliability coefficient to be calculated when only number of items, average score, and standard deviation of observed scores are known. It is computed as

$$_{21}\rho_{XX'} = \left(\frac{n}{n-1} \right) \left(1 - \frac{\mu_X(n - \mu_X)}{n\sigma_X^2} \right),$$

where μ_X is the mean observed score on the form.

Cronbach's α

Perhaps the most well-known internal consistency reliability coefficient is Cronbach's alpha, which assumes, in its basic form, that the total score on an instrument is computed as the simple (i.e., unweighted) sum of the scores from all items. Cronbach's alpha is a generalization of the KR-20 coefficient and is

applicable to dichotomously scored items as well as polytomously scored items. It is defined as

$$\alpha \rho_{XX'} = \left(\frac{n}{n-1} \right) \left(\frac{\sigma_X^2 - \sum_{\text{all items}} \sigma_{X_i}^2}{\sigma_X^2} \right)$$

$$= \left(\frac{n}{n-1} \right) \left(1 - \frac{\sum_{\text{all items}} \sigma_{X_i}^2}{\sigma_X^2} \right),$$

where σ_X^2 is the observed score variance for the total scores and $\sigma_{X_i}^2$ is the observed score variance for the item scores.

Reliability and Standard Error

High degrees of reliability for scores are, of course, desirable. The more reliable scores on an instrument are, the less random error there is in the observed responses, and thus, the more precise the information about respondents will be. While reliability coefficients are quantities that index in a single number the precision of an instrument, it is often equally important to quantify the resulting error that accompanies latent variable estimates for respondents as a result of the imperfection in measurement.

There are essentially two types of error that are relevant in a CTT model, (1) *unconditional standard error of measurement (SEM)* and (2) *conditional SEM*. The former is a single number that is assumed to be the same across all values of the latent variable (i.e., it is the same for all respondents), and the latter is different across

different values of the latent variable (i.e., is larger for some respondents and smaller for others). Unconditional SEM is simply the standard deviation of the error scores and can be shown to be $\sigma_E = \sigma_X \sqrt{1 - \rho_{XX'}}$. As the formula shows, a perfect reliability implies no standard error (i.e., the observed scores are the true scores), while no reliability implies that all observed variation is simply error variation (i.e., the observed scores contain no information about interindividual differences). Note that an estimate of the true reliability has to be inserted into this formula, and different estimates will produce different values of SEM.

Conditional SEM is, technically, the more appropriate measurement of error to use in practice. Essentially, error always varies across the range of latent variable values, and using the SEM is an unnecessary oversimplification. Different approaches can be taken to estimate conditional SEM under a CTT framework, including a binominal model for error, a normal model for error, and a combined model. Once a suitable model has been chosen, the conditional SEM can be computed and can be used to compute confidence intervals for the true latent variable scores of respondents. These intervals will differ in width at different points on the score continuum.

Properties of Reliability Coefficients

It is important to realize that the formulas for the coefficients presented so far include population values for variances. In practice, these coefficients are estimated on the basis of sample data. As a result, one needs to distinguish between (a) the sample estimate of the reliability coefficients, (b) the population value of the reliability coefficients, and (c) the theoretical value

Table 1 Relationship of the Population Values of Selected Internal Consistency Coefficients to the True Reliability

	<i>Spearman-Brown</i>	<i>KR-20</i>	<i>KR-21</i>	<i>Rulon</i>	<i>Flanagan</i>	<i>Coefficient a</i>
SP	=	=	=	=	=	=
E-SP	=	=	=	=	=	=
TE	≤	=	=	=	=	=
E-TE	≤	=	≤	=	=	=
C	≤	≤	≤	≤	≤	≤
E-C	≤	≤	≤	≤	≤	≤

Note: SP = strictly parallel; E-SP = essentially strictly parallel; TE = tau equivalent; E-TE = essentially tau equivalent; C = congeneric; E-C = essentially congeneric; KR = Kuder-Richardson

of the reliability coefficient that these are trying to estimate. This reliance on sample data has two key implications.

The first implication is that these coefficients estimate the true reliability differentially well depending on the relationship that exists between scores under a CTT framework. Simply put, there are three different types of score relationships that form a decreasingly restrictive hierarchy in terms of the assumptions that are made about terms in the CTT model. The three relationships are (1a) strictly parallel, (2a) tau equivalent, and (3a) congeneric test scores. If mean differences across forms are further taken into account, one can further distinguish between (1b) essentially strictly parallel, (2b) essentially tau equivalent, and (3b) essentially congeneric test scores. All these models for test score sets can be tested using methods from factor analysis with mean structures.

Scores from strictly parallel items or forms of an instrument, which have to be constructed according to identical sets of specifications or blueprints, possess identical statistical properties. From a factor-analytic perspective, this means that the loadings and error variances are identical across strictly parallel items or forms, which implies an equal level of reliability for the different items or forms. The requirements of strict parallelism are unlikely to hold in most practical situations; therefore, the following weaker forms have been defined. Scores from items or forms described as being tau equivalent are proportional to one another. From a factor-analytic perspective, this means that the loadings are still identical across tau-equivalent items or forms, but that the error variances are allowed to differ. Scores from congeneric items or forms assume only that the true scores are linearly related to one another. From a factor-analytic perspective, this means that the loadings and error variances are allowed to differ across congeneric items or forms. If mean differences across forms are further modeled, this leads to the essentially strictly parallel, essentially tau equivalent, and essentially congeneric items or forms, as introduced above. From a factor-analytic perspective, this implies that the items or forms can also differ in terms of their intercepts.

Table 1 lists selected properties of selected coefficients to illustrate how these different score relationships impact the relationship between the population values of the coefficients and the true reliability that they are trying to estimate. For example, it shows that the population value of Cronbach's α equals the true reliability if the scores on the items on which it is computed are at least essentially tau equivalent. It is important to note, however, that the sample value of the coefficient can still under- or overestimate the

population value and, thus, the true reliability due to random sampling error.

Thus, it is necessary to test which of the CTT models holds for a given instrument by using sample data to be able to gauge how well a reliability coefficient is likely to estimate the true reliability.

The second implication is that sample values of reliability coefficients should be used to construct confidence intervals and to conduct hypothesis tests to make inferences about the population values of the coefficients according to the appropriate statistical theory. For example, one can construct confidence intervals for the population value of Cronbach's α in a single population as well as across multiple populations.

Reliability in Alternative Measurement Frameworks

The previous discussion has focused on reliability estimation in a CTT framework, which is probably the most common measurement framework that is used in practice. However, alternative frameworks that provide definitions of reliability coefficients are available for modeling variation in latent variables. This section briefly discusses generalizability theory (g theory), factor analysis (FA), and item response theory (IRT).

G Theory

G theory breaks up the error component in the basic CTT model to differentiate multiple sources of error. To estimate the relative contributions of these different error sources, which are viewed as *factors* or *facets* from an experimental design perspective, random-effects analysis of variance procedures are used. Depending on the number of factors that are used in the design and depending on whether they are experimentally crossed with one another or nested within one another, different types of reliability coefficients can be defined and estimated.

There are two primary types of reliability coefficients in the g-theory framework, namely the generalizability coefficient and the dependability coefficient. The former is analogous to a traditional CTT reliability coefficient and is calculated as the ratio of true or universe score variance to the expected observed score variance. As in CTT, this coefficient is designed to quantify the uncertainty associated with norm-referenced or relative comparisons of respondents based on scores. The latter estimates the precision of an observed score in estimating a person's true score. Thus, unlike in traditional CTT models, this coefficient is designed to quantify the uncertainty associated with criterion-referenced or absolute decisions.

Mathematically, both coefficients can be defined as

$$\Phi = \frac{\sigma_p^2}{\sigma_p^2 + \sigma_E^2},$$

which resembles the formula for the reliability coefficient in the CTT framework. However, for the generalizability coefficient, σ_E^2 is composed of the variance of items (σ_I^2) only, whereas for the dependability coefficient, σ_E^2 is composed of the variance of the items and the person-by-item interaction ($\sigma_I^2 + \sigma_{pi}^2$). As a result, the error variance for the dependability coefficient is always greater than the error variance of the generalizability coefficient.

Factor Analysis (FA)

Factor-analytic techniques can be employed to investigate the score relationships for items on a single instrument or for items on multiple instruments. Specifically, FA can be used to empirically test which of the six basic CTT models is likely to hold in the population. This technique involves the use of sample data with appropriate restrictions on factor loadings, error variances, and latent means. The reliability for an instrument consisting of multiple items can be estimated as

$${}_{FA} \rho_{XX'} = \frac{\sum_{\text{all items}} \lambda_i^2}{\sum_{\text{all items}} \lambda_i^2 + \sum_{\text{all items}} \sigma_E^2},$$

where λ_i^2 is the factor loading associated with each item and σ_E^2 is the error variance associated with each item. Depending on whether factor loadings, error variances, or both are constrained to equality across items, reliability estimates for different CTT models can be computed.

Mean-structure models can also be fit, and the resulting models can be compared to models without mean structures, but the mean structures do not have an effect on the reliability estimate itself. However, testing for mean structure is important in order to find which CTT model is likely to hold in the population, which helps to explain the statistical properties of different reliability estimators. In general, FA is a powerful framework for estimating the reliability coefficient that is most suitable for the data structure at hand if the sample size is sufficiently large to provide stable estimates of loadings, error variances, and latent means.

IRT

IRT uses a nonlinear function to model the relationship of observed scores to true scores at the item level. Put simply, IRT is conceptually similar to a simple logistic regression model with a latent predictor variable, which gets estimated simultaneously across all items for an instrument. There are close relationships between some basic IRT and CTT models and, thus, between the concept of reliability in IRT and CTT.

More specifically, reliability in IRT is marginally defined as the average reliability across all potential values of the latent variable. Of greater interest than a single reliability coefficient in IRT are the information function and the standard error of estimation (*SEE*) function, however. The former shows how much statistical information each item provides for each value of the latent variable (i.e., for different respondents) while the latter shows how much uncertainty about the latent variable value there is for different respondents.

Just as with the relationship of reliability with unconditional and conditional *SEM*, there is a close relationship between reliability and the statistical information provided via *SEE* in IRT. Essentially, the statistical information at different latent variable values is inversely proportional to the *SEE* such that items that provide a lot of information about certain respondents have a small *SEE* for them (i.e., provide very precise estimates for them). Moreover, just as conditional *SEM* should always be used in a CTT framework to quantify the precision of latent variable estimates for respondents, *SEE* should always be used in an IRT framework in addition to simply computing reliability estimates.

REPEATED MEASURES DESIGN

Repeated measures experiments are appropriate when multiple measures of a dependent variable are taken on the same subjects or objects or matched subjects or objects under different conditions or over two or more time periods. Repeated measures cover a broad range of research models, from comparison of two treatments on the same subjects to comparisons of multiple treatments on multiple levels of two or more factors on the same subjects and to assessing the differences in means among several related scales that share the same system of measurement.

The terminology used for repeated measures varies among researchers and statisticians. For example, repeated measures designs are also known as repeated measures analysis of variance (ANOVA), repeated measures factors, or within-subjects designs. However, repeated measures may be performed within a multivariate ANOVA design as well. The logic of repeated measures is based on the calculation of difference scores (contrasts) for comparisons of treatment levels for each subject. For example, if there were no treatment effect, the difference between scores before and after the treatment would be close to zero. The number of contrasts is usually 1 less than the number of levels in a factor. A factor with two levels would produce one

difference score whereas a factor with three levels would produce two difference scores: one score for the difference between Level 1 and Level 2, and one score for the difference between Level 2 and Level 3, unless other specific comparisons are requested. Contrasts are pooled together to provide the significance test. The mean of contrast scores and variation around the sample mean difference based on the individual difference scores are used to determine whether there is a significant difference in the population.

Repeated measures designs include a broad class of statistical models with fixed effects and/or random effects. Fixed effects are changes in the means of the dependent variable that can be attributed to the independent variables. For example, differences in mean attitude scores about the environment between individuals who live in a rural location and those in an urban location may be attributed to the fixed effect of location. Location is a fixed factor because the researcher made a conscious decision to include only rural and urban locations, although other locations such as suburban could have been included. Random effects are changes in the variance of the dependent variable that can be attributed to the sampling units. For example, participants in a study are usually considered to be a random factor because the researcher selects a sample from a larger population. If another sample were selected, results would likely be different.

Repeated measures designs differ from the traditional between-groups designs that require a separate sample of subjects for each measurement or treatment condition. Observations in a repeated measures design may be from the same sample or experimental unit from one time to the next or from one condition to the next. In addition, repeated measures may be taken on matched pairs of individuals from different groups. Each individual in one of the groups is matched, on the specific variable being investigated, with a similar individual in another group. Measures may be taken over specified or unspecified time periods. Measures taken in a repeated measures study cannot be considered independent of one another because the measures are taken on the same or matched subjects, and one would expect that such measures would be correlated.

Applications

Repeated measures analyses are used for studies in many different disciplines, ranging from behavioral and social sciences to medicine, engineering, and agriculture. Following are examples of research problems

that are appropriate for repeated measures procedures: effects of three different treatments (chemicals or fertilizers) on two different kinds of crops; changes in behavior before and after an intervention; difference among scores on several related scales; reaction time under four different conditions; student performance before and after an intervention; performance of different machines at specified time periods; reactions to drugs or treatments over time; and ratings on specific products or services.

Repeated measures may be taken at two or more different times. For example, energy level of a sample may be taken at 7:00 a.m., 1:00 p.m., and again at 6:00 p.m. Measures taken at different times can vary based on amount and quality of sleep, type of breakfast that the individual ate, type of activity performed before each measure was taken, and so on. Measures taken on one group and compared with measures from a different group may be invalid because individual activities, habits, and natural body clocks vary. Repeated measures on the same subjects allow the subjects to act as their own control.

Repeated measures may be taken under two or more different conditions. When only two measures are taken, the design may be referred to as a paired-test design, as in a study comparing anxiety when measures are taken on the same subject tested in two different situations: high-stakes testing and testing with little or no consequences. The sample means for each testing condition are examined to assess statistically significant differences between the two testing conditions in the population.

Types

Paired Samples *t* Test

The paired samples *t* test is a basic research design in terms of convenience and analysis. This test is also known as a correlated samples design, and it is the simplest of the within-subjects designs. The purpose is to compare mean scores within subjects by testing the null hypothesis of no difference between the two measures. Paired samples *t* tests are performed on one sample in which each participant in the sample is measured two times on the dependent variable. This is the case in the pretest–posttest situation in which each participant is measured before a treatment and again after the treatment. For example, measuring college students' knowledge about the environment before a special unit of instruction is taught and again after the unit is taught is a paired samples *t* test design. Participants serve as their own control because both measures are taken on the same participants. Paired comparisons are also appropriate in cases in which repeated

measures are not collected from the same participants. Participants may be matched through a natural pairing process, such as sisters and brothers, or through a testing process in which participants are matched on the basis of test scores.

The paired samples *t* test should meet certain statistical assumptions; for instance, the data for each variable should be from a randomly selected and normally distributed population, individual scores within a group should be independent of one another, and population variances should be equal. The assumption of equal variances is known as homogeneity of variance. The null hypothesis of equal means is rejected or retained based on the *t* value at the associated degrees of freedom and *p* value. If there is a low probability that the results occurred by chance at the preset alpha level (generally .05), the null hypothesis is rejected; otherwise it is retained—never accepted.

One-Way Repeated Measures ANOVA

The one-way repeated measures ANOVA is an extension of the paired samples *t* test to more than two levels of a factor. The purpose of a one-way repeated measures ANOVA is to determine whether there are statistically significant differences between or among the means associated with different levels of a factor. The null hypothesis states that there are no differences among the levels of a factor ($\mu_1 = \mu_2 = \dots = \mu_n$). The design involves a treatment factor and a time or condition factor. Subjects are matched on one or more variables, with random assignment of subjects to levels of the independent variable. The number of treatments is set by the researcher. The order in which treatments are processed should be random if order could affect the results. The treatment on the same subject represents the between-subjects factor, and the time or condition factor for observations at different times or under different conditions on the same subject represents the within-subjects factor.

Statistical assumptions for the one-way repeated measures ANOVA are similar to those of the paired samples *t* test with two additions: treatment levels are independent of one another, and the covariance matrix for the orthonormalized contrasts have equal variances and covariances for all levels of a factor (compound symmetry). Equal covariances among levels of a factor are known as homogeneity of covariance or sphericity. The assumptions of compound symmetry and sphericity must be met in order for results of the statistical tests to be interpreted accurately. Violations of the homogeneity-of-variance assumption are more serious when group sizes are unequal.

One-way repeated measures ANOVA is also known as a *completely randomized design* if all subjects are assigned randomly to the treatments; therefore, there are no blocking effects. The absence of blocking poses problems in interpreting the results if the sampling units are not homogeneous. Repeated measures designs are usually balanced designs in that an equal number of subjects is included at each level of the independent variable. Null hypotheses are rejected or retained on the basis of multivariate test results, which are usually reported to avoid a possible violation of the sphericity assumption. Along with the F value, associated degrees of freedom, and p value, the Wilks's lambda is the most commonly reported multivariate test result for the one-way repeated measures ANOVA. For factors with more than two levels and significant multivariate test results, paired samples t tests or polynomial contrasts should be conducted to identify which levels are different from one another.

Two-Way Repeated Measures ANOVA

The two-way repeated measures ANOVA design involves two independent variables (factors) in the analysis, with two or more levels each. The two-way repeated measures ANOVA is sometimes referred to as a *factorial ANOVA* or *two-factor ANOVA*. The purpose of the two-way repeated measures ANOVA is to determine whether there is a significant main effect of each of the factors on the dependent variable and an interaction effect between the two factors. Three null hypotheses are tested: one for each main effect and one for the interaction effect. Each subject is tested at each level of both factors. Adding a second factor, such as time, with three levels, to an experiment with a condition factor with two levels would be considered a two-way design, as long as repeated measures are taken on the same or matched subjects. The addition of a control group with repeated measures on the experimental group and the control group would be a two-way repeated measures ANOVA design. If the repeated measures are taken on only one factor, the design is called a *mixed-model ANOVA*.

Assumptions for the two-way repeated measures take into account the two factors in the analysis. Like the one-way repeated measures ANOVA, the assumptions of normality, sphericity, and random selection of subjects should be met. In addition, the difference scores for the multivariate tests should be multivariately normally distributed, and the difference scores from one subject to the next should be independent.

Like the one-way repeated measures procedure, the results of the two-way repeated measures ANOVA are usually interpreted on the basis of the multivariate tests to avoid violations of the sphericity assumption. Each

factor and the interaction of the factors are listed in the multivariate table with their corresponding test results. Null hypotheses are rejected or retained based on Wilks's lambda, the F value, associated degrees of freedom, and the p value. Wilks's lambda is the most commonly reported multivariate test for main effects and interaction effects. Post hoc follow-up tests should be conducted for significant interaction effects. If there is no significant interaction, but a significant main effect, follow-up tests should be conducted on factors with more than two levels to identify which levels are different from one another.

Two-Way Mixed Model ANOVA

Two-way mixed model ANOVA designs test differences within groups with repeated measures, as well as differences between groups. Mixed models are also known as *two-factor between-within ANOVAs* or *split-plot ANOVAs*.

The major difference between the two-way repeated measures ANOVA and the mixed model ANOVA is that in a two-way repeated measures design, each subject is tested at each level of two different factors whereas in the mixed model ANOVA, repeated measures are made on only one of the two factors. For example, a study of environmental concerns between rural and urban citizens before and after a community awareness program would be important to sociologists. In this study, geographic location (rural or urban) is a between-groups factor, and the within-subjects (repeated measures) factor is pre-post measures of community awareness. The main effects of geographic location and the interactions of location with the pre-post measures can be examined. Another example is a single treatment applied to a large experimental unit, with multiple treatments administered randomly to subunits of the larger experimental unit. The between-subjects factor is derived from the larger unit, and the within-subjects factor is based on the treatments to the subunits. A more complex example of the between-within design is the random assignment of four subjects to three different conditions under which four different measures are taken on a variable of interest. The three conditions represent the between-factor variable and the four measures are the repeated factor.

Statistical assumptions for mixed models are more complex than for the one-way and two-way situations because assumptions for both between- and within-subjects analyses need to be considered. In addition, the variance and covariance structures are more complex. The assumptions of normality and independence should be satisfied for both between- and within- groups. The

assumption of homogeneity of covariance should be met for between-groups analysis, and the assumption of sphericity should be met for within-groups analysis. Null hypotheses should be rejected or retained based on results of the statistical tests. Wilks's lambda is the most commonly reported multivariate test for main effects and the interaction effect, along with the F value, associated degrees of freedom, and the p value. Post hoc follow-up tests should be conducted for significant interaction effects. If there is no significant interaction, but a significant main effect, follow-up tests should be conducted on factors with more than two levels to identify which levels are different from one another.

Latin Square Designs

The Latin square design counterbalances the order of treatments to ensure that each treatment condition occurs equally often in the experiment. The purpose is to compare the effects of repeated observations on multiple levels of a factor for multiple sampling units. Latin square designs include three factors, which may be visualized as levels of one factor (sampling units) represented on the rows of a square matrix, levels of another factor (conditions or time periods) on the columns of the matrix, and a third factor represented by the intersections of the rows and columns. Each factor must have the same number of levels, resulting in a square matrix, thus a Latin square design. Measures for the combinations of factors on the rows and columns are the treatment effects. All combinations of the factor levels may or may not be included in the design. Latin square designs are similar to nested designs, which offer control over the variation introduced by the sampling units. For example a study of consumer ratings of the usability of a specific product under four different conditions throughout the year could be structured as a Latin square design with the required three factors: four consumers listed on the rows, four conditions or time periods listed on the columns, and consumer ratings (treatment effects) listed in the row and column intersections. Assumptions for the Latin square design are the same as for other repeated measures designs. Trend analyses are recommended in cases in which order of treatments is important or practice or carry-over effects may be present. Results of a Latin square analysis are displayed in an ANOVA table.

Advantages and Disadvantages

Advantages

A major advantage of a repeated measures design is that subjects are used as their own control because each subject is a member of the control group and the

experimental group. Using the same participants in both groups can help cut the cost of a study, especially in situations in which participants are difficult to find. A measure taken on one individual and compared with the same measure on another individual does not give valid information on variability due to within-subject difference.

Disadvantages

The greatest disadvantage with repeated measures designs is possible carryover effects. Problems can arise with subject fatigue, boredom, or practice effects that carry over from one measure to the next. These problems can be minimized by increasing the time between measures and randomizing the order in which treatments are administered. There may also be unobserved or hidden effects that are not discovered unless a second treatment is introduced, which may not be feasible.

REPLICATION

Any research conclusion is suspect if it is based on results that are obtained by chance. An indication of happenstance is a failure to obtain the same results when the original study is repeated. *Replication* refers to obtaining the same results when a previous study is conducted again in as similar a way as possible. The replication issue is discussed here in the context of choosing experimentally two theories.

The *decay theory* says that learning dissipates with time if one does not rehearse what has been learned. It implies that longer delays give rise to more forgetting. Experimenter *D* manipulates *delay of recall* to test it and obtains data consistent with the theory.

The *interference theory* says that forgetting occurs when subsequent learning interferes with earlier learning. It is expected that one forgets more if one has more additional learning. Experimenter *E* finds support for it by manipulating *amount of the additional learning*.

The onus is on both *D* and *E* to render it possible for themselves or any interested researcher to repeat their respective study by describing succinctly its experimental objective, specific to-be-tested hypothesis, method and materials used, and data collection, as well as analysis procedures.

A failure to replicate either study does not necessarily mean that there is no support for either theory. First, the description of the original study may not be as succinct as required. Second, there may be subtle variations in execution when the original procedure is repeated (e.g., the tone used in instructing the subjects). Third, the repeat study cannot (or may not) have all the features of the original study. For example, it might be impossible (or inadvisable) to employ the same group of participants in the repeat study. When another random sample is selected from the original population for the repeat study, an atypical sample may be selected by chance. Even if it were possible to employ the original participants, the participants themselves might have changed in ways that are relevant to the study.

Be that as it may, replicating *Ds* (or *Es*) results proves neither the decay nor the interference theory. The variables, *delay of recall* and *amount of additional learning*, are confounded with each other in the sense that longer delays necessarily mean more additional learning; being given more additional learning may mean longer delays in testing the original learning. Hence, every successful replication of findings consistent with the decay theory is also consistent with the interference theory, and perhaps vice versa.

In short, repeating an original study may duplicate a *confounding variable*. That is, replication does not

Table 1 The Logic of Converging Operations in Theory Corroboration

<i>The Theory of Interest (T_1) and Its Contenders (T_2)</i>	
Theory T_1 and its implications (I_{1j}) in Situation ABC_k	A Contending theory (T_2) and its implication (I_{2j}) in Situation ABC_k
If Theory T_1 is true, then I_{11} in ABC_1 .	If Theory T_2 is true, then I_{21} in ABC_1 .
If Theory T_1 is true, then I_{12} in ABC_2 .	If Theory T_3 is true, then I_{32} in ABC_2 .
If Theory T_1 is true, then I_{13} in ABC_3 .	If Theory T_4 is true, then I_{43} in ABC_3 .
If Theory T_1 is true, then I_{14} in ABC_4 .	If Theory T_5 is true, then I_{54} in ABC_4 .
If Theory T_1 is true, then I_{15} in ABC_5 .	If Theory T_6 is true, then I_{65} in ABC_5 .

Note: T_i = the i th theory; I_{ij} = the j th implication of theory I_i ; ABC_k = the k th situation.

disambiguate the confounding between two variables. This difficulty necessitates the adoption of *conceptual replication*, which is better categorized as *converging operations*, as a means of substantiating theories.

To avoid duplicating confounds (real or potential) of the original study, experimenters find it more instructive to use a series of theoretically informed and related experiments in which different independent variables or different experimental tasks may be used.

Any testable theory (T_1) should have well-defined implications (e.g., I_{11} through I_{15} , as depicted in the left-hand panel of Table 1). The implicative relation is represented by the conditional proposition [CP], as shown in the left-hand panel of row 1 of Table 1.

[CP]: If Theory T_1 is true, then Implication I_{1j} should be observed in Condition ABC_k .

Relevant here are two rules of conditional syllogism. First, the *modus tollens* rule says that the antecedent of a conditional proposition (viz. T_1 in [CP]) is false if its consequent (i.e., I_{1j}) is not true. Hence, each of the implications of T_1 (viz. $I_{11}, \dots, I_{15}$ in Table 1) is a criterion of rejection of T_1 .

The second conditional syllogism rule is *affirming the consequent*. Knowing that a consequent (e.g., I_{1j}) is true does not guarantee that its antecedent (T_1) is true. It is for this reason that the tenability of T_1 is strengthened indirectly in the context of a contending theory (e.g., T_2 in the right-hand panel of row 1 in Table 1).

Not observing I_{11} in Situation ABC_1 means that T_1 is false (by virtue of the modus tollens rule). Hence, setting up and collecting data in Situation ABC_1 is an explicit attempt to reject T_1 . Observing I_{11} (instead of I_{21}) in Situation ABC_1 leads to the rejection of T_2 but not a conclusive acceptance of T_1 in view of the affirming the consequent rule.

By the same token, observing I_{12} (instead of I_{32}) in Situation ABC_2 leads to the rejection of T_3 but not a conclusive acceptance of T_1 . Every failed attempt to reject T_1 (in Situations ABC_3 , etc.) succeeds in rejecting a contending theory. At the same time, these attempts converge on the tenability of Theory T_1 from different angles. Hence, instead of appealing to replication, a series of theoretically informed converging operations should be used to substantiate a theory.

RESEARCH

Research is a form of organized intellectual work closely associated with the conduct of science. Like its cognates in French (*recherche*) and German (*Forschung*), the English word *research* carries connotations that distinguish it from such related terms as *discovery* and *scholarship*. This entry explores the differences between research, discovery, and scholarship, describes three crucial transition points from scholarship to research as a mode of inquiry, and offers some observations about research as a collective project of indefinite duration.

Research Versus Discovery and Scholarship

The differences between the three terms can be grasped most easily through etymology.

Discovery suggests the revelation of something previously hidden, possibly forgotten, typically for a long time. This perhaps captures the oldest sense of

knowledge in the Western intellectual tradition, traceable to the Greek *aletheia*. A discovery usually carries life-transforming significance because it purports to get at the original nature of things that are intimately connected to the inquirer's identity: We find out who we really are by learning where we belong in the great scheme of things. At the same time, though, in the words of Louis Pasteur, "Discovery favors the prepared mind," it is not clear that there is a method, let alone a logic, of discovery. Rather, discoveries are often portrayed as products of a receptive mind encountering a serendipitous event. The implication is that a discovery—as opposed to an invention—points to a reality that is never fully under the inquirer's control.

Scholarship suggests a familiarity with a wide range of established sources, the particular combination of which confers authority on the scholar. Scholarship thus tends to focus on the personality of the scholar, whose powers of discrimination are akin to those of a connoisseur who collects only the best works to perpetuate the values they represent. Unsurprisingly, the history of scholarship is intimately tied to that of editing and curation. Although some scholarship makes claims to originality, its value mainly rests on the perceived reliability of the scholar's judgment of sources. On this basis, others—especially students—may then study the scholar's words as accepted wisdom. Thus, the idea of scholarship already implies a public function, as if the scholar were conducting an inquiry on behalf of all humanity. This point is reflected in the traditional academic customs of annual public lectures and public defenses of doctoral dissertations.

Research suggests an exhaustive process of inquiry whereby a clearly defined field is made one's own. An apt metaphor here is the staking of a property claim bounded by the claims of other property holders. It is implied that a property holder is licensed to exploit the field for all the riches it contains. Indeed, research is strongly associated with the deployment of methods that economize on effort to allow for the greatest yield in knowledge. Unlike scholarship, research is by nature a private affair that is tied less to the intrinsic significance of what is investigated than to the effort invested in the activity. Consider it an application of the labor theory of value to the intellectual world. The transition between scholarship and research is most clearly marked in its public justification. The researcher typically needs to do something other than a version of his or her normal activities in order to demonstrate usefulness to others because of the inherently specialized nature of research.

Clearly, discovery, scholarship, and research are overlapping concepts for understanding the conduct of inquiry and the production of knowledge. For example, research can enhance the conditions of discovery by

producing inquirers whose minds are sufficiently disciplined to recognize the true significance of an unanticipated phenomenon. For Thomas Kuhn, such recognition constitutes an “anomaly” for the researcher’s “paradigm.” Moreover, as the information scientist Don Swanson has observed, relatively little of published research is read, let alone cited. In effect, researchers unwittingly manufacture a vast textual archive of “undiscovered public knowledge” whose depths need to be plumbed by scholars who, equipped with smart search engines and other data-mining tools, may then discover solutions to problems that researchers in the relevant fields themselves believe still require further original work. Add to that Derek de Solla Price’s observation that research activity has so rapidly intensified over the past half century that most of the researchers who have ever been alive are alive today, and one may conclude that, for better or worse, research is more in the business of manufacturing opportunities for knowledge than knowledge as such.

Implied in the above account is that discovery, scholarship, and research may correspond to specific phases in the life cycle of scientific activity. In that case, *discovery* refers to the original prospective phase of epistemic insight, *research* to the ordinary work that Kuhn called normal science, and *scholarship* to the retrospective significance assigned to scientific work. The phenomenon of undiscovered public knowledge, which gives rise to the need for knowledge management, suggests that we may soon return to what had been the norm for doctoral-level research, even in the natural sciences, prior to the final third of the 19th century, namely, the testing of a theory against a body of texts. This reflects not only the surfeit of unread but potentially valuable written material but also the diminishing marginal rate of return on original research investment. Concerns about the unwittingly wasteful repetition of research effort had been already voiced in the 1950s, sparking the U.S. National Science Foundation to pilot what became the Science Citation Index, which researchers were meant to consult before requesting a grant to ensure that they were indeed heading in a new direction.

Three Transition Points From Scholarship to Research

Three moments can be identified as marking the transition from scholarship to research as the leading form of organized inquiry in the modern era: the footnote, the doctoral dissertation, and the salary.

One significant trace is the *footnote*. Before the printing press enabled mass publishing, the growth of knowledge was slow, in large part because authors

spent much effort literally reproducing the texts to which they then responded. As books became more easily available and journals circulated more widely, this literal reproduction was replaced by referencing conventions, starting with the footnote. Whereas the medieval scholastics had written their commentaries on the margins of the pages of books they copied, early modern scholars dedicated the main body of their texts to their own interpretations, while citing and contesting source works and those of other scholars in often lengthy footnotes. This practice may have left the impression that scholarship was always a messy and unresolved business, such that whatever was allowed to pass without criticism was presumed true, at least until further notice. The shift from a separate realm of footnotes to author-date citations internal to the main text corresponds to the emergence of a research mentality. In this context, other researchers and their sources are rarely contested. At most, the validity of their work is restricted in scope. But normally such work is cited in service of a positive case that the researcher wishes to make for a hypothesis or finding.

Another significant trace is the *doctoral dissertation*. In the older era of scholarship, a dissertation was seen primarily not as an original contribution to knowledge but as a glorified examination that provided candidates an opportunity to display their own brilliance in the mastery of sources, which included the dismissal of alternative interpretations. However, these dismissals were normally treated not as definitive refutations but as instances of wit, typically involving the placement of work by earlier authors in an uncharitably ironic light. And it would be understood as such by those who witnessed the public defense of the dissertation. The elevation of a candidate to doctoral status did not by itself constitute a change in the course of collective inquiry. One could easily imagine a future doctoral candidate ironically dismissing that doctor’s arguments by reasserting the authority of the old texts. In this respect, knowledge in the world of scholarship certainly grew but without demonstrating any overall direction. Much of the humanities, including philosophy, may be seen as still operating in this mode.

Underlying the shift in mentality from scholarship to research vis-à-vis the doctoral dissertation was the significance accorded to originality, which William Clark traces to the reform of the German universities in the early 19th century. The modern requirement that dissertations constitute an “original body of research” is meant to capture two somewhat different ideas: First, there is the Romantic view—very much part of the modern German university’s ideological perspective—that research should be self-motivated and self-sustaining, something done for its own sake

and not to serve some other interest. But second, there is the more scholarly classical view of originality that one gets closer to the original sources of knowledge by eliminating various interpretive errors and placing salient truths in the proper light. Isaac Newton, who by the mid-18th century was already touted as the greatest human intellect ever to have lived, was seen as original in both senses: On one hand, he laid out a conceptual framework for understanding all matter in motion based on principles that he himself had derived. On the other hand, he presented this framework as the *prisca sapientia* (pristine wisdom) implied in Biblical theology, once shorn of its accumulated corruptions and misinterpretations.

A final trace from scholarship to research is provided by *salaried employment*. Even today scholarship may conjure up images of leisure, specifically of someone with the time to spend on reading and writing what he or she pleases. There is no sense of competition with others to reach some commonly agreed goal, let alone a goal that might provide untold benefits to all humanity. Rather, scholars set their own pace along their own intellectual trajectories. In contrast, it is rare for a research agenda to be pursued by an individual working alone. Nevertheless, just because research tends to be focused on problems of common interest, it does not follow that solutions will be quickly forthcoming. Chance plays a strong role in whether research effort pays off for the people doing it. Indeed, major research breakthroughs typically come after many people have been working in the same field, proposing competing hypotheses, for some time. Even Newton famously admitted that he saw as far as he did because he stood “on the shoulders of giants.” It was just this long-term perspective on the fruits of research that justified the need for researchers to be given regular salaries regardless of the ultimate significance of what they produced.

Several historical developments are indicative of this shift in mentality. The segregation of teachers and researchers in separate institutions starting in Napoleonic France enabled research to be conceptualized as a full-time job. In addition, the increasing need for complex specialized equipment in the natural sciences, starting with chemistry, forced a greater dependency of academics on support from the business community, which in turn opened the door to knowledge work being seen as a form of high-skill, high-tech industrial labor. The precedent was set by Justus Liebig’s establishment of the first university-based laboratory at the Hessian University of Giessen in 1840, soon followed by Lord Kelvin at the University of Glasgow. A downstream effect, evident in the global ascendancy of German academic research in the final quarter of the 19th

century, was what William Clark has identified as the Harnack principle, named after the minister for higher education who argued that research institutes should be organized around individuals with ambitious yet feasible research plans, even if others end up being employed to do most of the work. This principle is still very much in force in the funding of research teams through the vehicle of the principal investigator who acts as an entrepreneur who attracts capital investment that then opens up employment opportunities for researchers.

Research as a Collective Project of Indefinite Duration

As a sociologist concerned with the emergence of the role of the scientist in society, Joseph Ben-David stressed the significance of the research mentality, specifically that truth about some domain of reality is worth pursuing, even if it is very unlikely to be achieved in one’s lifetime, because others can then continue the project. Ben-David was struck by the cultural uniqueness of this idea of “science as a vocation,” which in the 20th century was most closely associated with Max Weber. After all, many of the metaphysical ideas and empirical findings of modern science were also present in ancient Greece, India, and China, yet by our lights there seemed to be relatively little appetite for improving and adding to those ideas and findings. If anything, the normative order of these societies tended to inhibit the free pursuit of science because of its potentially destabilizing consequences. In effect, they lacked a sense of the scientist as a distinct kind of person whose primary social identity might derive from affiliations with like-minded people living in other times and places.

Indicative of the establishment of such an identity is the gradual introduction in the 19th and 20th centuries of academic journals affiliated not with particular universities or even national scientific bodies but with internationally recognized scientific disciplines. This trend greatly facilitated the conversion of scholarship to research by introducing criteria of assessment that went beyond the local entertainment value of a piece of intellectual work. One way to envisage this transformation is as an early—and, to be sure, slow and imperfect—form of broadcasting, whereby a dispersed audience is shaped to receive the same information on a regular basis, to which audience members are meant to respond in a similarly stylized fashion. This transformation served to generate an autonomous collective consciousness of science and a clear sense of who was ahead and behind the cutting edge of research. However, there remained the question of

how to maintain the intergenerational pursuit of a research trajectory, such that one can be sure that unsolved problems in what has become a clearly defined field of research are not simply forgotten but carried forward by the next generation. Enter the textbook.

National textbooks that aspired to global intellectual reach were a pedagogical innovation adumbrated by Napoleon but fostered by Bismarck. They have served as vehicles for recruiting successive generations of similarly oriented researchers in fields that Kuhn would recognize as possessing a paradigm that conducts normal science. An unnoticed consequence of the increased reliance on textbooks has been that people with diverse backgrounds and skills can regularly become integrated into a common intellectual project. The clearest indicator is the textbook's integration of textual and visual representations. Just as text is no longer solely chasing text, an original medieval practice still common in most humanistic scholarship, so too craft-based knowledge required for experimental design is no longer treated as inherently tacit and hence subject to esoteric rites of guild-style apprenticeship. Arguably the textbook has done the most to convert modern science's research mentality into a vehicle for the democratization of knowledge production.

RESEARCH DESIGN PRINCIPLES

Research design is the plan that provides the logical structure that guides the investigator to address research problems and answer research questions. It is one of the most important components of research methodology. Research methodology not only details the type of research design to be implemented but includes the approach to measuring variables and collecting data from participants, devising a strategy to sample participants (units) to be studied, and planning how the data will be analyzed. These methodological decisions are informed and guided by the type of research design selected. There are two broad categories of research design: observational and interventional. Each research design emphasizes a different type of relationship to be explored between variables. The social issue or problem that needs further exploration and study is articulated in the research problem statement, which conceptualizes the problem or issue and identifies the main salient variables to be examined. Based on this conceptualization, research questions are developed to isolate the specific relationships among variables to be assessed: correlational and causal. The kind of research questions that the investigator wishes to answer will help determine the specific type research design that will be used in the scientific inquiry. Determining what kind of research questions should be posed and answered is one of the most important decisions to be made in the planning stages of a research study. It provides the foundation for selecting the actual design to be used in the study.

Research Problem

The research problem is an area of concern that the investigator is interested in exploring. It reflects a gap in knowledge about a specific social issue or problem discussed in the scientific literature. Often a research problem focuses on a situation that arises out of everyday life and that calls for a solution, an improvement, or some alteration; it is a problem that needs to be solved. Conceptualizing and describing the social problem lead the investigator to identify the most salient concepts or variables involved and guide the investigator's thinking about why and how the variables are connected to each other. Through this process of articulating and framing the research problem, investigators may discover that little is known about an issue or that there is conflicting information about it within the scientific literature. Depending on what is known about the research problem, the types of specific research questions to be asked and the purpose and objective of the research study could range from basic exploratory research to control experiments.

Research Questions and Hypotheses

Research questions involve examining a relationship between two or more variables. The relationship between variables can be expressed as either positive or negative correlation or causal. An example of a research question about a correlation would be, Are neighborhood characteristics of crime and low-income related to health status?

Causal relationships describe the cause-and-effect relationships between variables. Three criteria are used to assess causal relationships: (1) correlation between the variables, (2) temporal precedence or sequence, and (3) no alternative explanation. First, there must be a significant positive or negative correlation between the two variables. That is, as the value of one variable changes, the value of the other changes as well. Second, there is a defined temporal sequence of the variables. The variable that is considered to be the cause (the independent variable) must precede the effect variable (the dependent variable) in time. The temporal relationship is often diagrammed as $A \rightarrow B$ or expressed as, if A then B. Third, the cause-and-effect relationship between the variables cannot be plausibly explained by the presence of another variable. This is called the *third variable problem*, which is reduced or eliminated by controlling specific methodological procedures used to implement a particular research design. These controls attempt to combat specific threats to internal validity that can negatively affect the inferences made from a study. Examples of research questions examining a

causal relationship are, Does cognitive behavioral therapy reduce trauma symptoms among survivors of domestic violence? and Does neighborhood cohesion reduce community crime?

When there is an existing theory and/or the empirical literature provides some evidence about the relationship between variables, then an investigator is able to venture a hypothesis. A hypothesis is a formal statement about the expected relationships between two or more variables in a specified population. It is a translation of a research problem into a clear explanation or prediction of a study's results. A hypothesis is stated in a manner that allows for it to be tested, that is, either supported or refuted. Examples of hypotheses are: Cognitive behavioral therapy will reduce trauma symptoms among survivors of domestic violence, and The higher the neighborhood cohesion, the more community crime will be reduced.

Thus, research questions and hypotheses examine whether variables stated in a research problem are related or have a causal relationship. The types of questions and hypotheses that are expressed are strongly linked to the purpose of the research study.

Purpose of Research

Research can be grouped into exploratory, descriptive, explanatory, and evaluative. Research that is exploratory or descriptive examines the relationships among variables (correlational), and research that focuses on explanation or evaluation assesses causal relationships.

Exploratory studies are usually undertaken when relatively little is known about a phenomenon or an event. The goal is to determine whether a relationship exists among several variables under scrutiny. This type of study often operates as a pilot study to determine the feasibility of conducting a larger, more complex study. For example, investigators may be interested in exploring whether there is a relationship between neighborhood conditions and a person's physical health. Without making a simple connection between neighborhood conditions and health, implementing an intervention study to change the conditions would be premature, because it would be unknown which neighborhood condition to focus on (e.g., economic, political, social, psychological, housing, community resources, crime).

Descriptive research attempts to describe a group of people, a phenomenon, or an event. It is one of the first steps in understanding social problems and issues; it describes who is experiencing the problem, how widespread the problem is, and how long the problem has existed. An example of a simple descriptive study is an investigation of how many people within a community

are men, have less than a high school education, or earn less than the poverty threshold. Another purpose is to describe the prevalence of a phenomenon or event. These research questions might ask, What is the prevalence of methicillin-resistant *Staphylococcus aureus* (a type of bacterial infection that is resistant to antibiotics and difficult to treat) in the community? or What is the prevalence of homelessness in New York City?

Explanatory research focuses on why variables are related to one another. One main purpose of explanatory research is to test theory. A theory can be defined as a set of logically organized and interrelated propositions, statements, principles, rules, and assumptions of some phenomenon that can be used to describe, explain, predict, and/or control that phenomenon. Many theories describe essential cause-and-effect relationships between variables. They posit the direction (positive or negative), the strength, and the temporal (causal) sequence between variables. In an explanatory research study, the investigator measures these variables and then provides evidence that either supports or refutes the contention that there is a cause-and-effect relationship that exists between these variables. Specific research designs, such as experimental and prospective (longitudinal), provide an opportunity to observe and assess causal relationships directly. It is important to perform descriptive or exploratory research that describes the prevalence of a specific social problem, such as crime, substance abuse, or homelessness, and establishes basic relationships between variables before conducting more expensive and time-consuming research. Explanatory research can lead to research questions about how these conditions can be changed.

Evaluative research attempts to assess whether a particular intervention, process, or procedure is able to change behavior. Program evaluation falls under this type of research. Its goal is to evaluate the effectiveness of social programs that provide services. Program evaluations try to establish whether the intervention actually changed people's behavior and is responsible for improvements in client outcomes. For example, a federal educational program that has existed in the United States since 1965 is Head Start. An evaluation of Head Start could determine whether providing comprehensive education, health, nutrition, and parent involvement services to low-income children and their families can improve important developmental and education outcomes for preschool children.

Once the problem has been defined, the questions articulated, and the purpose of the research set, the next decision is to choose a research design that reflects these factors.

Research Designs

Research designs fall into two broad categories: observational and interventional. These designs vary in their approach to answering research questions and in how they depict relationships among variables. Observational designs examine the association among variables, and interventional designs focus on cause-and-effect relationships between variables. Thus, once an investigator poses a research question, then the choice of a specific research design becomes clearer.

Observational

Observational designs are referred to as *nonexperimental* because the investigator does not intervene or manipulate any variables. The most common observational designs are cross-sectional, cohort, and case-control, in which data can be collected at one time, prospectively (longitudinally), or retrospectively.

Cross-Sectional

In cross-sectional designs, the investigator collects all the data at the same time. These designs have been used extensively to describe patterns of variables within a population. Annually, U.S. federal agencies such as the Census Bureau, Centers for Disease Control and Prevention (National Center for Health Statistics), and Bureau of Labor Statistics conduct several nationally representative cross-sectional studies to describe and monitor the physical health, mental health, substance use, morbidity and mortality, births, health insurance, housing, employment, income, and other key characteristics of the population. In addition, survey organizations such as the National Opinion Research Center (NORC) and the Pew Research Center use cross-sectional designs to survey the U.S. population in order to monitor key social, economic, political, and health indicators. Many of these surveys are available for secondary data analysis.

Cohort Design

The word *cohort* is derived from *cohor*, which was 1 of 10 divisions making up a Roman legion. In research, the term refers to any group of individuals with something in common. That is, a collection or sampling of individuals who share a common characteristic, such as the same age, sex, or neighborhood. Epidemiological and clinical research identify a cohort as a well-defined group of people or patients who share a common experience or exposure and who are then followed for a time to examine the incidence of new diseases or events. Cohort designs are typically conducted either prospectively or retrospectively.

Prospective Cohort Design. In prospective cohort design, a cohort of individuals is followed over an extended time, such as 1 year, 5 years, or 10 years. The potential risk factors (predictors) and outcomes are collected from each participant during this time at a regularly scheduled interval, such as annually or every 2 years. Collecting data using a structured schedule allows the investigator to observe whether changes in potential risk factors precede changes in specific outcomes. By establishing a temporal sequence, the investigator is able to provide some evidence to determine whether the relationship between predictors and outcomes is potentially causal. The Framingham Heart Study is an example of a prospective study. The study began following a cohort of 5,209 men and women (between the ages of 30 and 62) who lived in Framingham, Massachusetts, in 1948. The purpose of the study was to identify a set of common risk factors that contributed to the development of cardiovascular disease. At the beginning of the study, individuals who did not have a history of a heart attack or stroke or any overt symptoms of cardiovascular disease were given a baseline physical examination and a lifestyle questionnaire. This cohort was then followed every 2 years with a detailed medical history, physical examination, and laboratory tests. The Framingham Heart Study has provided substantial evidence for the relationship between various risk factors and the development of heart disease.

Retrospective Cohort Design. A retrospective cohort design uses data that were collected in the past to determine the relationship between a set of potential risk factors and an outcome that is measured either in the past or the present. An example would be a study to examine the health of a community that was exposed many years ago to an industrial accident that released a harmful substance such as radiation (as in the Chernobyl disaster in Russia), a toxic gas cloud (such as the Bhopal disaster in India), or toxic waste (as in the Love Canal disaster in New York). The study would use past records (e.g., medical, school, employment, and insurance, and level of exposure to the toxin), questionnaires, or both to assemble a set of past risk factors that could be related to a person's current health status.

Case–Control Design

Case–control studies compare potential risk factors of individuals who already have a specific condition or disease (*cases*) with individuals who do not (*controls*). The selection of study subjects is based on the outcome variable (condition or disease). Controls are selected and matched to the cases by important demographic variables (age, gender, ethnicity, socioeconomic status).

The goal of the matching is to make the controls as comparable to the cases as possible on the most important characteristics. The controls serve as a reference group with which to compare the cases on potential risk factors. Differences between cases and controls on these risk factors could suggest factors that either elevate or reduce the risk of the occurrence of a disease or condition. Thus, the investigation goes from the effect (case status) to the potential cause (risk factors). An example of a case–control study would be a comparison of children with (cases) and without (controls) attention deficit/hyperactivity disorder (ADHD) and their prenatal exposure to maternal alcohol, smoking, and drug use during pregnancy. If children with ADHD have a higher prevalence of these risk factors than do comparable children without ADHD, then there may be a potential causal connection between the exposure and ADHD.

Interventional Designs

Interventional designs focus directly on an examination of the cause-and-effect relationship between independent and dependent variables. Their purpose is to create a situation in which the investigator is able to observe the change in a dependent variable (outcome) as the result of the introduction or manipulation of a stimulus, called the *independent variable*. Interventional designs are able to control or reduce the influence of other, confounding variables (called threats to internal validity) that may impact the relationship between independent and dependent variable. Interventional designs can be categorized as experiments, quasi-experiments, preexperiments, or natural experiments.

Experimental Designs

Experiments are designed to assess the causal relationship between an independent and a dependent variable. The classical experimental design is the *pre–post test control group*, in which individuals are randomly assigned to an experimental or control group and then compared on an outcome variable. Experimental designs assist the investigator in reducing or controlling many sources of bias and threats to internal validity that may influence the inference made about a cause-and-effect relationship between the independent and dependent variable. A defining feature of these experiments is *random assignment* of participants to experimental or control groups. The goals of random assignment are to ensure that subjects have an equal chance (or at least known probability) of being selected for either an experimental or a control group and that these groups are as similar as possible to each other in

personal characteristics and outcome variables prior to any intervention. The latter criterion is called the *equivalence of groups*. Random assignment lets chance place individuals into groups rather than allowing an investigator to choose who should be in a specific group. This approach does not guarantee group equivalence, but it does reduce selection bias.

After random assignment, the experimental group would be exposed to the intervention or stimulus, but the control group would just be measured over the same time. If the experimental group significantly changes on the dependent variable from the baseline measurement to the posttest measurement but the control group remains relatively the same, then it could be concluded or inferred that the intervention or the stimulus may be causing the difference between the two groups. In order for this inference to be considered, all other sources of bias or internal validity threats must be controlled for during the experiment. If the two groups do not differ from one another on the dependent variable, then it can be concluded that either the intervention did not work or that some form of error or bias was introduced by the study's procedures and impacted the validity of the study.

Educational, social, and psychological experiments introduce a stimulus to examine its influence on animal or human behavior. For example, an experiment could assess the effect of noise (stimulus) and the performance of a task (dependent variable), such as number of recalled new words from a list. For various psychosocial problems or conditions, experimental designs are used to assess existing and new treatments that are purported to improve an individuals' behavior or quality of life. For example, an experiment could be designed to examine a new approach for treating people with hypochondriasis. The experimental group would receive cognitive-behavioral therapy, and the control group would receive usual care. By comparing groups on several outcome variables, such as the level of health anxiety or number of visits made to primary care physicians, it could be shown that the treatment approach was similar, better, or worse than the usual care in helping individuals with hypochondriasis.

There are many types of experimental designs, beyond the classic pre-post test control group, that are used to control or minimize various biases and threats to ensure that the inference made about the cause-and-effect relationships from a study are valid. These designs include the following: posttest-only control group, alternate treatments, multiple treatments and controls, Solomon four group, Latin square, crossover, factorial, block, and repeated measures (longitudinal, nested [hierarchical], mixed).

Quasi-Experimental Designs

Similar to experimental designs, quasi-experiments manipulate an independent variable and compare the performance of at least two groups on an outcome variable. However, quasi-experimental designs do not have some of the elements of control that are found in experiments, and thus the groups are referred to as intervention and comparison. The main difference between quasi-experimental and experimental designs is the lack random assignment. Not randomly assigning participants to groups can result in the nonequivalence of groups. That is, the intervention and comparison groups may begin the study with differences in personal characteristics and/or the outcome variable. These differences can reduce the ability to make inferences about causal relationships. Quasi-experimental designs are used when it is not feasible to perform a true experiment. Often random assignment is not possible for ethical reasons or because of policies of social programs that will not allow interventions to use random assignment, whereby some clients would not receive any form of treatment (viewed as withholding effective treatment). The investigator would have to use statistical techniques such as analysis of covariance or propensity scoring to statistically reduce the bias due to these covariates that lead to initial group differences. An example of a quasi-experimental study would be a comparison of the effectiveness of two treatment approaches, Housing First and Supportive Housing, to help individuals who are homeless and have both a mental illness and a substance abuse disorder. Two emergency shelters, whose administrators are opposed to random assignment, could be used as sites in the study. Site A could be provided with the Housing First intervention and Site B could be given the Supportive Housing intervention. The two interventions would be compared at the end of the study on outcome measures such as housing stability and duration, quality of life, and use of psychiatric hospitalizations. However, lacking random assignment, these sites could vary significantly in many client characteristics before the study even begins, thus affecting any inferences of causality regarding the intervention.

Pre-Experimental Designs

Pre-experimental designs are designs that do not share the same strong features of experimental or quasi-experimental designs that control for internal validity threats. These designs typically lack a baseline measurement of important outcomes and/or a comparison group. The *one-shot case study* examines a group of participants after the introduction of an intervention

or stimulus; however, there is no ability to compare to baseline measures or other groups to establish a simple correlation. The *one-group pretest–posttest design* has pre–post measurements of the important independent and dependent variables; however, it lacks a control group for comparison. The *static-group comparison design* has a posttest measurement of the dependent variable on the one group and compares this group to a nonequivalent group that did not receive the intervention. However, the lack of random assignment and/or baseline measurements of the dependent variable limit the inferences that may be made. These designs are considered the weakest designs that try to establish causal relationships between independent and dependent variables.

Natural Experiment

Natural experiments are not true experiments, because the investigator does not manipulate the independent variable. Events such as natural disasters, wars, environmental accidents, or manufacturing plant closings that occur in everyday life can dramatically change human behavior. All these events can have a devastating impact on individuals, families, and communities. For example, hurricanes and floods can change a community with great ferocity and speed by destroying homes, businesses, and communities, as well as taking the lives of family, friends, and neighbors. Hurricane Katrina, in August 2005, was one such event that affected Gulf coast states including Louisiana, Mississippi, Alabama, and Florida, as well as the city of New Orleans. A natural experiment would involve studying the impact of the hurricane on individuals' psychological, social, and physical health by comparing a community that was directly impacted by the hurricane with a similar community that was not.

Threats to Validity

Validity focuses on the approximate truth of an inference. In a study, many inferences can be made about what caused the relationship among the variables. However, the investigator is never certain which inferences are true and which ones are false. By controlling the many threats to validity, the investigator is able to eliminate many variables that can influence the results of a study and lead to false inferences that can distort the relationship between independent and dependent variables. These threats are often referred to as *alternative explanations*.

There are four main sources of threats: internal, statistical conclusion, construct, and external.

Internal validity focuses on what occurred during the implementation of the study that could influence the relationship between the independent and dependent variables. Threats to internal validity involve specific design elements that impact the temporal precedence of the independent and dependent variables and the selection of participants, as well as the effects of history, maturation, differential attrition, testing, and instrumentation on the outcomes of the study. *Statistical conclusion validity* involves inferences about the correlation or covariation between an independent and dependent variable. The power of a study is often examined as one of the main issues: does the study have a sufficient number of subjects to detect a relationship if one exists? *Construct validity* focuses on the inferences made about the higher ordered constructs represented in the study by the independent and dependent variables. *External validity* refers to the generalizability of the findings to other persons, settings, or times.

The choices an investigator makes of the type of design to be used and how the study will be implemented will impact the overall validity of the study. These decisions are often trade-offs between theoretical, practical, and ethical issues in conducting a study. Further, correcting or adjusting for one threat may increase the likelihood of another threat.

RESEARCH HYPOTHESIS

To conduct research is to collect, analyze, and interpret data systematically so as to answer specific questions about a phenomenon of interest. These questions may be derived from conjectures about (a) an efficacious cause that brings about the phenomenon, (b) the intrinsic nature of the phenomenon, or (c) how the phenomenon is related to other phenomena. Tentative answers to these questions are research hypotheses if they are (a) consistent with the to-be-explained phenomenon, (b) specific enough to serve as guidelines for conducting research, and (c) testable (i.e., there are well-defined criteria of rejection).

Depending on the level of abstraction adopted, underlying an empirical research are three hypotheses at different levels of theoretical sophistication or specificity, namely, *substantive*, *program*, and *individual* research hypotheses (see Table 1).

A practical problem or a new or intriguing phenomenon invites speculations about its cause or nature or relation to other phenomena. For example, it is commonly accepted that people in small townships are friendlier than their counterparts in bigger cities. To investigate whether or not this is the case, as well as the reason, researchers would first offer a speculation (e.g., environmental effects) that, if substantiated empirically, would explain the phenomenon (see row 1 of Table 1). Such a conjecture is a *substantive hypothesis* because it explains a real-life (substantive) phenomenon (see row 2).

Substantive hypotheses are typically too general or vague to give directions to empirical research. Part of the reason is that the phenomenon is multifaceted. For example, environmental factors are air quality, noise level, amenities of various sorts, traffic volume, and the like. By itself, any one of these environmental factors also has multiple components. Hence, an investigation of a substantive hypothesis implicates a program of related hypotheses. Such a related set of hypotheses may be characterized as *program hypotheses* (see R_1 , R_2 , and R_3 in row 3).

To the extent a program hypothesis is well defined, researchers can conduct an experiment by specifying

the to-be-used research method, materials, procedure, and to-be-measured behavior (see [i] in row 4a). Specifically, the independent variable envisaged is *Ion M*, whose two levels are *presence* and *absence*. A hypothesis of such specificity is an individual research hypothesis, which may be in the form of an experimental hypothesis (see E_1 in row 4b).

Ion M is the independent variable in the present example (a) because Implication R_1 (namely, E_1) in [i] of row 3 is adopted, and (b) because of the methodological assumption that *Ion M* cleanses the air. Had R_2 in row 3 been used instead, a different independent variable (e.g., food supplement *H*) would be used (e.g., see [ii] in rows 4a and 4b).

In short, *research hypothesis* may refer to any one of three hypotheses underlying an empirical research study, namely, the substantive, program, and individual study hypotheses. Although the three hypotheses are literally different and may ostensibly be about different things, they are theoretically bounded. Specifically, the substantive hypothesis implies any one of the program hypotheses, which, in turn, implies one or more individual study hypotheses. For these implicative relations to be possible, the substantive or research hypothesis must be well defined. An individual *study hypothesis* of sufficient specificity becomes an experimental hypothesis. At the same time, even when one is collecting data to test a specific experimental hypothesis, one's ultimate conclusion is about the substantive hypothesis via the research hypothesis.

Note that the experimental hypothesis, let alone the research or the substantive hypothesis, is neither the statistical alternative (H_1 ; see row 5b) nor the statistical null hypothesis (H_0 ; see row 5a). While the nonstatistical hypotheses are conceptual conjectures about a phenomenon or the conceptual relationships between the independent and dependent variables, the statistical hypotheses are hypotheses about the effects of chance influences on research data. That is, the conceptual and statistical hypotheses implicated in a research belong to different domains.

Table I The Substantive, Program, Research, Experimental, and Statistical Hypotheses

<i>Level of Abstraction</i>	<i>Phenomenon or Question of Interest</i>	<i>Conjecture or Hypothesis</i>
1 Phenomenon	Residents in small cities are friendlier than their big-city counterparts.	Environments in big cities are less pleasant than in small towns.
2 Substantive	How would a more pleasant environment make people friendlier?	T_1 : Environmental pleasantness eliminates irritability.
3 Program	Would less irritable people be more polite? Would cultural enrichment make people more polite? Would less traffic make people more polite?	R_1 : Less irritated people are more polite. R_2 : Antibiotics in meat render people irritable. R_3 : People are more polite in situations of lower traffic density.
4a Research manipulation	[i] Suppose that <i>Ion M</i> eliminates air pollution. <i>Ion M</i> is used in the experimental condition (the <i>Ion M Present</i> condition), whereas there is no <i>Ion M</i> in the control condition (the <i>Ion M Absent</i> condition). [ii] Suppose that <i>Supplement H</i> in food eliminates antibiotics in the body. <i>Supplement H</i> is used in the experimental condition (the <i>Supplement H Present</i> condition), whereas there is no <i>Supplement H</i> in the control condition (the <i>Supplement H Absent</i> condition).	
4b Individual study (e.g., an experiment)	[i] Would people be more polite in a condition with cleaner air? [ii] Would people be more polite when they have fewer antibiotics in their system?	E_1 : People use more polite words in a condition with cleaner air. E_2 : People use more polite words when they have fewer antibiotics in their system.
5a Statistical	Are the data the result of chance influences?	$H_0: \mu_E \leq \mu_C$ H_0 : The mean number of polite words used in the <i>Ion M Present</i> condition is smaller than or equal to that in <i>Ion M Absent</i> condition.
5b	Are the data the result of non-chance influences?	$H_0: \mu_E \leq \mu_C$ H_1 : The mean number of polite words used in the <i>Ion M Present</i> condition is larger than that used in <i>Ion M Absent</i> condition.

Notes: E = individual research hypothesis; R = program hypothesis; T = substantive hypothesis; Subscript E = *Ion M Present*; Subscript C = *Ion M Absent*.

RESEARCH QUESTION

One of the most important decisions a researcher will make is deciding on a question that will be examined in the research process. This can be a very difficult decision because there can be many questions a researcher wants and needs to address. Good supervision will guide a researcher to a focused area of study that can lead to a focal question. The debate continues on whether this focus should be singular or plural, and the decision can be influenced by the subject of study and various quantitative or qualitative methodologies employed. John Creswell has suggested that before searching the literature, a researcher should identify a topic, using such strategies as drafting a brief title or stating a central research question. Researchers need to be aware of the following issues in relation to creating the research question.

Choosing the Right Research Question

Choosing the right research question involves a number of decisions that will shape both the research project and process. The “right” question has to involve several issues: an adequate knowledge of the area being considered for research, constructive support from a supervisor, and the time a researcher has to carry out the research. First, the researcher must have knowledge of the general and specific subject area. This knowledge may have been obtained from previous study; otherwise, research evidence from recent, published literature has to be examined. The researcher needs to realize that the research to be undertaken contributes to ongoing debates within a subject area being researched. Some students and academics do not realize that the rules and regulations that apply to senior researchers also apply to students and novice researchers at the undergraduate level (termed *junior researchers*). Literature reviews have to begin at the earliest possible stage of research because this knowledge has to inform the development of the research question. The first evidence base in research is published and edited literature, and the application of key and core texts within the subject has to inform the creation and evolution of the research question. This strategy suggests that the research question might have to change when a researcher acknowledges what has been published in a subject area.

A supervisor plays a crucial role in directing or nudging the researcher in the right direction. As Thomas Murray and Dale Brubaker suggest, it is important to identify potential sources of help and to

recognize the advantages and limitations of each. Those sources of most value are usually academic advisers, fellow graduate students, experts outside one's own department or institution, the researcher him- or herself, and the professional literature. The supervisor can advise which research direction a researcher can travel. This direction can be absolutely controlled if the researcher is working within a funded team, in which a supervisor can be a senior researcher. Relative control exists when a research supervisor informs the researcher about research design, which consists not only of devising the right question but also of literature review, methods and methodology, data collection, presentation, analysis, and answering the question in a research project conclusion. Third, time is an issue that has to be considered by all researchers when thinking about how to answer a research question. On reflection, planning and organization are crucial techniques in research design, but time still shapes what can and what cannot be done. As Elizabeth Wilson and Dorothy Bedford have argued, What are the consequences for full- and part-time students and staff who have full-time responsibilities outside academia? Time is an issue that also concerns both the quality of research and supervision.

Justifying the Research Question

Following these three issues, the researcher must justify which subject and question or hypothesis is going to be researched. Justification involves choice. Which decisions have to be made before a research project can begin? These choices involve how specific a subject area needs to become when addressing a problem. Which problem can be addressed when considering knowledge, supervision, and time? That narrowing down or becoming focused on a research area is possibly one of the most important processes involved within research because justifying the research project makes it not only viable but indeed possible. Focusing on a research area allows the next focal decision, which involves which question can be asked and addressed. Even at this early stage, ethical issues need to be considered. For example, what happens when a research project involves participants age 16 or younger in a methodology? Which questions can be asked? What experiments can take place within a laboratory?

The type of research question needs to also be addressed. Patrick White divides question types into descriptive and explanatory, the W-questions (who, what, where, when, why, and how), and purpose-led typologies. The purpose issue also helps in finding that focus and reducing the number of questions or

subquestions. This is subject oriented, and different subjects and disciplines have different methods in relation to these research choices. Justification of research question is both subject based and situational. For example, a dissertation needs to be focused within roughly a 6-month time frame. If time is longer, then the purpose can be multifocal, but a single research question may produce more focused results and recommendations for further research.

RESIDUAL PLOT

Residual plots play an important role in regression analysis when the goal is to confirm or negate the individual regression assumptions, identify outliers, and/or assess the adequacy of the fitted model. Residual plots are graphical representations of the residuals, usually in the form of two-dimensional graphs. In other words, residual plots attempt to show relationships between the residuals and either the explanatory variables ($X_1, X_2, \dots, X_p$), the fitted values ($\hat{y}_i$), index numbers (1, 2, . . . , n), or the normal scores (values from a random sample from the standard normal distribution), among others, often using scatterplots. Before this entry discusses the types of individual residual plots in greater detail, it reviews the concept of residuals in regression analysis, including different types of residuals, emphasizing the most important standard regression assumptions.

Concept

Defining a linear regression model as

$$Y = \beta_0 + \beta_1 X_1 + \dots + \beta_p X_p + \varepsilon, \quad (1)$$

the i th fitted value, the value lying on the hyperplane, can be calculated as

$$\hat{y}_i = \hat{\beta}_0 + \hat{\beta}_1 x_{i1} + \dots + \hat{\beta}_p x_{ip} = 1, 2, \dots, n, \quad (2)$$

where p refers to the number of explanatory variables and n the number of observations. For $p = 1$, the regression model represents a line; for $p = 2$, a plane; and for $p = 3$ or more, a hyperplane. From here on, the term *hyperplane* is used, but the same concepts apply for a line, that is, for the simple regression model, or a plane.

The i th residual (e_i), is then defined as

$$e_i = y_i - \hat{y}_i, \quad (3)$$

and it represents the vertical distance between the observed value (y_i) and the corresponding fitted values ($\hat{y}_i$) for the i th observation. In this sense, the i th residual (e_i) is an estimate for the unobservable error term (ε) and, thus, represents the part of the dependent variable (Y) that is not linearly related to the explanatory variables ($X_1, X_2, \dots, X_p$). One can also say that the i th residual (e_i) is the part of Y that cannot be explained by the estimated regression model.

In regression analysis, the error terms incorporate a set of important and far-reaching assumptions. These are that the error terms are independently and identically distributed normal random variables, each with a mean of zero and a common variance. This assumption can be expressed as

$$\varepsilon \sim NID(0, \sigma^2 I_n). \quad (4)$$

The residuals, however, do not necessarily exhibit these error term assumptions. By definition, for instance, the sum of all residuals must be equal to zero, or

$$\sum e_i = 0 \quad (5)$$

The direct implication from this residual property is that although the error terms are independent, the residuals are not. In addition, residuals resemble only estimates of the true and unobservable error terms and as such do not have the same variance σ^2 , as implied in Equation 4. The variance of the i th residual is defined as

$$Var(e_i) = \sigma^2 (1 - p_{ii}), \quad (6)$$

where p_{ii} is the i th leverage value, that is, the i th diagonal element in the projection matrix, also known as the hat matrix. This unequal variance property can be coped with by means of standardization of the residuals.

Standardization of the residuals is achieved by dividing the i th residual by its standard deviation,

$$z_i = \frac{e_i}{\sigma \sqrt{1 - p_{ii}}}, \quad (7)$$

where z_i denotes the i th standardized residual, which now by definition has a mean of 0 and a standard deviation of 1. For practical purposes, however, σ is not known and must therefore be replaced by the unbiased standard error of the estimate ($\hat{\sigma}$), where $\hat{\sigma}$ is defined as

$$\hat{\sigma} = \sqrt{\frac{\sum e_i^2}{n\sqrt{1 - p - 1}}}. \quad (8)$$

Using the standard error of the estimate ($\hat{\sigma}$) for the standardization of the i th residual then gives us the i th internally studentized residual r_i :

$$r_i = \frac{e_i}{\hat{\sigma} \sqrt{1 - p_{ii}}}, \quad (9)$$

Internally studentized residuals have a standard deviation of 1, that is, they all have the same variance, but they no longer result in a sum of zero. It should be further noted that when one refers to standardized residuals, one is often referring to internally studentized residuals. Given the fact that the true standard deviation (σ) is not known, and is usually replaced with an unbiased estimate, that is, the standard error of the estimate ($\hat{\sigma}$), the remainder of this discussion on residual plots also refers to internally studentized residuals.

Residual plots can be very powerful explanatory diagnostic tools when the task is to check the standard regression assumptions. The standard regression assumptions include the following:

1. the linearity assumption that the regression model is linear in its parameters $\beta_0; \beta_1; \dots; \beta_p$;
2. error term (ε) assumptions, which state that the error terms are independently and identically distributed (iid) normal random variables, each with a mean of zero and a common variance:

$$\varepsilon \sim NID(0, \sigma^2 I_n). \quad (\text{see Equation 4})$$

3. explanatory variable (X) assumptions, which indicate that the X s are supposed to be nonrandom variables, that they are measured without error, and that they are to be linearly independent of each other.

Residual plots provide valuable diagnostic insights when one is evaluating these standard regression assumptions, particularly the assumption about the error terms. Residual plots are done after a model has been fitted to available data, often in conjunction with formal statistical tests. To do so, the internally studentized residuals need to be saved first, a standard option usually available in statistical software packages. In a second step, using the saved studentized residuals allows derivation of different residual plots in order to visually explore whether violations of the standard regression assumptions may be present.

Commonly Used Residual Plots in Regression Analysis

For the following discussion of the various types of residual plots, internally studentized residuals (r_i)\$ are meant unless otherwise stated.

Normal Probability Plot of Standardized Residuals

To check the normality assumption, one plots the ordered residuals against the ordered normal scores. The normal scores are what one would get when taking a random sample of size n from a standard normal distribution with mean 0 and standard deviation of 1. Under the normality assumption, a plot of the ordered

Figure 1 Normal probability plot

residuals against the ordered normal scores should resemble a straight line with a slope of 1 that passes through the origin (see Figure 1).

The more the graph deviates from a straight line, the more the normality assumption is violated and the less likely it is that the residuals are normally distributed.

Scatterplots of Studentized Residuals Versus the Explanatory Variables

A very common practice in regression analysis is plotting the residuals against each of the explanatory variables ($X_1, X_2; \dots; X_p$), meaning that for p explanatory variables, there will be p individual scatterplots. In regression analysis, changes in the dependent variable (Y) are explained through a set of explanatory variables. More specifically, it is the part in $X_1, X_2; \dots; X_p$ captured by the residuals. In other words, the scatterplot of the residuals versus one of the explanatory variables exhibits a random pattern if the linearity assumption holds and there indeed exists a linear relationship between Y and X_j , as shown in Figure 2. For those explanatory variables (X_j) for which there is no significant linear relationship with the dependent variable (Y), the scatterplot will not exhibit a random pattern. Obviously, the nonlinear relationship outweighs the linear component of the relationship of Y and X_j , which shows in the form of a distinct nonlinear pattern, as indicated in Figure 3.

One uses the same scatterplots of the residuals (r_i) versus the explanatory variables (X_j) when checking for the homogeneity of the residual variances, that is, the common variance assumptions, also referred to as *homoscedasticity*. Contrarily, *heteroscedasticity* refers to unequal error variance, that is, error variance that is not constant across all observations. The idea is that standard deviations of the error terms are

Figure 2 Scatterplot of residuals versus X showing random pattern

Figure 3 Scatterplot of residuals versus X indicating nonlinear relationship

constant and independent of the values of X . If heteroscedasticity is present, the estimated regression coefficients remain still unbiased, but their standard errors are likely to be underestimated. As a consequence, the corresponding t -statistics are inflated, and regression parameters can turn out to be statistically significant, even though they are not. If the scatterplots of the residuals versus the explanatory variables show random scatters of points, no sign of heteroscedasticity is present (again, see Figure 2). When the scatterplots show that the band within which the residuals lie either increases or decreases with increasing X values, heteroscedasticity might be present. Figure 4 is an example of increasing residual variance.

Scatterplot of Studentized Residuals Versus Fitted Values

Fitting the regression hyperplane to observed data establishes a linear relationship between the explanatory variables and the fitted values ($\hat{y}_i$), as indicated in Equation 2. Analogously, the standard regression assumptions can also be checked by plotting the standardized residuals against the fitted values ($\hat{y}_i$), rather than using the individual scatterplots of the standardized residuals versus the explanatory variables ($X_1, X_2; \dots; X_p$) as described above. However, the outcome of an analysis of the residual plots has to be the same by use of either the explanatory variables (X_{ij}) or the fitted values ($\hat{y}_i$). As a matter of fact, in the case of the simple regression analysis (i.e., only one explanatory variable X), the plots of the residuals versus X and versus $\hat{y}_i$ would be identical. Analogously, a pattern indicating heterogeneity would resemble a scatterplot as shown in Figure 4.

Figure 4 Scatterplot of residuals versus X exhibiting heteroscedasticity

Scatterplot of Standardized Residuals Versus Index Numbers (Index Plot)

Residuals in regression analysis are supposed to be independent of one another. Especially in time series or spatial regression analysis, this assumption does not necessarily hold. Plotting the studentized residual against the index numbers, that is, plotting the residual in serial order, might be a first indication of whether the assumption of the independence of residuals holds. Again, a random pattern of the residuals indicates no violation of the regression assumptions, whereas a distinct pattern points toward the presence of auto- or spatial correlation. A case of severe autocorrelation is shown in Figure 5, where one clearly can identify a distinct pattern in the ordered residuals.

A second important application of the index plot of residuals is as a check for outliers. When using studentized residuals to identify outliers, reference is made to the outlyingness in Y -space, as residuals measure the vertical distances between the observations and the regression hyperplane. These outliers are not to be confused with outliers in X -space, which are usually identified using leverage values, that is, the entries on the main diagonal of the hat (projection) matrix. Though there is no standard rule on when one may call an observation an outlier, it is common practice to consider observations with studentized residuals that lie more than 2 to 3 standard deviations away from the mean of 0 as outliers. For instance, Figure 6 shows two observations that can be considered outliers.

Potential Residual Plot

The potential residual plot is a quick and convenient way of checking observations for their outlyingness in X -space (i.e., high-leverage points) and in Y -space

Figure 5 Index plot exhibiting correlated residuals

(i.e., outliers) together in one scatterplot. The *potential* function defines an observation's outlyingness in X -space, and the *residual* function analogously does the same for the Y -space. The potential and the residual functions are, respectively, defined as

$$\frac{p_{ii}}{1 - p_{ii}} \text{ and } \frac{p+1}{1 - p_{ii}} \cdot \frac{d_i^2}{1 - d_i^2}.$$

An example of a potential residual function with one high-leverage point and two outliers is shown in Figure 7. For either form of outlyingness, further investigation of the corresponding observations is recommended to determine whether the observation is influential and whether further action is required. Influential observations are data points that uniquely influence the outcome of the estimated regression coefficients.

Partial Residual Plot

The partial residual plot is well suited to situations in which the task is to graphically present the slope coefficient of X_p , namely $\hat{\beta}_j$. As shown in Figure 8, the slope of $\hat{\beta}_j$ is presented by plotting the residual + component against X_p or

$$(e + \hat{\beta}_j X_j) \text{ versus } X_j.$$

The slope presented in the partial residual plot by all the individual points reflects the contribution of the explanatory variable X_j on the fitted values $\hat{y}$. Note that each observation can be judged individually with respect to its own contribution toward the estimated regression coefficient $\hat{\beta}_j$. The straight line in Figure 8 is the equivalent to a fit of a simple regression model to the points in the partial residual plot.

Figure 6 Index plot exhibiting two potential outliers

Figure 7 Potential residual plot with one high-leverage point and two outliers

Figure 8 Partial residual plot (residual plus component plot)

The partial residual plot, or residual plus component plot, is useful in helping one visualize the marginal effect added variables have on the fitted values. Usually, the t -statistics in regression analysis are standard for deciding whether an explanatory variable should be retained or omitted from the model. In addition, the partial residual plot is useful in identification of whether the relationship between Y and X_i is linear. It is therefore suggested that the partial residual plot be used in conjunction with the t test.

Partial Regression Plot

Also useful in determining the marginal effect on the regression model of adding an explanatory variable is the partial regression plot, or *added variable plot*, a scatterplot of

Y -residuals versus X_i residuals

where the Y -residuals are obtained from regressing Y on all explanatory variables except X_i , and the X_i residuals are obtained by regressing X_i on all other explanatory variables. The interpretation of the slope represented by the points is similar to that for the partial residual plot. In addition, partial regression plots are very useful in identifying high-leverage points and influential observations.

RESIDUALS

In statistics in general, the concept of residuals (e) is used when referring to the observable deviation of an individual observation in a sample to its

corresponding sample mean. Not to be confused with the statistical error (ε) which refers to the often unobservable deviation of an individual observation from its often unknown population mean. The residual serves as an estimate for the unobservable statistical error when a sample is drawn from the population of interest, but the population mean cannot be computed because the researcher simply does not have all individual observations belonging to the target population.

In this entry, the concept of residuals in regression analysis is defined, the use of residuals for checking the standard regression assumptions is discussed, and the role of the residuals in assessing the quality of the regression model and in hypothesis testing of the estimated regression coefficients is explained. In addition, the need for different types of residuals is described.

Regression Analysis

The concept of residual in regression analysis is of utmost importance, particularly when one is applying the regression method of ordinary least squares. In ordinary least squares regression analysis, the goal of which is to fit a line or (hyper)plane to observed data when one is using more than one explanatory variable, residuals depict the vertical distances between observed values and the corresponding fitted values. Conceptually, the residual is the part of the dependent variable (Y) that is not linearly related to the explanatory variables ($X_1, X_2, \dots, X_p$). In other words, it is the part of Y that cannot be explained by the estimated regression model. In a regression model defined as

$$Y = X\beta + \varepsilon, \quad (1)$$

the i th fitted value, the value lying on the hyperplane, can be calculated as

$$\hat{y}_i = \hat{\beta}_0 + \hat{\beta}_1 x_{i1} + \dots + \hat{\beta}_p x_{ip}; \quad (2)$$

$$i = 1, 2, \dots, n,$$

where p refers to the number of explanatory variables and n , the number of observations.

Analogously, the vertical distance between observed and fitted values for the i th observation, the i th residual (e_i), is defined as

$$e_i = y_i - \hat{y}_i, \quad (3)$$

which is graphically shown for the simple regression model in Figure 1.

Figure 1 Residual (e_i) in ordinary least square regression analysis.

Standard Regression Assumptions

The assumptions about the error terms for the ordinary least square estimation are that the error terms are independently and identically distributed normal random variables, each with a mean of zero and a common variance, often expressed as

$$\varepsilon \sim NID(0, \sigma^2 I_n) \quad (4)$$

where $\sigma^2 I_n$ denotes a (n, n) matrix with the individual error variances on the main diagonal being equal to σ^2 and all the covariances on the off-diagonal being zero. For instance, for $n = 6$, the matrix $\sigma^2 I_n$ is

$$\begin{pmatrix} \sigma^2 & 0 & 0 & 0 & 0 & 0 \\ 0 & \sigma^2 & 0 & 0 & 0 & 0 \\ 0 & 0 & \sigma^2 & 0 & 0 & 0 \\ 0 & 0 & 0 & \sigma^2 & 0 & 0 \\ 0 & 0 & 0 & 0 & \sigma^2 & 0 \\ 0 & 0 & 0 & 0 & 0 & \sigma^2 \end{pmatrix}.$$

Because of these error term assumptions, a standard practice in applied regression analysis is to include a series of tests and/or residual plots to check whether the residuals violate some of these assumptions. The literature is rich on statistical tests based on the calculated residuals, which include the Durbin–Watson test for autocorrelation (i.e., the errors are independent of each other) and the Breusch–Pagan test for heteroscedasticity (i.e., constant variance of the errors).

In addition to all these statistical tests, residual plots are an excellent and necessary tool to check for potential violations of the standard regression assumptions.

As explained below, however, for better interpretation, most residual plots do not use the original estimated residuals but rather use transformed residuals, such as standardized or studentized residuals. For instance, the normal probability plot of studentized residuals is suitable to check for the normality assumption, while the scatterplot of studentized residuals versus the explanatory variables is usable to check for the linearity and the constant variance assumptions. Further, the index plot of studentized residuals will point toward violations of the independence of errors, such as autocorrelation or spatial dependence of the error terms.

Regression Model Quality and Hypothesis Testing

The importance of checking the assumptions about the error terms becomes more obvious when one considers that the residuals are not simply distance measures of how far individual data points are away from the regression line or in multiple regression analysis from the (hyper)plane but that they play an important role in assessing the quality of the estimated regression model as well as in hypothesis testing of the estimated regression coefficients. In either case, the standard error of the estimate $\hat{\sigma}_2$ needs to be calculated:

$$\hat{\sigma} = \sqrt{\frac{\sum e_i^2}{n\sqrt{1-p-1}}}, \quad (5)$$

which in return is used in the calculation of the variances of the estimated regression coefficients:

$$\text{Var}(\hat{\beta}) = \hat{\sigma}^2 (X'X)^{-1}. \quad (6)$$

Taking the square roots of the variances of the estimated regression coefficients in Equation 6 in return gives us the corresponding standard errors of regression parameters:

$$se(\hat{\beta}_j) = \sqrt{\text{Var}(\hat{\beta}_j)} = \hat{\sigma} \sqrt{c_{jj}}, \quad (7a)$$

where $C=(X'X)^{-1}$. The standard errors can also be expressed as

$$se(\hat{\beta}_j) = \frac{\hat{\sigma}}{\sqrt{\sum (x_{ij} - \bar{x})^2}}; \quad (7b)$$

$i = 1, 2, \dots, n; j = 1, 2, \dots, p.$

In regression analysis, the standard error is a common measure of the precision of the estimated

parameters. Thus, the smaller the sum of squared residuals, the more precise are the estimated parameters.

In regression analysis, the most commonly used measure for the goodness of fit of the regression model is R^2 , also referred to as the *coefficient of determination*. R^2 is defined as

$$R^2 = \frac{SSR}{SST} = 1 - \frac{SSE}{SST} = 1 - \frac{\sum e_i^2}{(y_i - \bar{y}_i)^2}. \quad (8)$$

where SST is the total sum of squared deviations in Y , SSR is the sum of squares explained by the regression model, and SSE is the sum of squared residuals. Although SSR is an indicator for the quality of chosen $(X_1, X_2, \dots, X_p)$ as predictor variables, SSE is a measurement for the error in the prediction. This decomposition of the total sum of squared deviations in Y (SST) is part of the analysis of variance.

A second important statistic in regression analysis that relies on the sum of squared residuals (SSE) is the F -statistic:

$$F = \frac{SSR/p}{(SSE)/(n-p-1)} = \frac{\sum (\hat{y}_i - \bar{y}_i)^2 / p}{\sum e_i^2 / (n-p-1)}. \quad (9)$$

Rather than examining the hypotheses of the individual regression coefficients, the β s, the F -statistic tests whether all the regression coefficients are simultaneously zero. An important feature of the F -statistic is its versatility when one is testing different scenarios. Assuming, for instance, that adding explanatory variables to the regression model will improve its overall predictive power, a significant decrease in the SSE would imply that the addition of explanatory variables improved the fit of the regression model. For this scenario, the F -statistic is calculated as

$$F = \frac{[SSR(RM) - SSE(FM)] / (p+1-k)}{SSE(FM) / (n-p-1)} \quad (10)$$

where $SSE(FM) = SSE$ of the full model, $SSE(RM) = SSE$ of the reduced model, p = number of explanatory variables in the full model, and k = the number of explanatory variables in the reduced model.

As this example indicates, differences in the sums of squared residuals of the reduced versus the full model lead to various hypothesis tests. Besides the already described standard hypothesis test—whether all estimated coefficients are simultaneously zero—other commonly used F -tests check whether (a) a subset of the estimated parameters is zero, (b) some of the β s are equal to each other,

and (c) some imposed constraints on regression coefficients are being satisfied (e.g., $\beta_1 + \beta_2 = 1$).

Types of Residuals

One *important* property of residuals in ordinary least square regression analysis is that they always sum to zero:

$$\sum e_i = 0. \quad (11)$$

In other words, the sum of the vertical distances above the fitted regression line, or the sum of all positive residuals, is equal to the sum of the vertical distances below the fitted regression line, or the sum of all negative residuals. The direct implication is that although the error terms *are* independent, the residuals are not. A second important property of the residuals is that they resemble only estimates of the true and unobservable error terms and as such do not have the same variance σ^2 . For a direct comparison of residuals, such as for the detection of outliers, the residuals need to be standardized first. The variance of the i th residual is

$$\text{Var}(e_i) = \sigma^2(1 - p_{ii}), \quad (12)$$

where p_{ii} is the i th leverage value. In multiple regression analysis, the i th leverage value is the i th diagonal element in the projection matrix, also known as *hat matrix*. The projection matrix is defined as

$$P = X(X'X)^{-1}X', \quad (13)$$

and its importance in regression analysis becomes more apparent when rewriting the vector of residuals as

$$e = Y - \hat{Y} = Y - PY = (I_n - P)Y. \quad (14)$$

Dividing the i th residual by its standard deviation then defines the standardized residual z_i :

$$z_i = \frac{e_i}{\sigma\sqrt{1 - p_{ii}}}, \quad (15)$$

which by definition has a mean of zero and a standard deviation of 1. The problem is that the standardized residual depends on the unknown standard deviation of the error terms σ . Using the unbiased standard error of the estimate, the i th internally studentized residual r_i is defined as

$$r_i = \frac{e_i}{\hat{\sigma}\sqrt{1 - p_{ii}}}. \quad (16)$$

While the internally studentized residuals all have a standard deviation of 1, or they have the same variance, they no longer result in a sum of zero. Further, it should be noted that when one is usually referring to standardized residuals, the reference is often being made to internally studentized residuals.

Externally studentized residuals, on the other hand, use a slightly different unbiased estimate of the error term variance σ^2 :

$$F = \frac{\sum e_{(i)}^2}{n - p - 2} = \frac{SSE_{(i)}}{(n - p - 2)}. \quad (17)$$

The difference between this and the commonly used estimate for σ^2 is that in this alternative estimate, the i th observation is excluded from the regression analysis when one is obtaining the $SSE_{(i)}$, as indicated by the subscript (i). A second adjustment in the degrees of freedom in the denominator states that only $(n - 1)$ observations are used in the regression analysis. Externally studentized residuals are then defined as

$$r_i^* = \frac{e_i}{\hat{\sigma}(i)\sqrt{1 - p_{ii}}}. \quad (18)$$

The advantage of the externally studentized over the internally studentized residuals is that they follow a t -distribution with $n - p - 2$ degrees of freedom. However, for larger sample sizes, internally studentized residuals also approximate a standard normal distribution.

When the goal is to check the regression assumptions using residual plots, usually either version of residual is sufficient because one would use the residual plots only to identify a distinct pattern, which points toward one or the other model violation. In cases, however, in which a direct comparison between residuals is necessary, as for instance for the detection of outliers in Y -space, studentization of the residuals is necessary. It is a standard convention among researchers to consider observations with studentized residuals larger than 2 to 3 standard deviations away from the mean as potential outliers in the dependent variable. To complete this discussion, outliers in the explanatory variables can be detected with leverage values, and observations with large leverage values are potential outliers in the explanatory variables. Note that leverage values by definition fall between 0 and 1, and observations with leverage values, that is, leverage values that are larger than twice the mean of all leverage values, should be marked for further investigation.

Once outliers in either the dependent or explanatory variables are identified, one can determine, using both the studentized residual, r_i , and the leverage value, p_{ii} , whether the i th observation is influential or not. In other words, would deleting the i th observation from the data set change significantly the estimated regression coefficients? The *Cook's distance measure*, one of the many influence measures available to check whether an outlier is influential, is defined as

$$C_i = \frac{r_i^2}{p+1} \cdot \frac{p_{ii}}{1-p_{ii}}; i=1, 2, \dots, n, \quad (19)$$

where the first term of the product defines the outlyingness of the i th observation in Y -space based on its internally studentized residual, and the second term, also referred to as the *potential function*, defines the outlyingness of the i th observation in X -space based on the corresponding leverage value. An index plot of Cook's distance measures is a first step in identifying large C_i values that stand visually apart from the other distance measures and that indicate that deleting the i th observation from the data set will significantly change the outcomes of the regression results.

Final Thoughts

Although regression analysis focuses on obtaining robust, unbiased, and meaningful regression coefficients that show the functional linear relationship between the response variable and a set of explanatory variables, an equal amount of attention should be paid to the residuals. In fact, residuals are the main source of information when one is checking the regression assumptions, conducting hypothesis tests, or assessing the quality of the estimated regression model.

RESPECT FOR PERSONS

Respect for persons is an ethical principle in research that requires researchers to treat individuals as autonomous agents and to provide additional protection to individuals with diminished autonomy (e.g., comatose patients, persons with intellectual disabilities, children). The ethical principle is outlined in the Belmont Report (1979), a foundational set of national guidelines by the National Commission for the Protection of Human Subjects of Biomedical and Behavioral Research. This entry addresses the philosophical foundation of respect for persons, how the concept is explained in the Belmont Report, and its application in other statements of human research protection.

Philosophical Foundation

Among the philosophers whose work is important in setting the basis for the notion of respect for persons is Immanuel Kant (1724–1804). Kant built his ethical standard of respect for persons on the idea that all persons are to be treated with respect because we are free, rational beings with inherent dignity. Kant believed that it is our rationality that distinguishes humans from things and endows us with autonomy and dignity. As free, rational beings, humans are capable of setting goals, making decisions, and behaving based on reasons they consider right.

To treat persons with respect requires not treating others as a means to an end but as ends in themselves. We must also avoid harming others or manipulating or using others without their consent to achieve our own purposes. We must not thwart but rather should promote others' rationality, autonomy, rights, and choices by allowing them to make their own free and consensual choices. When others' decision-making process is denied or overturned, their autonomy is violated. Even if a person would have acted in the same way had they been given the chance to decide, manipulation or coercion in the decision-making process violates that person's autonomy and denies their status as a moral agent.

Respect for Persons in the Belmont Report

The Tuskegee syphilis experiments by the U.S. Public Health Service (1921–1971) egregiously abused human subjects and caused large-scale criticism of ethical violations and discrimination. As a result, the National Research Act was signed into law in 1974, establishing the National Commission for the Protection of Human

Subjects of Biomedical and Behavioral Research to (1) identify the basic ethical principles to be followed when conducting biomedical and behavioral research involving human subjects and (2) to develop guidelines to be followed to guarantee the application of those principles. In the Belmont Report, the commission included the three comprehensive ethical principles of beneficence, justice, and respect for persons.

According to the Belmont Report, respect for persons requires that (1) individuals be treated as autonomous agents and (2) individuals with limited autonomy be protected. Autonomy is to be respected when persons' deliberated goals, opinions, and choices assuming their personal beliefs and values do not harm others. Lack of respect is shown when individuals' deliberated judgments are rejected, their freedom and capacity to behave according to their judgments are denied, or information necessary to make a deliberated judgment is withheld without a compelling reason. Respect for persons is mainly operationalized in research as acquiring informed consent. Without outlining the risks and benefits of research and without the participant or their representative granting consent to participate, there should not be any examination of human subjects or interference in their lives from researchers.

To respect potential participants' self-determination, researchers must disclose information to the extent that potential participants understand that (1) there are possible benefits and risks pertinent to participation, (2) they have the right to voluntarily participate or refuse to participate in the studies, (3) declining to participate will not affect their access to current or subsequent care in any way, and (4) they have the right to withdraw from the study at any time for any possible reason without fear of penalty. The presentation of the information must be adapted to comply with individuals' capacity in terms of intelligence, rationality, maturity, and language to make sure they have completely and adequately comprehended the information to make knowledgeable decisions. For persons with diminished autonomy due to but not limited to immaturity (e.g., children who may assent), severe or terminal illness, disability, or circumstances that severely restrict liberty (e.g., prisoner), respect for persons requires additional protections to be provided beyond acknowledging their own wishes during the period when they are incapable of behaving autonomously. This may cause prudent exclusion from the potentially detrimental studies or seeking the permission of the third parties to keep them from harm. Respect for persons also requires that researchers not obtain consent through coercion or undue influence (e.g., extreme rewards).

A special problem of acquiring consent is that respect for persons demonstrated by fully disclosing information about the study might invalidate the research when deception or incomplete disclosure is a part of the study design (e.g., pharmaceutical trials with placebos). According to the Belmont Report, such studies can be justified only if they meet the criteria that (1) the goal of the research cannot be achieved without deception or incomplete disclosure, (2) there are no more than minimal risks concealed from the potential participants, and (3) a sufficient plan of debriefing and sharing research results to potential participants is made.

Respect for Persons in Other Statements of Human Research Protection

The concept of respect for persons is not exclusive to the Belmont Report. The Nuremberg trials at the end of the World War II resulted in creating the Nuremberg Code in 1947 as the first international code of ethics for human research protections. Among the 10 basic principles set forth in the Nuremberg Code, the concept of respect for persons is incorporated by requiring voluntary consent and potential participants' free right of withdrawal.

Under the influence of the Nuremberg Code and the 1948 World Medical Association (WMA) Declaration of Geneva, the World Medical Association published the Declaration of Helsinki in 1964. In the revision in 2013, the concept of respect for persons is incorporated mostly in the general principles (Articles 7–10) in terms of respecting, prioritizing, and protecting the rights and interests of participants, principles regarding vulnerable groups, and individuals in terms of providing specific and considered protection (Article 19), and the principles about informed consent (Articles 25–32).

RESPONSE BIAS

The response to a survey question is said to be biased if it does not reveal, on average, the true value of the target variable. This definition is closely related to the definition of a bias in statistics: The bias of an estimator is the difference between its expected value (when computed for a given sample) and the true value of the corresponding parameter (in the population). Biased responses may arise for many types of target variables: attitudes, behaviors, preferences, and expectations; sociodemographic characteristics such as age, level of education, or labor-market status; frequencies such as the number of purchases of a good or the number of doctor visits in a specified period; and monetary quantities such as income, financial assets, or consumption expenditure. This entry examines sources and implications of response bias and presents strategies for dealing with biased responses.

Sources of Response Bias

For several decades, psychologists, sociologists, and survey researchers have worked to understand the cognitive and communicative processes that generate survey responses. A central insight is that answering a survey question is a complicated process consisting of several distinct tasks (even though these tasks are not completely sequential or independent processes). Biased responses may arise at any of these stages. It is important to note that there is no single process that would be responsible for response bias. Potential sources of biased responses can be illustrated with a conceptual model of the survey response process that distinguishes four stages.

- First, the respondent needs to comprehend the question: He or she needs to understand what information is sought. Poor wording may easily lead to systematic misunderstanding of the question and thus to biased responses.
- Second, the respondent must retrieve the relevant information from his or her memory. This stage activates retrieval strategies that often require filling in missing details. The success of these retrieval strategies depends on many variables, such as the respondent's cognitive ability and memory capacity.
- The third stage involves making a judgment: Is the information just retrieved from memory complete? If not, the respondent uses estimation strategies that integrate the retrieved information with other salient information that is contained in the survey

questionnaire, provided by the interviewer, and so on. These estimation strategies often involve a notion of *satisficing*, that is, the respondent uses just as much time and effort as is needed to construct a response that is "good enough." Estimation strategies and the corresponding heuristics typically result in biased responses rather than random errors.

- The final stage is to report the response that has been constructed in the first three stages. The respondent may alter his or her response because he or she does not want to reveal the constructed response for reasons of confidentiality or social desirability.

Examples

Measurement of Attitudes and Behaviors

Many survey measurements refer to attitudes or behaviors that may or may not be socially desirable. For instance, in a country in which the death penalty is considered immoral, respondents who are in favor of it may nevertheless report that they oppose it. Other examples are questions on substance use or on donations to charities. Depending on the circumstances, social desirability will result, on average, in under- or overreporting of attitudes or behaviors. Such effects are likely to be stronger in personal interviews than in self-administered mail or Internet surveys.

Frequency Reporting

When respondents are asked to report the frequency of events, they use a variety of estimation strategies: They count salient episodes; they base their estimate on an interval-specific rate; or they rely on cues about typical frequencies that are provided by the response categories. Depending on the context (e.g., the length of the period for which a frequency is to be reported), these strategies may result in systematic over- or underreporting.

Expenditure Measurement

Household surveys often ask respondents to report the amount spent on a certain class of consumption goods in a previous period. Since such quantities are not directly represented in a respondent's memory, the respondent must use an estimation strategy whose accuracy depends on many variables: how well the target quantity is described in the question, how easily typical purchases can be retrieved from memory, and so on. Respondents may integrate salient features of the questionnaire, such

as numerical clues provided by the response categories. The errors introduced by such estimation strategies are nonrandom and lead to biased responses.

Statistical Implications of Response Bias

When responses to a survey question are biased, the measured variable is subject to measurement error (this is only one of several forms of survey error, the others being coverage error, sampling error, and nonresponse error). Crucially, measurement error that stems from biased responses does not conform to the paradigm of classical measurement error, which assumes that errors are random, that is, statistically independent of the true value of the measured variable (and of other variables in a statistical model). In fact, it is hard to imagine a realistic response process that would generate a survey response that meets the classical measurement error assumptions.

The statistical analysis of data that are subject to response bias requires the specification of an explicit, nonclassical error model that, in turn, requires making assumptions about the process that generates the bias. Typically, such assumptions are untestable with the available data.

Strategies for Dealing With Biased Responses

The best strategy to deal with biased responses is to avoid them in the first place. Consulting the established literature on survey response behavior helps one avoid well-known potential pitfalls. Often, the existing literature will suggest that a specific question or other survey design feature may introduce response bias, but it may be difficult to judge *ex ante* whether in a specific situation a potential bias will in fact be large enough to affect the subsequent analysis of the data and the substantive conclusions one may draw. In these situations, a researcher may vary the wording, framing, or other design features experimentally—either in a pretest or in the main study. Such survey experiments allow the researcher to test whether a bias actually exists, that is, whether response distributions differ between treatments. If a significant bias exists, the researcher can either adjust the design to avoid the bias or, in case this is not possible, deal with the bias at the analysis stage, using advanced statistical methods and explicit error models.

RESPONSE SURFACE DESIGN

A response curve is a mathematical function representing the relationship between the mean of a response variable and the level of an explanatory variable. The curve might be linear, a higher degree polynomial, or some nonlinear function. A response surface is a mathematical function representing the relationship between the mean of a response variable and the levels of several explanatory variables. The surface might be linear, a higher order polynomial, or a nonlinear function. In an experiment, the explanatory variables, or treatment factors, are under the control of the experimenter, and the level of each must be chosen for each experimental run. A response surface design is the set of combinations of the levels of the explanatory variables used in a particular experiment.

There are many reasons experimenters might want to fit response surface models, such as (a) to gain a simple mathematical and graphical description of the effects of the treatment factors on the response, (b) to identify the factors that have important effects on the response, (c) to estimate the effects of changing the levels of the factors from standard operating conditions, or (d) to enable estimation of the levels of the factors that optimize (maximize, minimize, or achieve a target level of) the response. The use of economical response surface designs can help researchers answer research questions precisely with considerably less time and cost than more ad hoc methods of experimentation. Response surface designs are particularly useful when combined with the experimenters' expert knowledge and previous results.

In many areas of research, especially applied research, questions arise that can be answered by experimenting to determine the effects of several factors on one or more responses of interest. In such cases, the use of factorial-type experiments, in which all factors are studied in the same experiment, have long been known to be the most economical way of experimenting. In standard factorial designs, it is usually assumed that the factors are qualitative, or at least that their effects will be modeled in terms of main effects and interactions, ignoring the quantitative nature of the levels.

In contrast, if the factors represent continuous variables, it is natural to fit a response surface model. Occasionally, mechanistic information will be available to determine the specific response surface function that should be used, but more often a purely empirical polynomial response surface model will be used to approximate the unknown function. Statistical methods for empirical modeling, collectively known as *response surface methodology*, were developed by George Box and his colleagues at Imperial Chemical Industries, in England, in the 1950s and have been further refined since then. This entry describes useful designs for fitting and checking first-order and second-order models and then considers complications that can arise.

First-Order Designs

Factorial Designs

Although there are several other designs for fitting first-order, that is, multiple linear regression, models, the only ones used in practice are two-level factorial designs, or *fractional factorial designs*. The two levels of a factor, usually coded -1 and $+1$, represent low and high levels of that factor. For example, with three factors, the following design, presented in a standard order, might be used.

X_1	X_2	X_3
-1	-1	-1
-1	-1	$+1$
-1	$+1$	-1
-1	$+1$	$+1$
$+1$	-1	-1
$+1$	-1	$+1$
$+1$	$+1$	-1
$+1$	$+1$	$+1$

The usual advice is to use levels that are far enough apart that experimenters can be confident of identifying any practically meaningful effects, but close enough that a low-order polynomial model can be expected to give a reasonable approximation to the response surface. The order of the runs should be randomized before the experiment is run, and the levels of each factor reset for each run. The model can be written as

$$Y = \beta_0 + \beta_1 x_1 + \cdots + \beta_q x_q + \varepsilon,$$

where Y represents the response, $x_1, \dots, x_q$ represent the coded levels of the factors, and ε is a random error term with mean zero, representing deviations of individual observations from the mean. The error terms are usually assumed to have constant variance and to be independent and are often assumed to have normal distributions. Data analysis proceeds exactly as for any multiple regression model except that the coded levels of variables are usually used.

Factorial designs are particularly useful for identifying a small number of important factors out of many potentially important ones and for identifying new levels of the factors that should be explored in future experiments. For example, if the high level of one factor gives a much better response than the low level, it might be fruitful to explore some even higher levels.

Pure Error and Lack of Fit

Although two-level factorial designs allow the first-order model to be fitted efficiently, they do not allow the appropriateness of this model to be assessed. A simple modification, which allows this, is to include a few center points (i.e., runs in which each factor is set at a level halfway between the low and high levels). Often, only 3 to 5 center points are run. The design, again in a standard order, then becomes the following:

X_1	X_2	X_3
-1	-1	-1
-1	-1	$+1$
-1	$+1$	-1
-1	$+1$	$+1$
$+1$	-1	-1
$+1$	-1	$+1$
$+1$	$+1$	-1
$+1$	$+1$	$+1$

0	0	0
0	0	0
0	0	0
0	0	0

The run order should again be randomized, and the levels of each factor reset for each run. In particular, the center points must be genuine replicates, fully reset for each run, and not just repeated measurements from the same run. The variance of the responses from the center points then measures the run-to-run variance in the absence of treatment differences, often called *pure error*. This design allows more reliable hypothesis tests of the terms in the response surface model. It also allows the difference in response between the factorial points and the center points, which measure curvature in the response surface, to be used to assess the lack of fit of the first-order model. A hypothesis test that shows lack of fit indicates that the first-order model is inadequate and that one should consider doing more experimentation to fit a model of second order.

Second-Order Designs

Three-Level Designs

In order to fit the second-order polynomial model,

$$Y = \beta_0 + \beta_1 x_1 + \cdots + \beta_q x_q + \beta_{11} x_1^2 + \cdots +$$

$$\beta_{qq} x_q^2 + \beta_{12} x_1 x_2 + \cdots + \beta_{(q-1)q} x_{q-1} x_q + \varepsilon,$$

at least three levels of each factor are used, and it is most efficient to use equally spaced levels. The most commonly used second-order response surface design is the central composite design, which includes factorial points and center points, as above, and other so-called axial points, in which one factor is at its high or low level and all other factors are at their middle levels. For three factors, the central composite design is as follows:

X_1	X_2	X_3
-1	-1	-1
-1	-1	+1
-1	+1	-1
-1	+1	+1

+1	-1	-1
+1	-1	+1
+1	+1	-1
+1	+1	+1
-1	0	0
+1	0	0
0	-1	0
0	+1	0
0	0	-1
0	0	+1
0	0	0
0	0	0
0	0	0
0	0	0
0	0	0
0	0	0

The model is easily fitted by least squares by a standard multiple regression program. The central composite design is very popular because it uses relatively few runs and is reasonably efficient and because it allows sequential experimentation since it can be obtained by the addition of the axial points, and usually some additional center points, to the two-level factorial design.

A useful class of three-level designs when experimentation is very expensive or time-consuming is the small composite designs, which replace the factorial portion of the central composite design with a small fractional factorial.

X_1	X_2	X_3
-1	-1	-1
-1	+1	+1
+1	-1	+1
+1	+1	-1
-1	0	0
+1	0	0
0	-1	0
0	+1	0

0	0	-1
0	0	+1
0	0	0

Another popular class of designs are the Box–Behnken designs, which have very specific structures and are available in several books and packages. With three factors, the Box–Behnken design is as follows:

X_1	X_2	X_3
-1	-1	0
-1	+1	0
+1	-1	0
+1	+1	0
-1	0	-1
-1	0	+1
+1	0	-1
+1	0	+1
0	-1	-1
0	-1	+1
0	+1	-1

0	+1	+1
0	0	0
0	0	0
0	0	0

One advantage of the Box–Behnken design over the central composite design is that it does not use points with extreme levels of all factors simultaneously. This can be advantageous when such points might be expected to give very untypical responses or be dangerous or unethical to use.

All the designs described so far emphasize the estimation of the second-order model with relatively few experimental runs. This is appropriate when experimentation is costly and run-to-run variation is small, such as with many physical systems. In other types of experiment, especially when biological materials are being used, run-to-run variation will be considerably higher. It might then be advantageous to use somewhat larger designs in order to improve the estimation of the response surface. In such cases, the class of subset designs can be useful. These are made up of the subsets $S_0, \dots, S_q$, where S_r is the set of points with r factors at ± 1 , the other $q-r$ factors being at 0. By combining different numbers of replicates of these subsets, researchers can find many useful designs. With three factors, the subsets are as follows:

	S_3			S_2			S_1			S_0	
X_1	X_2	X_3	X_1	X_2	X_3	X_1	X_2	X_3	X_1	X_2	X_3
-1	-1	-1	-1	-1	0	-1	0	0	0	0	0
-1	-1	+1	-1	+1	0	+1	0	0			
-1	+1	-1	+1	-1	0	0	-1	0			
-1	+1	+1	+1	+1	0	0	+1	0			
+1	-1	-1	-1	0	-1	0	0	-1			
+1	-1	+1	-1	0	+1	0	0	+1			
+1	+1	-1	+1	0	-1						
+1	+1	+1	+1	0	+1						
			0	-1	-1						
			0	-1	+1						
			0	+1	-1						
			0	+1	+1						

The best designs depend on the number of runs that can be done and the precise objectives of the experiment. For example, with 30 runs, the design $2S_3 + S_2 + 2S_0$ gives good estimation of the linear and interaction coefficients and of pure error but not such good estimation of the quadratic coefficients, whereas $S_3 + S_2 + S_1 + 4S_0$ gives better estimation of the quadratic coefficients but allows only 3 degrees of freedom for pure error.

Designs With More Levels

Although three levels are enough to fit the second-order model and estimate pure error, they do not allow a very good test for lack of fit, since at least four levels are needed to estimate pure cubic effects. Four-level designs are sometimes used, but much more commonly the central composite design is adapted to have five levels by placing the axial points farther out than ± 1 . Any value can be used for the axial points, but a popular choice is $\sqrt{q}$ so that, in terms of the coded factor levels, the region of experimentation becomes a sphere, or hypersphere. With three factors, for example, a central composite design is

X_1	X_2	X_3
-1	-1	-1
-1	-1	+1
-1	+1	-1
-1	+1	+1
+1	-1	-1
+1	-1	+1
+1	+1	-1
+1	+1	+1
$-\sqrt{3}$	0	0
$+\sqrt{3}$	0	0
0	$-\sqrt{3}$	0
0	$+\sqrt{3}$	0
0	0	$-\sqrt{3}$
0	0	$+\sqrt{3}$
0	0	0

0	0	0
0	0	0
0	0	0
0	0	0
0	0	0

Small composite designs and subset designs can be modified in a similar way, but with subset designs it is always necessary to include at least one center point.

Sequential Design

It was noted above that the central composite design lends itself to sequential experimentation, with the factorial points and some center points being run first to fit and check the first-order model. If this seems inadequate, then the axial points and some more center points are added to allow the second-order model to be fitted and checked. If, however, the first-order model seems adequate, the first experiment might suggest that different levels of the factors should be used; for example, higher responses can be obtained outside the region of experimentation. In such cases, the next experiment should probably be run in a new region of experimentation. For example, if, in the original first-order design, it seemed that the response at $(+1, +1, -1)$ was much higher than anywhere else in this experimental region, a new first-order design with levels $(+1, +3)$ for X_1 and X_2 and $(-3, -1)$ for X_3 could be run. There are many other possibilities; for example, the levels of some factors could remain the same, the range of levels could be expanded or contracted, or some factors could be dropped from the experiment.

If the results of the initial experiment suggest that the optimal response might be achieved far from the region of experimentation, then some experiments could be run along the direction of steepest ascent. For example, if the estimated coefficients for the three factors' linear effects are $-2, 1$, and 3 , respectively, runs could be made at $(-1, 0.5, 1.5)$, $(-2, 1, 3)$, $(-3, 1.5, 4.5)$, and so on. These can either be made as a batch, possibly with some replication, or one at a time. This technique was popular in the early days of response surface methodology but seems to be used less now. It probably works best if run-to-run variation is very small.

Optimal Design Criteria

An approach to choosing a response surface design that is different from the standard designs described above is to search for a design that optimizes some

design criterion. An obvious criterion is to minimize the average variance of the parameter estimates, and this is known as *A-optimality*. A computationally simpler, and hence more popular, criterion is *D-optimality*, which minimizes the volume of a joint confidence region for the parameters. Other criteria are based on minimizing the average (*I-optimality*) or maximum (*G-optimality*) variance of the estimated response in the region of experimentation.

Choosing an optimal design usually involves specifying a large set of candidate points, such as the full three-level factorial design, and running a search algorithm to find the combination of these that optimizes the relevant criterion. Most of these combinations work by starting with a randomly chosen design and then systematically exchanging points in the current design with points in the candidate set, accepting any exchange that improves the design. Such algorithms are available in many statistical software packages.

There is no agreement among statisticians or users about whether it is better to use an optimal design than one of the standard designs. In theory, it would be best to define an optimality criterion that exactly encapsulates all the objectives and limitations of the experiment and then choose a design that will optimize this criterion. However, it is probably impossible to define such an exact criterion in practice, or to do so would cost more time and effort than doing the experiment. This is why many experimenters prefer to use standard designs that are known to have many good properties.

Blocking

Up to now this discussion has assumed that the run order would be completely randomized within each experiment and that run-to-run variation would be used to assess the effects of factors. Sometimes, however, it is known or expected before the experiment that there will be systematic variation between runs, irrespective of which treatments are applied. For example, runs made on the same day might tend to be more similar than runs made on different days. Then the technique of blocking can be used in order to separate variation between days from variation between runs on the same day. The advantage of this separation is that the effects of the factors can then be assessed relative to the variation between runs made on the same day so that more precise estimates of these effects can be made.

Unfortunately, unlike simple treatments or factorial designs, theory provides no simple mathematical method for arranging response surface designs in blocks. Instead, one usually has to use a search algorithm with some optimality criterion. Again different criteria can be used, although the choice of criterion is

less crucial for arranging a design in blocks than it is for searching for optimal treatment designs. Typical algorithms start with a random allocation of treatments to blocks and then systematically interchange them, accepting any interchanges that improve the criterion. Several algorithms have been suggested in recent years, and these have now started to appear in statistical software packages.

Sometimes there might be two (or more) types of blocks that can be used, either such that they are nested, such as days within weeks, or such that they are crossed, such as days and machines. Interchange algorithms can easily be extended to such nested block designs and row-column designs.

Multistratum Designs

It is very common in industrial and engineering experiments to have some factors whose levels are harder to set than others. For example, it might be convenient to set the temperature just once every day, whereas other factors can be varied in several runs within each day. This randomization restriction is then very similar to that used in the split-plot factorial design, but again the designs do not have such a simple mathematical structure. The same idea can be extended to having factors at more than two levels of variation. The general class of such designs is called *multistratum response surface designs*. This is an area of much current research. Several algorithms and strategies for constructing these designs have been suggested but are not yet readily available in widely used software packages.

RESTRICTION OF RANGE

Restriction of range is the term applied to the case in which observed sample data are not available across the entire range of interest. The most common case is that of a bivariate correlation between two normally distributed variables, one of which has a range less than that commonly observed in the population as a whole. In such cases, the observed correlation in the range restricted sample will be attenuated (lower) than it would be if data from the entire possible range were analyzed.

The context in which restriction of range is discussed most often is that of criterion-related validity evidence of predictors in a selection context such as employee selection or educational institution admissions. For instance, common cases include those in which job applicants take a test of some type, and then only a subset of those applicants is hired. When the selection decision is based on the test scores, the range of the sample will be restricted.

How Range Restriction Affects Correlation Coefficients

Figure 1 illustrates the effect of restriction of range on observed correlations. In Figure 1(a), data for 50 persons appears for both a predictor and a criterion. With this full sample, the correlation is .82. Figure 1(b) illustrates the effect of restriction of range on the predictor. Such a scenario is a common one in validation research that uses predictive validity designs in which there is a large pool of job or college applicants, yet only a subset of applicants with the highest scores on the predictor is selected. In this example, only persons with the top 15 scores on the predictor were selected. Thus criterion data would be available only for these persons. The observed correlation is attenuated from .82 in the full sample to .58 in the range-restricted sample.

Conversely, Figure 1(c) illustrates the effect of restriction of range on the criterion in which only the 15 persons with the highest criterion scores are included.

Figure 1 Effects of Restriction of Range

Such a scenario is often encountered in validation research in which a concurrent validation design is employed. In such a design, current employees are given a predictor measure of interest and the correlation between predictor scores and the criterion is assessed. In this case, poorly performing employees likely would have been fired or would have quit their jobs, thus restricting the range of the performance criterion. In this example, the observed correlation is .51.

Types of Restriction of Range

Most researchers recognize a distinction between different types of restriction of range. The most obvious type is known as *direct* (or explicit selection) restriction of range. Direct restriction of range is that depicted in Figure 1(b), in which there is a predictor of interest that is given to a set of applicants and only those with the highest scores on the predictor are selected. In this case, the restriction of range is direct and purposeful. Direct restriction of range is witnessed

in predictive validation designs in which the predictor data are collected, persons are selected into the organization based on the predictor, and later a criterion performance measure is collected. Because of the effect of restriction of range on the correlation between the predictor and the criterion, the American Educational Research Association, American Psychological Association, and National Council on Measurement in Education recommend that the predictor of interest not be used for selection until the validation process is complete.

A second type of restriction of range is *indirect* (or incidental selection) restriction of range. Indirect restriction of range occurs in either predictive or concurrent validation designs. In these cases, the predictor of interest is not used to make selection decisions in the organization; however, the predictor of interest is correlated with another predictor that is used for selection decisions. In the example of a predictive validation design, both the predictor of interest and a correlated other predictor are given to a set of applicants. Only those applicants with the highest score on the other predictor are selected; however, because of the correlation between the predictors, persons selected will tend to be those with the highest scores on the predictor of interest. In the concurrent validation design, a predictor of interest is given to existing employees. If those current employees were selected on the basis of their scores on another predictor that correlates with the predictor being validated, only employees with scores in the upper range of the predictor of interest will be available.

Note that formulas are available to estimate the unrestricted correlation coefficient given a range-restricted sample:

$$r_c = \frac{r(\sigma_u / \sigma_r)}{\sqrt{1 - r^2 + r^2(\sigma_u^2 / \sigma_r^2)}},$$

where r_c is the corrected correlation, r is the observed correlation in the range-restricted sample, and σ_u and σ_r are the standard deviation of the predictor in the unrestricted and range-restricted samples, respectively.

RESULTS SECTION

The purpose of the results section of a research paper is to present the key results of a research study without interpreting their meaning. The results should be presented (a) in an orderly sequence so that their sequencing tells a story and (b) where appropriate, with the use of summary techniques and visual aids, such as tables and figures. The results section does not need to include every result obtained or observed in a study. It presents only those results that are relevant to the objectives and the research questions of the study.

Usually the results section is not combined with the discussion section unless specified by the journal to which the research paper will be submitted. The results section in general should not refer to the discussion section, which has not yet been written (but the discussion section should frequently refer to the results section). The results section, however, should closely reflect the methods section. For every result there must be a method in the methods section.

Below is a checklist of the items to be included in a results section:

Text. First, the results must be organized in an orderly sequence, such as chronological order, logical order, or in order of most to least important. One recommended order in the results section is as follows: (a) Summary of what the data set “looks like,” with descriptive statistics (e.g., mean and standard deviation) for the relevant variables as found in preliminary analyses. (b) Examination of the hypotheses through further analyses. (c) Verification of which findings were or were not in the predicted direction, based on confirmatory analyses.

Second, whether the results are best presented in the form of text, tables, figures, or graphs is determined. Tables are good for including large amounts of

information, especially of a repeated or comparative nature, for completeness. Scatterplots or histograms can provide a real feel for the data (including the noise). With complex data sets, bar graphs are useful so that the reader is not overwhelmed with too many data points at once. When results are presented in tables or figures, the text should describe only the highlights of the findings and point the reader to the relevant tables and figures. The text should provide background information for the tables and figures, as well as observations not presented in the tables and figures. In other words, the text should complement the tables and figures, not repeat the same information.

Third, the text—not the statistics—should describe the patterns in the data. Statistics should not be used as though they were parts of speech. For example, “the correlation between variables A and B was $r = -.26$, $p = .01$ ” should be translated into words, with the statistics provided as evidence for the reported findings; for example, “a negative correlation was found between variables A and B, indicating that an increase in A was associated with a decrease in B ($r = -.26$, $p = .01$).” The word *prove* should be used with caution. Because statistical tests are based on probability and can be in error, they do not really prove anything. The meaning of the alpha level or the null hypothesis need not be elaborated if the intended audience of a research paper is the scientific community; in this case, the researcher can assume the reader will have a working knowledge of statistics. The word *significant* should also be used with care. A statistically significant difference is one in which the probability that the groups of data are identical with respect to the characteristic under study is so low (e.g., less than .05) that the investigator can confidently conclude that the difference exists. The opposite is “statistically nonsignificant.” A clinically significant difference is one that is considered important. The opposite is “clinically insignificant.” The sentence “It is significant that we found no significant differences among the groups studied” is a valid, though perhaps confusing, statement.

Tables and Figures. When used correctly, these are good summary techniques and visual aids to help describe the results. The common mistakes, however, are that tables and figures are too complex and too many. The following are several techniques to improve the presentation of tables and figures. First, tables and figures must be linked to the text in the results section. A citation in the text, such as “See Table 1” or “Figure 2 shows that . . .” should always be included in the results section for each table and figure. Second, each table and figure should “stand alone,” that is, a reader should be able to understand each one without having to refer to the text. For example, each table and figure

should have a comprehensive heading that describes its content (including the country, name, and year of the study if applicable); the number of cases or sample size to which the table or figure refers should be given; and any abbreviations used in the figure or table should be defined in a footnote, even if they are explained in the text. Third, tables and figures must be linked to the methods section. All statistical techniques used to generate tables and figures must be described adequately in the methods section. Finally, approval for reproduction of any material (including figures and tables) published elsewhere should be obtained from the copyright holders and/or authors before submission of the manuscript to a journal. Authors usually are responsible for any copyright fee involved.

The following are some general technical guidelines.

For tables and figures:

- Check the journal guidelines on the maximum number of tables or figures allowed, and find out whether the journal uses color (often there is a charge) or black and white.
- Number tables and figures consecutively in the same sequence they are first mentioned in the text.
- Number tables and figures in separate sequences; for example, Table 1, 2, and so on; Figure 1, 2, and so on.
- Do not put a box around tables and figures.
- Avoid decorative background, such as shading or patterned bars.
- Depending on the journal, tables and figures should be placed at the end of the report, after the references section (some journals require authors to indicate in the text of the results section the approximate location of the tables and figures), or located appropriately within the text of the results section.

For tables:

- Many journals allow only horizontal lines and no vertical line in tables.
- Use horizontal lines to separate rows only if the rows deal with different types of variables, such as age, income, and education.
- Make sure that all numbers, especially if they have decimal points, line up properly.
- Make sure that the percentages of the categories of a variable add up to 100; round all numbers, except p values, to two decimal places.
- To indicate that some numbers represent statistically significant differences, give the test used and p values or confidence intervals.
- Give column and row totals where appropriate.

- If a table continues for more than one page, repeat the table heading with “(continued)” at the end, and repeat column headers for each page.

For figures:

- Two-dimensional figures work best.
- Label both axes of figures.

Here are some helpful tips for writing the results section: (a) Write with accuracy, brevity, and clarity. (b) Use past tense when referring to the results; use present tense when referring to tables and figures. (c) Do not interpret the reasons for the results achieved; such interpretation can be addressed in the discussion section. (d) If a lot of material is to be presented in the results section, sub-headings may be helpful. (e) Do not include raw data or intermediate calculations in a research paper. (f) Do not present the same data more than once (e.g., in a table and then in a figure, or in a table or figure and then in the text). (g) Include results only from the study performed, not from other studies.

The results section is important because it describes the key results of a researcher's study. It should provide a clear and accurate description of the major findings in the form of text, tables, figures, or graphs.

RETROSPECTIVE STUDY

In a retrospective study, in contrast to a prospective study, the outcome of interest has already occurred at the time the study is initiated. There are two types of retrospective study: a case-control study and a retrospective cohort study. A retrospective study design allows the investigator to formulate hypotheses about possible associations between an outcome and an exposure and to

further investigate the potential relationships. However, a causal statement on this association usually should not be made from a retrospective study.

In conducting a retrospective study, an investigator typically uses administrative databases, medical records, or interviews with patients who are already known to have a disease or condition. Generally, a retrospective study is the method of choice for the study of a rare outcome, for a quick estimate of the effect of an exposure on an outcome, or for obtaining preliminary measures of association. After a brief discussion of the history of case-control and retrospective cohort studies, this entry discusses the use, advantages, and disadvantages of the retrospective study design.

History

Case-Control Study

As with other types of clinical investigation, the case-control study emerged from practices that originally belonged to the field of patient care. This form of disease investigation can be viewed as a combination of medical concepts (case definition, etiology, and a focus on the individual) and medical procedures (medical history taking, case series, and comparisons between the diseased and the healthy). The analytic form of the case-control study can be found in medical literature of the 19th century, but it did not appear to be viewed as a special or distinct methodology until the 20th century. The most fully developed investigation of this type was Janet Lane-Claypon's 1926 study of breast cancer. This special field was crystallized in the years following World War II, when four case-control studies of smoking and lung cancer were published, and since then case-control study has been accepted as an approach to assessing disease etiology.

Retrospective Cohort Study

Retrospective cohort studies have almost as long a history as the prospective studies. The first study was described by Wade Hampton Frost in 1933, based on assessment of tuberculosis risk in the black population in Tennessee. Interviews identified 556 persons from 132 families, which created 10,000 person-years of observation. In the presence of family contact, the attack rate of tuberculosis, standardized for age, was found to be about double that in the absence of such a contact (12.9 per 1,000 vs. 6.8 per 1,000). Although unable, because of the small number of people under study, to provide evidence of the importance of family contacts in the spread of tuberculosis, this study revealed the way records of past events could be used

for the study of public health and is notable in particular for its clear description of the way person-years at risk can be calculated and its success in gaining the cooperation of almost an entire population.

Earlier studies of significance include the 1920s study by Bradford Hill of company records of nickel refinery workers and pensioners and the risk of cancers in the lung and nose, and the success in reducing this risk through changes in the refinery process, the study by R. E. W. Fisher on coal-gas workers' risk for lung cancer in 1920s, and many others.

Use of the Study Design

Case-Control Study

Case-control studies are retrospective, analytical, observational studies designed to determine the association between an exposure and outcome in which patients who already have a certain condition are compared with people who do not. Cases and controls are selected on the basis of the presence of the outcome condition, and exposure is assessed by looking back over time. It is very important in a case-control study that the cases be as similar to the controls as possible on all factors except the outcome of interest. Investigators then look to see what proportion in each group were exposed to the same risk factors.

These studies are commonly used for initial, inexpensive evaluation of risk factors and are particularly useful for rare conditions or for risk factors with long induction periods. Due to the nature of data sources, the results from case-control study are often less reliable than those from randomized controlled trials or cohort studies. In a case-control study, the statistical measure for the association is the *odds ratio*. A statistical relationship does not mean that one factor necessarily caused the outcome, however. Because of the potential for multiple forms of bias to occur in case-control studies, they provide relatively weak empirical evidence even when properly executed.

The case-control study is distinguished by six essential elements, each of which evolved separately in medical history.

1. The case definition: The disease entities are specific and are likely to have one or more specific causes.
2. An interest in disease etiology and prevention, in contrast to its prognosis or treatment.
3. A focus on individual, as opposed to group, etiologies.
4. Anamnesis, or history taking from patients, which permits the collapse of time past without enduring its slow passage until outcomes under study evolve.

5. Grouping individual cases together into series.
6. Making comparisons of the differences between groups in order to elicit average risk at the level of the individual.

Retrospective Cohort Study

A retrospective cohort study allows the investigator to describe a population over time or obtain preliminary measures of association for the development of future studies and interventions. The exposure and outcome information in a cohort study are identified retrospectively by the use of administrative data sets or through reviews of patient charts, interviews, and so on.

This type of study identifies a large population, studies patients who have a specific condition or have received a particular treatment over time, and compares them with another group that has not been affected by the condition or treatment being studied.

Case Reports and Case Series

Case reports and case series are descriptive and exploratory, consisting of collection of reports on the treatment of individual patients or a report on a single patient. Because they are reports of cases and use no control groups with which to compare outcomes, they have no statistical validity. For example, a foot and ankle surgeon might describe the characteristics of an outcome for 100 consecutive patients with hammertoe who received a simple metacarpophalangeal joint release.

Advantages and Disadvantages

One advantage of the retrospective study is that it is simple, quick, and inexpensive to conduct. It is also the only feasible method for studying very rare disorders or those with long lag between exposure and outcome. Other advantages are that fewer subjects are needed than for cross-sectional studies and that odds ratios can be calculated.

Some disadvantages include obtaining a single outcome and relying on recall or records to determine exposure status. In addition, retrospective studies must cope with confounders, risk of bias, and difficulty in selecting control groups. Furthermore, relative risk cannot be calculated, and there are no data on prevalence or incidence.

RISK IN HUMAN SUBJECTS RESEARCH

Research often exposes human subjects to risks, which can range from minimal harms, such as mild bruising or headache, to significant harms, such as liver toxicity or even death. Researchers have ethical and legal obligations to use research designs, methods, and procedures that minimize risks to human subjects, to ensure that risks are reasonable in relation to benefits to subjects or society, and to inform subjects about risks. This entry defines research risks; distinguishes between different types of risks; describes researchers' ethical and legal obligations related to risks, strategies for minimizing risks, and methods for assessing risks; and reviews some of the controversial issues pertaining to research risks.

Research Risks

Risk can be defined as the chance that an adverse outcome (or harm) will occur. Risk is the product of two components: the probability of the harm and the magnitude (or severity) of the harm. Given this definition, an adverse outcome with a low probability and high magnitude could be viewed as a greater risk than an adverse outcome with a high probability and low magnitude. For example, a study that has a 1% chance of death would be viewed as much riskier than one whose only risk is a 75% chance of a headache.

Types of Risks

There are four types of risks that human subjects may encounter in research:

1. medical risks (such as bleeding, nausea, infection, adverse drug reaction, fatigue, cardiac arrhythmia, or death),
2. psychosocial risks (such as pain, anxiety, stress, loss of confidentiality, or stigma),
3. economic risks (such as loss of income or liability for medical expenses), and
4. legal risks (such as employment discrimination or the discovery of misattributed paternity).

The type of risks associated with a study depends on the study's design, methods, and procedures. For example, a clinical research study may expose subjects to medical, psychosocial, economic, and legal risks, whereas an anonymous survey may expose subjects only to psychosocial risks.

Ethical and Legal Obligations

Research regulations (such as the U.S. federal government's Common Rule, 45 CFR 46) and ethical guidelines (such as the Nuremberg Code or the World Medical Association's Helsinki Declaration) impose three distinct ethical and legal obligations on researchers related to risks:

1. the obligation to minimize risks,
2. the obligation to ensure that risks are reasonable in relation to the possible benefits to the subjects or the value of the knowledge expected to be gained, and
3. the obligation to inform research subjects (or their legal representatives) about the reasonably foreseeable risks of research.

Ethics review boards, such as institutional review boards (IRBs), should not approve a study unless they determine that these obligations will be met.

Research regulations and guidelines also distinguish between minimal risk and more than minimal risk research. Minimal risks are risks that are not greater than the risks of routine medical or psychological tests or the risks ordinarily encountered in daily life. For example, a mild bruising or bleeding from a blood draw would be minimal risk. Minimal risk is an important concept in research ethics for two reasons. First, research regulations and guidelines place restrictions on the participation of vulnerable subjects, such as children, fetuses, prisoners, and adults who are mentally disabled, in more than minimal risk research that does not offer the subjects direct, medical benefits. Second, under the U.S. federal regulations, an IRB can review studies that it determines to be minimal risk on an expedited basis. The IRB chair or a designated IRB member can review expedited research instead of the full board.

Except for fetuses, regulations and ethical guidelines do not address risks to third parties. However, most ethicists agree that researchers have an ethical and legal obligation to minimize risks to identifiable third parties.

Identifiable third parties include people who are not participants or researchers but who may be directly impacted by a research study, such as members of the participant's family or household or members of a community being studied. For example, if researchers enroll a woman in a drug study with a child who is young enough to breastfeed, they should anticipate potential risks to the child from breastfeeding and they should take appropriate steps to minimize these risks if the child is likely to be exposed to the drug through breastfeeding. They could, for example, warn the woman about potential risks to her child and advise her not to breastfeed during the study, or if the woman intends to continue breastfeeding, they could exclude her from the study if the risks to the child would be significant. Similarly, if researchers are conducting a study of substance abuse and sexually transmitted diseases in an identifiable community, they should be aware of potential bias or stigma against community members that could arise when the public learns about the research results, and they should take appropriate steps to address these risks.

Strategies for Minimizing Risk

There are many different strategies that researchers can use to minimize risks, depending on the type of research and the study design. In clinical research, researchers can minimize risks by conducting a thorough review of prior literature to identify and estimate risks, excluding prospective subjects who may be at greater risk due to a disease or medical condition, closely monitoring subjects while they are in the study, withdrawing subjects who become too ill to participate, following up with subjects after they have completed the study, collecting the minimal amount of blood or tissue needed for research, exposing subjects to the minimal amount of radiation needed for research, protecting the confidentiality of research data and subjects' privacy, using a data and safety monitoring board to monitor study data to protect subjects from risks, and providing subjects with medical care for research-related injuries. In social and behavioral research, researchers can minimize risks by protecting subjects' confidentiality and privacy, debriefing subjects after they participate in research that involves deception, and offering subjects counseling if they experience psychological distress from participating in a study.

Risk Assessment

Risk assessment includes three steps:

1. risk (or hazard) identification, in which researchers identify possible risks to human subjects related to their research;
2. risk estimation, in which researchers estimate the probability that risks will materialize; and
3. risk evaluation, in which researchers and ethics review boards evaluate the magnitude of risks and decide whether the risks are reasonable in relation to the benefits to the subjects and the value of the knowledge expected to be gained.

Risk identification and estimation should be based on updated information from prior human or animal studies. The scientific and medical literature contains a great deal of information about the risks of standard medical procedures, such as venipunctures, lumbar punctures, biopsies, cardiac stress tests, magnetic resonance imaging scans, and computerized axial tomography scans. However, often researchers may not have the empirical data they need to accurately identify or estimate risks, especially when they are testing new drugs, biologics, or medical devices that have not been used in human beings. Also, novel experiments in the social sciences, such as some types of studies involving deception or role-playing, may create risks that are not well understood. When researchers lack data on risks, they can make rough estimates of known risks based on their scientific knowledge and inform the review board and research subjects that there may be some risks that are not known.

The overall risks of a study can be estimated by aggregating the risks of different study procedures, tests, and interventions. For example, if a study includes four 50 mL blood draws, two skin biopsies, and a magnetic resonance imaging scan using a contrast media, then the overall risks of the study would be an aggregation of these various risks. The risks of the study do not include risks that are related to usual clinical care a patient will already be receiving. For example, if a patient is receiving a colonoscopy as part of clinical care, and the research study will involve collecting three small pieces of tissue from the colon during the colonoscopy and asking the patients to complete a health survey, the risks of the research would include the risks of the additional tissue collection and the survey but not the risks of the colonoscopy.

Controversies

Risk evaluation is not a purely scientific process because it involves moral judgments about the magnitude of risks and the reasonableness of risks in relation to benefits. People often form moral judgments based on intuitions, gut feelings, cultural traditions, or religious doctrines rather than scientific data. Consequently, ethics board members and researchers may

have varying opinions about exposing human subjects to risks, which can lead to ethical controversies.

For example, some studies, such as Phase I clinical trials and vaccine challenge experiments, expose healthy volunteers to significant risks, such as the risk of drug toxicity, serious illness, hospitalization, or even death. These studies are controversial, in part, because research regulations and ethical guidelines do not establish an upper risk limit for research risks; they only require that risks be reasonable. Several commentators have argued that there should be a limit on the risks that healthy volunteers are exposed to in research, but they disagree about where that limit should be. Some have argued that healthy volunteers should not be exposed to risks greater than those that people face in risky socially acceptable altruistic or paid activities, such as kidney donation or construction work.

Phase I drug trials involving terminally ill cancer patients have also been controversial. These studies are not conducted on healthy volunteers because the risks are very high and often include a significant risk of death. The ethical rationale for using cancer patients as research subjects is that they may derive medical benefits from their participation. However, this assumption has been questioned, because Phase I trials are designed to test safety, not efficacy, and the participants may not receive an effective dose of the experimental medication. Furthermore, the participants may view the research as a form of therapy and may not understand that the research is designed to develop generalizable knowledge, not to provide patients with medical benefits. Since the participants are desperately ill, they may be eager to volunteer for studies that offer them only a slim chance of a medical benefit.

Studies that expose healthy children to more than minimal risks have also been controversial, because the subjects will not benefit medically from their participation. Some commentators have argued that these studies are unethical because they are not in the child's best interests and parents and researchers have an ethical and legal obligation to promote the child's best interests. Others argue that these studies can be ethical if they are likely to produce valuable knowledge that can benefit other children and cannot be obtained by other means. For example, many pediatric drug studies include a population of healthy controls who may be exposed to more than minimal risks but are not likely to benefit medically from their participation. The healthy control group is included in the study to minimize bias and promote reproducibility. The U.S. federal research regulations,

for instance, allow children to participate in more than minimal risk research when the risk is a minor increase over minimal risk and is likely to yield generalizable knowledge about the child's disorder or condition.

ROBUST

Robust statistics represent an alternative approach to parameter estimation, differing from nonrobust statistics (sometimes called *classical statistics*) in the degree to which they are affected by violations of model assumptions. Whereas nonrobust statistics are greatly affected by small violations of their underlying assumptions, robust statistics are only slightly affected by such violations. Statisticians have focused primarily on designing statistics that are robust to violations of normality, due to both the frequency of nonnormality (e.g., via outliers) and its unwanted impact on commonly used statistics that assume normality (e.g., standard error of the mean). Nevertheless, robust statistics also exist that minimize the impact of violations other than nonnormality (e.g., heteroscedasticity).

Notes: a: $\mu = 0$; $s = 1$. b. Distribution 1: $\mu = 0$; $s = 1$, weight = .9; Distribution 2: $\mu = 0$; $s = 10$, weight = .1.

The Deleterious Effects of Relaxed Assumptions

In evaluating the robustness of any inferential statistic, one should consider both efficiency and bias. Efficiency, closely related to the concept of statistical power and Type II error (not rejecting a false null hypothesis), refers to the stability of a statistic over repeated sampling (i.e., the spread of its sampling distribution). Bias, closely related to the concept of Type I error (rejecting a true null hypothesis), refers to the accuracy of a statistic over repeated sampling (i.e., the difference between the mean of its sampling distribution and the estimated population parameter). When the distributional assumptions that underlie parametric statistics are met, robust statistics are designed to differ minimally from nonrobust statistics in either their efficacy or bias. When these assumptions are relaxed, however, robust statistics are designed to outperform nonrobust statistic in their efficacy, bias, or both.

Source: For an example of how relatively minor nonnormality can greatly decrease efficiency when one relies on conventional, nonrobust statistics, consider sampling data from the gray distribution shown in Figure 1. This heavy-tailed distribution—designed to simulate a realistic sampling scenario in which one normally distributed population contaminates another ($\mu = 0$, $\sigma = 1$) with outliers—differs only slightly from the normal distribution, in black. Such

nonnormality would almost surely go undetected by a researcher, even with large n and when tested explicitly. And yet such nonnormality substantially reduces the efficiency of classical statistics (e.g., Student's t , F ratio) because of their reliance on a nonrobust estimate of population dispersion: sample variance. For instance, when sampling 25 subjects from the normal distribution shown in Figure 1 and an identical distribution one unit apart, a researcher has a 96% chance of correctly rejecting the null hypothesis via an independent-samples t test. If the same researcher using the sample sizes and statistics were to sample subjects from two of the heavy-tailed distributions shown in Figure 1—also spaced one unit apart—however, that researcher would have only a 28% chance of correctly rejecting the null. Modern robust statistics, on the other hand, possess high power with both normal and heavy-tailed distributions.

The above example is one of many realistic circumstances in which classical statistics can exhibit nonrobustness with respect to either bias or efficiency. Table 1 presents some other common circumstances. Advocates of robust statistics argue that assumptions such as normality are grounded in historical convention more than in empirical fact, observing that Gauss derived the normal curve to justify the use of sample means (not vice versa), as well as the frequently documented nonnormalities of real-world populations.

Types of Robust Estimators

Today, the most widely used robust estimators of location are *M-estimators* and *trimmed means*. Whereas the former rely on the technique of *maximum likelihood estimation* (hence their name), the latter rely on the removal of a fixed proportion (commonly 20%) of a sample's smallest and largest observations. It is worth noting that although both of these sets of estimators characterize the "typical" value of a population based on sample data, neither are alternative estimates of the population mean: Instead, both estimate their respective population parameter (which, for symmetrical distributions, happens to equal the mean). Depending on the distribution, *M-estimators* may outperform (in terms of efficiency and bias) trimmed means or vice versa. For example, if outliers constitute more than 20% of the largest observations in a sample or are concentrated heavily in one tail of the distribution, *M-estimators* will likely outperform trimmed means.

To conduct a significance test with a robust estimator, one can rely on either parametric methods

Table 1 Commonly Used Classical Statistics and General Conditions Under Which Studies Have Documented Their Nonrobustness

<i>Statistic</i>	<i>Conditions of Efficiency Nonrobustness</i>	<i>Conditions of Bias Nonrobustness</i>
sample mean	asymmetrical distributions heavy-tailed distributions	
sample variance	asymmetrical distributions heavy-tailed distributions	
one-sample <i>t</i>	asymmetrical distributions heavy-tailed distributions	asymmetrical distributions
two-sample <i>t</i> and ANOVA	heavy-tailed distributions differences in symmetry heteroscedasticity	differences in symmetry heteroscedasticity

(e.g., *Yuen's test* for trimmed means) or nonparametric ones (usually *bootstrapping*).

Why Not Transform Data or Remove Outliers?

Conventional wisdom asserts that researchers can combat the problematic effects of nonnormality without the use of robust statistics by transforming their data and removing outliers. Advocates of robust methods, however, point to several limitations in this approach. First, as the heavy-tailed distribution in Figure 1 makes clear, small perturbations of normality are difficult to detect with both visual and statistical analysis; tests of normality possess notoriously low power, and thus researchers often fail to detect—let alone correct for—nonnormality. Second, although curvilinear transformations can make distributions more normal, they cannot make distributions entirely normal; thus, normalizing transformations does not necessarily reduce the need for robust methods. Third, methods to detect outliers based on nonrobust statistics (e.g., sample mean and variance) often fail because of problems such as masking (in which one outlier masks the presence of another), and the deletion of outliers introduces unwanted dependence into the data that classical statistics fail to account for. Modern methods such as trimming and *M*-estimation account for the problematic effects of extreme data, and they do so in a robust manner that takes into account such dependence.

Recommendations

As their pioneers have duly noted, robust statistics come with a cost of lower power under ideal circumstances of perfectly met model assumptions. For this reason, robust statistics have been described as a sort of insurance policy in which this small cost of lowered power protects researchers against the damaging effects of approximately met model assumptions. As with most situations in which two alternative analyses exist, however, the best policy is to blindly accept neither and instead conduct both. Thus, generally speaking, researchers are advised to conduct both classical and robust estimates, interpreting any meaningful differences in terms of either lowered power or relaxed assumptions.

ROBUST MAXIMUM LIKELIHOOD

Robust maximum likelihood is used to adjust the model fit test statistic and standard errors when estimating structural equation with non-normally distributed data. A major assumption of normal theory maximum likelihood estimation is that the data follow a multivariate normal distribution. When data violate this assumption, commonly through measures of skewness and kurtosis, statistics based on normal theory maximum likelihood estimation can be misleading. While the parameter estimates under normal theory maximum likelihood estimation remain relatively robust to violations of normality, the test statistics and standard errors break down under normal theory maximum likelihood estimation and correction is required through use of robust maximum likelihood.

After providing some background information, this entry details the assumptions needed to determine whether the data are multivariate normal, the statistical adjustments made through robust maximum likelihood, and the implementation of robust maximum likelihood in common software applications.

Background

The goal of structural equation modeling (SEM) is to specify a model whose model-produced population covariance matrix is a good approximation of the observed covariance matrix. The options for model specification are seemingly endless (as long as the model is identifiable) but are considered a confirmatory technique and should be based on a testable theory. Once specified, the model will be tested by comparing the model-produced population covariance

matrix to the observed sample covariance matrix through test statistics, fit indices, and the significance of parameter estimates.

To test the specified model, the most appropriate estimation algorithm can be determined by several practical issues about the data such as sample size, missing data, outliers, and multivariate normality. The most commonly utilized (and generally the default estimation method for most SEM software) is maximum likelihood because it produces the most precise parameter estimates with the smallest standard errors. Maximum likelihood can also be appropriately applied with smaller sample sizes. This estimation method is appropriate when the data are continuous, or can be treated as continuous, and they follow a multivariate normal distribution. When, however, the data violate the multivariate normality assumption, the test statistics and standard errors are no longer valid indicators of model fit or significance tests for the parameter estimates, respectively. Robust maximum likelihood becomes the appropriate estimation algorithm with non-normal data because it provides adjustments for these statistics.

Assessing Assumptions

Departures from normality can generally be identified through measures of skewness and kurtosis. Kurtosis is the main concern for any SEM analysis involving the covariance structure, while skew only becomes an issue when the means are modeled.

Skewness refers to the degree of asymmetry in a distribution. A normal distribution, or other symmetrical distributions, has zero skewness. A positively skewed distribution, or right skew, has a long right tail with most values piled on the left side of the distribution, while a negatively skewed distribution, or left skew, is in the opposite direction. Because outlying cases can also influence the asymmetry of the distribution, and hence contribute to the non-normality, outlier cases should also be avoided.

Kurtosis refers to the amount of the distribution located in the tails relative to the center or body of the distribution—essentially, the *tailedness* of the distribution. The kurtosis value for a normal distribution is 3. Kurtosis values smaller than 3 indicate a distribution with few extreme values, a platykurtic distribution. However, kurtosis values larger than 3 indicate a distribution with heavier tails, a leptokurtic distribution, which contains more outliers than a normal distribution. Kurtosis can also be normed to zero so that negative kurtosis refers to a platykurtic

distribution and positive kurtosis refers to a leptokurtic distribution. Positive kurtosis, in particular, affects the maximum likelihood test statistic and the standard errors. Specifically, the maximum likelihood test statistic becomes inflated and no longer follows a chi-square distribution, thus invalidating the model test. In addition, while the parameter estimates are unaffected, the standard error estimates become downwardly biased (too small) with positive kurtosis. Since the significance test of the parameter estimates is computed by dividing the parameter estimate by the corresponding standard error, this downward bias in the standard errors invalidates the significance tests.

Statistical Adjustments

Robust maximum likelihood estimation provides corrections to the test statistic and standard errors to restore their utility in model and parameter testing, respectively. The test statistic is adjusted by a scaling constant so that it more closely follows the chi-square distribution, known as the *Satorra-Bentler* (1994) scaled chi-square. While the complicated function used to compute the scaling constant is beyond the scope of this entry, the scaling constant corrects the mean of the sampling distribution of the corrected test statistic to more closely approximate the expected mean of the chi-square distribution, which are the model degrees of freedom. This restores the utility and validity of the model test. The standard errors are adjusted through a sandwich estimator that appropriately incorporates the additional variability in the estimates caused by the non-normality. These adjusted standard errors are known as *robust* standard errors.

Software Implementations

Robust maximum likelihood estimation can be specified in the following common SEM software programs or packages:

EQS: ME = ML, ROBUST; in the \Specifications section of the syntax

LISREL: RO in the model options portion of the syntax

Mplus: Estimator = MLR; in the Analysis section of the syntax

The *lavaan* package in R: estimator = "MLM" within the sem function

ROOT MEAN SQUARE ERROR

The term *root mean square error* (RMSE) is the square root of *mean squared error* (MSE). RMSE measures the differences between values predicted by a hypothetical model and the observed values. In other words, it measures the quality of the fit between the actual data and the predicted model. RMSE is one of the most frequently used measures of the goodness of fit of generalized regression models.

RMSE for Regression

In the application of regression models, unless the relationship or correlation is perfect, the predicted values are more or less different from the actual observations. These differences are prediction errors or residuals. These residuals are measured by the vertical distances between the actual values and the regression line. Large distances are indicative of large errors. However, for a given fitted regression line, the average or the sum of the residuals equals zero, as the overestimation of some scores can be canceled out by underestimations of other scores. Thus, a common practice in statistical work is to square the residuals to indicate the magnitude of absolute differences. Indeed, a primary goal in linear regression is to minimize the sum of the squared prediction errors to best model the relations among variables.

To acquire *RMSE*, one can square and average the individual prediction errors over the whole sample. The average of all the squared errors is the *MSE*. The *MSE*, in essence, is an average of the spread of the data around the regression line and reflects how big the “typical” prediction error is. Furthermore, the *MSE* can be “square rooted” to obtain *RMSE*. *RMSE* is used to represent prediction errors in the same units as the data, rather than in squared units.

Mathematical Definition

Since *RMSE* is the square root of *MSE*, a thorough knowledge of *MSE* is important to an understanding of the mathematical definition and properties of *RMSE*.

MSE

MSE is the mean of the overall squared prediction errors. It takes into account the bias, or the tendency of the estimator to overestimate or underestimate the actual values, and the variability of the estimator, or the standard error.

Suppose that $\hat{\theta}$ is an estimate for a population parameter θ . The *MSE* of an estimator $\hat{\theta}$ is the expected value of $(\hat{\theta} - \theta)^2$, which is a function of the variance and bias of the estimator.

$$\begin{aligned} \text{MSE}(\hat{\theta}) &= E[(\hat{\theta} - \theta)^2] \text{ and} \\ \text{MSE}(\hat{\theta}) &= V(\hat{\theta}) + (B[\hat{\theta}])^2, \end{aligned}$$

where $V(\hat{\theta})$ denotes the variance of $\hat{\theta}$ and $B(\hat{\theta})$ denotes the bias of the estimator $\hat{\theta}$.

An *MSE* of zero means that the estimator $\hat{\theta}$ predicts observations of the parameter θ perfectly. Different values of *MSE* can be compared to determine how well different models explain a given data set. The smaller the *MSE* is, the closer the fit is to the data.

RMSE

RMSE is the average vertical distance of the actual data points from the fitted line. Mathematically, *RMSE* is the square root of *MSE*.

$$\text{RMSE}(\hat{\theta}) = \text{MSE}(\hat{\theta})^{1/2} = (E[(\hat{\theta} - \theta)^2])^{1/2}$$

For an unbiased estimator, *RMSE* is equivalent to the standard error of the estimate, and it can be calculated using the formula

$$s = \frac{\sqrt{\sum_{i=1}^n (x_i - \bar{x})^2}}{n-1},$$

where n denotes the size of the sample or the number of observations, X_i represents individual values, and $\bar{x}$ represents the sample mean.

In many statistical procedures, such as analysis of variance and linear regression, the *RMSE* values are used to determine the statistical significance of the variables or factors under study. *RMSE* is also used in regression models to determine how many predictors to include in a model for a particular sample.

Properties

As the square root of a variance (*MSE*), *RMSE* can be interpreted as the standard deviation of the unexplained variance. Thus, *RMSE* is always above zero. Its minimum occurs only when the estimate is indefinitely close to the real data. In other words, *RMSE* is an indicator of the fit between an estimate and the real data points. Smaller *RMSE* reflects greater accuracy.

However, there is no absolute criterion for an ideal value for *RMSE*, because it depends on the scales of the measured variables and the size of the sample. *RMSE* can be compared only between models whose errors are measured in the same units. While a particular value of *RMSE* greater than zero is not meaningful in and of itself, its magnitude relative to other *RMSE* values can be used to compare models. A model with a smaller *RMSE* is often preferred.

As the squaring process gives disproportionate weight to large errors, the *RMSE* is very sensitive to the occasional large error. When many extreme values are present, a model is likely to get large values on the *RMSE*.

Relations to Other Fit Measures

As *RMSE* has the same units as the predicted quantity, it is more easily interpretable than *MSE* is. In addition, *RMSE* is associated with the R^2 : Large *RMSE* corresponds to low R^2 . To be more specific, *RMSE* can be computed by the standard deviation of the sample and r^2 . However, *RMSE* is a better measure of goodness of fit than is a correlation coefficient because *RMSE* is interpretable in terms of measurement units of the assessed variables. *RMSE* is also more advantageous than the mean absolute error in detecting extremely

large errors, because the mean absolute error is less sensitive to extreme values.

ROSENTHAL EFFECT

A general characteristic of human nature is that people tend to judge themselves, especially their competence and worth, based on the perception of others. The term *Rosenthal effect* refers to this internalization of expectations from a perceived authority figure by the recipient. Four terms are used to describe this same phenomenon, generally interchangeably: *Pygmalion effect*, *Rosenthal effect*, *self-fulfilling prophecy*, and *expectancy effect*. Another associated term—*Hawthorne effect*—underscores the complete understanding of the Rosenthal effect. In this entry, these terms are further examined, and implications for research and practical applications, particularly within the education system, are examined for the Rosenthal effect. It is imperative that researchers obtain a clear understanding of the Rosenthal effect because the impact of another person's expectations of recipients can generate very powerful effects on them and their resultant behaviors. As a result, researchers may wish either to research this phenomenon further or guard against its impact when collecting data.

History

The term *Pygmalion effect* first came into existence with the Greek mythological tale of Pygmalion and

Galatea. Pygmalion was a sculptor who wished to create the perfect woman, whom he proceeded to carve from ivory. His creation was the epitome of his idea of womanhood, and he wished with all his heart for her to be a real woman. He prayed to the goddess Aphrodite and entreated her to allow Galatea to become flesh and blood. The goddess granted his wish, and Pygmalion and Galatea became husband and wife.

In 1916, George Bernard Shaw wrote the play *Pygmalion*, in which the lead character, Professor Higgins, transformed a common flower girl into a lady, so much so that he could pass her off as a duchess. The flower girl internalized the fact that the professor was convinced that she could metamorphose, and this boosted her own confidence in her ability to successfully transcend her meager and lowly beginnings to become—the desire of her own heart—a lady. It was from these stories that the term *Pygmalion effect* was coined. Specifically, Shaw's plot demonstrated a real-world application of the expectancy effect. However, both of these stories reflect one basic premise: that if a person believes that something can be achieved, then it really can be achieved!

Real-World Application

The Rosenthal effect was named in honor of Robert Rosenthal, who studied the expectancy phenomenon extensively, originally with a student sample. To best illustrate the power wielded by the Pygmalion effect, Rosenthal and Lenore Jacobson conducted research at an elementary educational institution. They were curious about what would happen to the expectations of both teachers and students if students were unsuspectingly and randomly chosen and touted as having high potential. A deception involved the students' having to take a supposedly highly credible test that would make the predictions about the student's potential. The results of the deception on subsequent teacher expectations—which in turn influenced the levels of student confidence in their own potential—confirmed the Pygmalion/Rosenthal effect. Once the high-potential students were identified by the "test," the researchers found that when positive expectations were evident from teachers, the students were motivated to strive toward the goal due to renewed or increased self-confidence. As a result, success was usually and significantly apparent. However, the converse also proved to be true: When teacher expectations about students were negative, the students become convinced of their incompetence, and failure was the common result.

When the Rosenthal Effect Meets the Hawthorne Effect

Associated with the Rosenthal effect or the self-fulfilling prophecy is the Hawthorne effect. The research carried out by Rosenthal and Jacobson can serve to illustrate the relationship. For example, the Hawthorne, or *reactivity*, effect can result in improvement in task performance because more attention is provided to a group of people. From the example, the teachers may have, either consciously or unconsciously, provided more attention and more praise to the students who were identified as having high potential. As a result, the students bloomed under the additional attention and confirmed the positive teacher expectations through what is termed the *self-fulfilling prophecy* or *Rosenthal effect*. These results have been confirmed by other researchers.

Research into the Rosenthal effect and self-fulfilling prophecy indicated that the earlier that teachers were informed about their students' potential, the greater would be the advantages. Further research suggested that it was necessary for the teacher who initially expected the students to perform well to continue to influence the students. If the original teacher was replaced as the students progressed through higher grades, then the expectancy effect tended to decrease markedly. If, however, the students continued to be exposed to the original teacher, then the expectancy effect was maintained. Research has also shown that younger children are more susceptible to the Rosenthal effect, but older children tend to be able to retain the effect for a longer time period. As the example indicates, the Rosenthal effect has been identified within the classroom with regards to performance on tests. However, it has also been found in response to teacher attitudes about minority students and gender bias. Areas of study on expectancy effects in therapy have also been included.

The Rosenthal Effect on Animals

Rosenthal conducted studies on *experimenter expectancy effect*, which encapsulates the idea that experimenters tend to confirm the existence of what they expect to find. In one such experiment with animals, Rosenthal identified two sets of rats: one set was said to have been smart enough to learn the maze while the other group was downplayed as the exact opposite. In reality, both groups of rats were from the same set of offspring. Once it was indicated that the groups were different and the specific nature of that difference was outlined, the experimenter in the study would proceed

to confirm that the "smarter" rats performed better at the maze task than did the other group.

Advantages of Understanding the Rosenthal Effect

The hundreds of studies conducted on the Rosenthal effect have not only added to the current literature but have also provided a pathway for practical application. The work of Rosenthal and his colleagues has in fact triggered other researchers to try to realign effects of negative expectations that confront certain groups. This shift suggests that investigation into the expectancy phenomenon and its associated implications can provide the springboard for deliberate and effective strategies to convert that which is negative (e.g., stereotypes) into a positive outcome.

Although much of the work on the Rosenthal effect has been conducted by Rosenthal and his colleagues, other researchers have also found that teacher expectations do in fact enhance performance despite the actual ability of the students in question. Examples in support of these findings range from the progress of students in Head Start programs to that of intellectually challenged children. However, some researchers have been severely critical of the methodology employed by Rosenthal. Over the years, Rosenthal addressed these methodological issues, with the result that his current studies are reflective of greater scientific rigor.

Limitations on Research and Possible Solutions

Unless the Rosenthal effect and its correlates are being investigated specifically, the results of other types of research may be confounded by the expectancy effect. Even within a laboratory environment, there are many factors besides the independent variable that can impact the results. For example, if the Hawthorne effect is added to the experimenter expectancy effect, two methodological problems occur that may lower the internal validity of the study. First, people tend to do better when they realize that they are under observation; the added attention can cause them to perform better even if conditions are made worse than usual. Second, experimenters may either consciously or unconsciously look only for evidence to confirm their hypothesis. In order to surmount these problems, two strategies may be employed. First, a control or placebo group may be formed. If the results of this group are almost the same as or as good as the group in which the independent variable is being examined, then the experimental methodology needs to be revised. Second, to minimize the impact of experimenter expectancy

effects, a double-blind procedure may be used in which both the participants and the experimenters are unaware of the characteristics of the groups under investigation. For example, if three groups have to perform a task but the experimenter does not know which group is smart, which group is obtuse, and which group forms the control for the experiment, then this situation minimizes the experimenter expectancy effect. It also follows that if participants do not know to which group they belong, the Rosenthal effect and self-fulfilling prophecy may be avoided.

Even if experimenters use standardized instructions, nonverbal and totally unconscious cues may be picked up by the participants. One of the most famous cases of unconscious cuing is that of Clever Hans. This horse, trained by William Von Osten, was able to answer many questions involving the alphabet, mathematical calculations, and names of people by pawing the ground. No evidence of cheating was ever uncovered, and researchers were baffled by the horse's ability. To fully test him, he was placed in a tent, devoid of spectators and consequent distractions, with a panel of scientists who provided questions on all facets of knowledge that Hans was supposed to know. What they discovered was that Hans was actually responding to unconscious cues provided by the various questioners. For example, when the questioner's face relaxed, Hans stopped pawing the ground as this became a cue that the answer was correct. If the questioner's face was tense, then the answer had not been obtained as yet. If Hans was blindfolded, he was totally inaccurate in his responses. It was concluded that the questioners were unconsciously cuing the horse. Thus, experimenter expectancy bias was certainly evident in animals and in humans.

Therefore, another strategy that may lessen the impact of experimenter expectancy effects via unconscious cuing is the use of audiovisual technology to record the instructions. The use of a prerecording maintains the standardization and avoids any extra cues that do not exist in the original recording. Furthermore, the participants may be able to record their answers on audiovisual technology in order to preserve the objectivity of the study and avoid having any cues from a tester influence the answers of the participant. For example, not all testers can maintain expressionless features, especially if the participant is doing extremely well or extremely poorly. The participant's recording answers can help increase the objectivity of the task at hand.

RUBRICS

Rubrics are descriptive scoring systems that allow observers to assign a numeric value to a piece of work or a performance. While rubrics or scoring guides are most often associated with the field of measurement, specifically performance assessment, the use of such assessment tools can be applied more generally to any research endeavor in which one intends to apply a rating or a score to a complex task, product, or process. Rubrics provide a set of guidelines or criteria that allow researchers or evaluators to describe a set of characteristics that represent an underlying continuum of performance. The use of order categories that represent the different levels associated with a given performance or product allows for subjective judgments to become more objective in nature. This entry focuses on developing and assessing the quality of rubrics.

Rubric Development

Rubrics may be characterized as general or task-specific and may use an analytic or holistic scoring system. The purpose of the assessment determines the

type of rubric most appropriate for use. For example, if the purpose is to gather information regarding specific components of performance, then a task-specific rubric may be the most appropriate tool. On the other hand, if the purpose is to examine a broader range of tasks, then the evaluator may select a more general rubric for scoring. In much the same way, the scoring system itself can be either analytic or holistic in nature. When a product or performance comprises a variety of criteria on which judgment is made and each of these criteria is set along a continuum for scoring, the rubric is considered to be analytic. In cases in which only one score is assigned without the emphasis on specific criteria associated with the performance or product, the rubric is considered to be holistic. An example of a commonly used holistic scoring system is the assignment of grades, such as A, B, C, D, and F. Again, the format of the rubric is determined by the purpose of the evaluation.

General guidelines have been established in an effort to assist in the development of scoring rubrics. The first step is to identify the objective of the evaluation. Once this has been determined, the evaluator should identify a series of observable attributes and then thoroughly describe characteristics associated with each. Once the attributes have been identified and the characteristics determined, narratives are written along the continuum (either holistic or analytic), and score points are assigned at each interval. Prior to full implementation of the scoring system, anchors of performance are gathered to ensure that all levels of performance have been identified. Finally, rubrics are revised as needed. The key to the development of any rubric is clearly identifying the goals and objectives to be evaluated. Clear objectives for scoring the product or performance will help determine the format as well as the levels of performance to be scored.

Rubrics can be either too task-specific or too general, having the potential to make scoring difficult. Because rubrics are a measurement tool, attention must be paid to the reliability and validity of the scoring system. Development of a quality rubric is based primarily on the ability of a judge or rater to apply the performance criteria in an objective and consistent manner, ensuring that the scoring criteria adequately measure the objectives of the assessment. The descriptive characteristics of each score point along the scoring continuum may need to be reexamined and sometimes rewritten so that raters can accurately and consistently identify the level of performance based on the descriptors provided. Consistency within and across raters is crucial to the reliability of the rubric. In addition, the degree to which the content or the attributes of performance are aligned with stated goals and

objectives should be examined. In some cases, comparisons with existing measures may be useful in helping one determine the quality of the rubric. As with any measurement tool, the overall goal is to collect validity evidence that supports the rubric's ability to accurately measure the underlying psychological construct for which it was intended.

Rubric Quality

When assessing the quality of a rubric, one might consider four components: (1) purpose, (2) criteria, (3) scoring, and (4) organization of the instrument. The purpose of the assessment should be clearly stated and objectives identified. Evaluators must also determine whether the use of a rubric is the best method of measurement for any given situation. Once the purpose or objective(s) are clearly delineated, one must determine whether the performance criteria are clearly written. Clarity and detail increase the objectivity of the rubric for evaluators. The degrees of performance must also be precisely measured through an accurate scoring system that represents a continuum of performance represented by significant differences among score points. Finally, the overall organizational structure of the rubric must be examined to be sure that spelling, grammar, and physical layout are appropriate and user friendly.

Although rubrics may be developed for any situation in which one wishes to judge a performance or product, they have become most popular among educators, especially classroom teachers. The use of rubrics in educational settings has the potential to influence learning by providing formative feedback to learners on their progress as well as providing feedback to instructors on teaching.

SALAMI SLICING

Salami slicing, also known as *salami publishing* or *minimal/least publishable units*, refers to inappropriate fragmentation of data to inflate academic outputs. An unethical practice detrimental to science and society, salami slicing should be avoided by researchers at any stage of their career. This entry first defines salami slicing and then discusses why this practice is harmful, how common the practice is, and how to avoid salami slicing.

Defining Salami Slicing

Salami slicing represents a *piecemeal* approach to publication, where content that could have been published in one paper is artificially divided into multiple papers. Salami slicing may or may not involve self-plagiarism and is distinct from duplicate, redundant, or dual publication, which refers to publishing identical or very similar intellectual content multiple times.

Detecting salami slicing is difficult, because distinguishing between slices of salami and appropriate splitting of data is generally considered context-specific and not black and white (as is the case for duplicate/redundant publication). Still, several general rules could be considered when determining whether a *slice* is justified.

First, multiple papers with different hypotheses/research questions using the same data are acceptable. For example, studies on the effects of body mass index on all-cause mortality and the effects of physical activity on breast cancer, both based on the Nurses' Health Study, are quite different research questions and should be published separately. Conversely, excessive isolation of exposures or outcomes when research questions are

closely related is not acceptable. For example, the effects of fruit and vegetable intake on colorectal cancer should not be sliced into two publications with one on fruit and one on vegetable; residential green space and walking on weekdays and weekend days should not be published as two papers.

Second, testing carefully considered a priori hypotheses are acceptable, but *data dredging* is not. Testing many possible combinations of exposures and outcomes in the same study without hypotheses will inevitably lead to false-positive findings, such as having curly hair causing depression. Similarly, excessive post hoc subgroup analysis in separate papers is considered bad practice. This can include submitting multiple articles for publication exploring the intervention effects in subsamples that are not selected prior to the research projects or submitting separate articles on the relationship between an exposure (e.g., physical activity) and an outcome (e.g., all-cause mortality) in various subgroups (e.g., men and women, young and old, and those with and without a chronic condition).

Harmful Effects of Salami Slicing

First, salami slicing wastes the time of authors, peer reviewers, journal editors, and research consumers such as peer scientists, policymakers, and the public. Considering that taxpayers' money is often involved in the production and consumption of scientific research, using valuable resources to *produce more research* solely for the sake of artificially inflating academic output is unethical. Second, salami slicing deceptively inflates the evidence base without substance. By flooding the literature with the least publishable units, salami slicing could give a false sense of research progress and mislead decision-making. By encouraging *data dredging* and biasing data synthesis, salami

slicing could eventually distort scientific evidence, such as by double counting or overweighting data in systematic reviews. Third, because research outputs are usually evaluated based on quantitative metrics, salami slicing may result in rewarding the wrong people for unethical behavior in the hypercompetitive academic environment and could encourage others to do the same.

Prevalence of Salami Slicing

Salami slicing is not uncommon. Several studies of narrowly defined fields in medicine have found that around 10% of the publications involved some redundancy. However, these studies did not explicitly distinguish duplicate and salami publication. Because of the lack of a consistent and straightforward definition, salami slicing has remained unquantified and there has been little discussion of the phenomenon in most research fields. It is important that the scientific community, including researchers, journal editors, and the academic system, engage in ongoing conversations about salami slicing and agree on its definition. A clear definition based on consensus is critical for gauging the *true* scope of the problem and for informing specific policies (e.g., scientific journals, academic evaluation system) to prevent salami slicing.

Avoiding Salami Slicing

For researchers, it is important to note that even though salami slicing seems to be a shortcut to career advancement, it backfires in most cases. The Committee on Publication Ethics considers salami slicing inappropriate and provides specific recommendations on how journal editors should handle suspected cases of duplicate and salami publication. In addition, some journals have adopted specific policies against salami slicing. If detected, salami slicing could lead to rejection, retraction, or even notifying authors' institutions or funding organizations. Even if salami publication gets through the peer-review process, the practice may damage the reputation and credibility of authors and harm their career in the long term.

Dozens of authors and editors have written about how to prevent salami slicing. It is generally believed that researchers, journal editors, peer reviewers, and the scientific community as a whole all need to be involved for there to be a meaningful reduction in the use of the practice. Recommendations found in the literature on salami slicing include that researchers should follow principles of good scientific practice, such as conducting research for scientific advancement and societal impact instead of self-interest,

minimizing overlap across publications, avoiding *data dredging*, and declaring other related publications from the same study during submission. Journal editors should adopt and implement policies against salami slicing. Journals should consider including salami slicing detection in the peer-review checklist for reviewers. Peer reviewers should routinely check for salami slicing and report suspicious practices to the editors. Finally, the scientific community should reconsider the current academic reward system that rewards quantity over quality and instead consider ways to reward a focus on quality that disincentivizes salami slicing.

SAMPLE

Samples are used in much of the research conducted in both the social and natural/physical sciences. Even in the fields of history, music, and English, samples are often used in empirical investigations. Because the quality of the sample(s) used in a study has such an important bearing on the trustworthiness of a researcher's conclusions, here the following six critical aspects are considered:

1. The definition of *sample*
2. Why researchers use samples

3. How sample data are used
4. What kinds of samples researchers use
5. Why the concept of “sampling error” is important
6. The misconceptions people have about samples

Definition and Examples

A sample is a subset of a population. The population can be a set of people, animals, or things. For example, the population might be made up of all children who, on a given day, are enrolled in a particular elementary school; the dogs, during a given month, that are treated at a particular veterinary hospital; or the boats, on a given evening, that are docked at a particular marina. With these entities as the possible populations, a sample would be a *subset* of school children, a *subset* of dogs, or a *subset* of boats, respectively. The notion of *subset* implies that a sample must be smaller than the population to which it is connected. If n represents the size of the sample and N represents the size of the population, then it is mandatory that $n < N$. If the sample and the population are identical in quantity, then only the population exists.

Reasons Why Researchers Use Samples

Most researchers use samples in their studies because they do not have the resources—time, money, or access—to measure or observe all members of the population of interest. If a researcher wants to describe the eating behavior of the dogs observed at a particular veterinary hospital, the researcher’s available time and money would likely prohibit the in-home observation of every dog. However, observing a subset of those dogs might be feasible given the study’s budget and duration. Here, as in many other situations, the researcher chooses “what’s possible” (even though it is not best) instead of “what’s best” (because it is not possible).

In certain studies, researchers use samples because they have no choice. In laboratory and field experiments, and in clinical trials, a group of people, animals, or things is given some form of treatment. Posttreatment measurements are used as a basis for comparing the treated group against a control group, a placebo group, or a different treatment group. Or the treatment group’s posttreatment scores are sometimes compared against the same group’s pretreatment scores. In such investigations, the treatment group typically is considered to be a sample of a larger group that, in the future, might also receive the treatment. For obvious reasons, it is not possible to observe or measure the entire population.

Typical Use of Sample Data

After the members of a sample are identified and measured, researchers normally summarize the sample data and then use what they know about the sample to make an educated guess (i.e., a statistical inference) about the population. For example, if the population of interest is defined as the freshmen who enter a particular university in the fall of a given year, a sample of those freshmen might be interviewed to find out what they worry about. If these interviews reveal that 60% of the students in the sample say they worry about “doing well academically,” this information concerning the sample—referred to as the *statistic*—would be used to make a guess about the percentage of students in the freshman class who worry about grades—the *parameter*.

Typically, the sample-based inference involves one of two kinds of statistical thinking and analysis. One is *estimation*; the other is *hypothesis testing*. In estimation, the sample statistic can be used by itself as an estimate of the population parameter, or a confidence interval can be created to generate a “ball-park estimate.” In hypothesis testing, the sample data are used to determine whether a possible value of the population parameter, which is contained in the null hypothesis, can be rejected.

Types of Samples

Many different kinds of samples are used in research studies. The various types of samples differ from one another mainly in terms of the procedure used to determine how members of the sample are selected. The two main categories of samples are probability samples and nonprobability samples.

Probability Sampling Techniques

A probability sample is a subset of a population in which each member of the population has a precise probability of being included in the sample. For example, in a Bingo game where balls numbered 1 through 75 are blindly selected until a contestant has a winning card, the probability is $\frac{1}{75}$, or .0133, that any given ball (e.g., the ball with the number 34) will be the first ball selected. Although there are many types of probability samples, the following four are frequently used in research investigations: simple random samples, systematic random samples, stratified random samples, and cluster samples.

Simple Random Samples

With simple random samples, each member of the population must have an equal probability of being included in the sample. It follows that each possible sample of size n has an equal probability of being selected from the population. After a list of the population's members (i.e., the sampling frame) is created, a random number generator, a random numbers table, or some other unbiased method is used to generate the sample. The method used can involve *sampling without replacement* or *sampling with replacement*. With the former method, members of the sampling frame are eliminated from the list once they are selected for inclusion in the sample; with the latter method, the sampling frame remains intact and thus makes it possible for members of the population to appear two (or more) times in the sample.

Systematic Random Samples

Systematic random sampling is another way to select a random sample from a population. Four steps are involved. First, the researcher must specify the number of members in the population of interest (N). Second, the desired size of the sample (n) must be specified. Third, the researcher divides N by n —with this result rounded, if necessary, to the nearest integer—to establish the *sampling interval* (k). Finally, after establishing the values of N , n , and k , the sample is created in n stages. First, a member of the population is randomly selected from among positions 1 through k in the sampling frame. Next, k is added to that initial “starting spot” so as to identify the second member of the sample. The third member of the sample is identified by adding k to that value, and so on, until the specified sample size is reached.

Stratified Random Samples

If the population contains two or more mutually exclusive categories (i.e., strata), a stratified random sample can be created. To do this, simple random sampling is used within each stratum to identify members of the sample. Often, the size of each stratum in the sample is made to be proportionate to corresponding stratum in the population. For example, if a population is made up of 70% men and 30% women, the sample might be set up to contain these same sex proportions. Researchers sometimes *oversample* one or more of the population's strata; this is done if it is known that the members of certain strata are less likely to return surveys, less likely to remain in a study until its completion, and so on.

Cluster Samples

Sometimes, naturally occurring samples exist. For example, students in a classroom within a university represent a cluster of potential participants for a researcher interested in evaluating the effects of a new curriculum. Or the members comprising a population might be so spread out geographically that simple random sampling could be difficult or even impossible. A researcher using cluster sampling first creates a list of all possible clusters within the population of interest (e.g., counties in a state or classes within a school). Then, a random sample of these clusters is chosen. Finally, the researcher either selects all subjects from these selected clusters (*single-stage cluster sampling*) or selects a random sample of subjects from within them (*two-stage cluster sampling*).

Nonprobability Sampling Techniques

Instead of starting with an existing, tangible population and then extracting a sample from a sampling frame, researchers often begin with a sample and then create an imaginary population that fits the sample. Such samples are called *nonprobability samples*, and they differ from probability samples in two main respects, as follows: (1) the temporal sequence in which the sample and population come into existence and (2) the nonuse of random sampling procedures.

With both probability and nonprobability samples, the typical goal is to generalize information gleaned from the sample to the relevant population. As indicated earlier in this discussion, such generalizations often involve estimation and/or hypothesis testing. These two kinds of statistical procedures can be used with nonprobability samples just as easily as they can be used with probability samples. The main difference is that the statistical inference based on a nonprobability sample is aimed at a population that is abstract rather than concrete.

The four main types of nonprobability samples are convenience samples, quota samples, snowball samples, and purposive samples.

Convenience Samples

Sometimes researchers choose their samples based on who or what is available at the time an investigation is undertaken. Such samples are called convenience samples. (Convenience samples are also called *haphazard* or *accidental* samples.) For instance, many researchers gather data from college students (especially freshmen) because they are readily available and willing to participate in research. Or suppose a researcher goes to a local nursing home and measures the mobility

of all residents. If the resulting data from this study are used to generate confidence intervals or to evaluate stated null hypotheses, then those data can be said to come from a convenience sample.

Quota Samples

Quota samples are similar to stratified random samples; however, quota sampling does not use random selection. For example, suppose that a researcher wishes to correlate people's gender and hand preference in a city where there are as many males as females. Suppose also that this researcher stands at a busy street corner in a large city and asks this simple question to the first 50 males and the first 50 females who pass by: Are you right-handed, left-handed, or ambidextrous? The resulting sample of 100 people in this study is a quota sample. Once the predetermined number of male or female slots is filled, no more people of that gender would be queried about their handedness.

Snowball Samples

Snowball sampling is used by researchers who need to identify people who, for one or more reasons, are difficult to find. For example, suppose a researcher wants to interview natives of Guam living in Florida. There most likely is no directory of such individuals from which a sample could be drawn. Therefore, the researcher might ask a few Guam-born Floridians to identify others they know who match the study's criteria. Those newly identified individuals might be asked to identify additional people living in Florida who came from Guam. Although snowball sampling, in certain studies, can generate an impressively large sample, the valid population is abstract in nature and can be defined only after the sample is formed.

Purposive Samples

In certain studies, the nature of the research questions necessitates that certain criteria be used to determine who or what goes into the sample. For example, suppose a market researcher wants to explore the marketability of a new twin stroller. Also suppose that this researcher would like to tap the opinions of women between the ages of 20 and 30 who have twins younger than 3 years. If data are collected from a group of individuals who possess these specific characteristics (mothers in their 20s with twins under the age of 3), then that group of individuals is a purposive sample. The relevant population to which valid generalizations can be made is abstract and cannot be conceptualized until we know where the sample was located geographically, what inducements (if any) were offered for

participating in the investigation, what experience (if any) the mothers had with strollers, and so on.

The Concept of "Sampling Error"

The data on a variable of interest gathered from a sample usually are summarized into a condensed, single-number representation (e.g., mean) of the sample called the sample *statistic*. Using estimation or hypothesis testing, the observed data from the sample are used to make an inferential statement about the population's unknown standing on the targeted variable, which is the population *parameter*.

Sampling error exists if the sample statistic differs in size from the population parameter. There usually will be a discrepancy between the sample statistic and the population parameter, even with randomly selected probability samples. The precise amount of sampling error is usually unknown because the magnitude of the population parameter is not known. However, the data from a sample can be used to estimate how probable it is that the sample statistic lies any given distance away from the population parameter. Such probabilities constitute the foundation of the statistical procedures that lead to confidence intervals or decisions to reject or fail to reject null hypotheses.

The likely size of sampling error can be determined by using sample data to estimate the *standard error* of the sample statistic. For example, if a study's focus is on the mean, then the sample data can be used to estimate the standard error of the mean SE_M via the formula

$$SE_M = \frac{s}{\sqrt{n}},$$

where s is the sample-based estimate of σ and n is the size of the sample. The estimated standard error provides a scientific guess as to amount of variability that would exist if many samples of the same size were drawn from the same population. Just as a standard deviation measures the amount of spread in a set of numbers, the estimated standard error indicates the expected amount of dispersion in the values of the sample statistic.

Misconceptions About Samples

A Random Sample Will Be Identical to the Population, Only Smaller

A common misconception about random sampling is that a random sample drawn from a population will have the exact same numerical characteristics as that population. In other words, many people think that a sample will have the same mean, median, standard

deviation, and so on, as the population from which it was drawn. This is a misconception because sampling error is likely to be present rather than be absent when a sample is extracted from a population.

Suppose a simple random sample of 100 people is taken from a large population containing equal numbers of males and females. It is possible, of course, for the sample to have as many males as females. However, the binomial distribution reveals that such an outcome has less than an 8% chance of occurring. Change the variable of interest from something that is dichotomous (such as gender) to something that is continuous (such as height or weight) and it is far less likely that the sample will be just like the population.

The Distribution of the Sample Statistic Has the Same Form as the Population's Distribution

Another common misconception about sampling concerns distributional shape. Many people think that the distributional form of a sample statistic, for example, the mean, will be identical to the shape of the population. People who believe this expect the sampling distribution of the mean to be negatively skewed if the population is negatively skewed, with both distributions having the same degree of skewness. This is not the case.

The Central Limit Theorem states that the sampling distribution of $\bar{X}$ tends toward normality as n increases, *regardless of the shape of the population*. Moreover, simulation studies have shown that the sampling distribution of the mean is fairly normal even if n is small and even if the population is far from normal. For example, if the sample size is 10 and if the population is rectangular, it is striking how close to normal the sampling distribution of $\bar{X}$ is. Increase n to 25, and the sampling distribution appears exceedingly bell shaped (with only slight deviations from the skewness and kurtosis indices of the normal curve).

Large Populations Require Large Samples

Intuition leads many people to believe that a sample's quality is related to the relative size of n to N . According to this line of reasoning, a sample needs to be larger if it is being drawn from a larger population. In reality, it is the absolute size of n that most influences the quality of a sample, not the relative size of n to N . This becomes apparent if one examines the formula for the standard error of the statistic. When a finite population exists, the size of N plays a meaningful role only when a tiny sample is drawn from a small population. When n is not small, the size of the standard error is determined almost totally by n ; in this situation, it

matters little whether N is slightly or greatly larger than n . This is why political polls can end up being so accurate even though they are based on data from only a tiny fraction of the sampled population.

SAMPLE SIZE

Sample size refers to the number of subjects in a study. If there is only one sample, then the sample size is designated with the letter "N." If there are samples of multiple populations, then each sample size is designated with the letter "n." When there are multiple population samples, then the total sample size of all samples combined is designated by the letter "N."

A study's sample size, or the number of participants or subjects to include in a study, is a crucial aspect of an experimental design. Running a study with too small of a sample runs numerous risks including not accurately reflecting the population a sample was drawn from, failing to find a real effect because of inadequate statistical power, and finding apparent effects that cannot be replicated in subsequent experiments. However, using more subjects than necessary is

a costly drain on resources that slows completion of studies. Furthermore, if an experimental manipulation might pose some risk or cause discomfort to subjects, it is also ethically preferable to use the minimum sample size necessary. This entry focuses on the factors that determine necessary sample size.

Magnitude of Expected Effect

In general, when possible it is preferable to design an experiment looking for large effects that can be more easily detected with relatively small sample sizes. However, in many cases, small to modest effects can still be very important. For instance, important psychological processes might be associated with relatively subtle changes in detectable biological measures, such as the relatively minor changes in blood oxygen level dependent signaling (BOLD) that corresponds with neural activity. Additionally, treatments that produce relatively modest clinical improvements could still significantly benefit and improve the quality of life of afflicted individuals. Likewise, an even slightly more accurate diagnosis process could save countless lives. For studies looking to detect relatively small to modest effects, larger sample sizes will be needed.

Variability

The variability of data is a crucial factor for estimating what sample size is needed. The sample sizes needed in descriptive studies are dependent on the variability of measures of interests in the population at large. If the measures of interest are narrowly distributed in the population, then smaller sample sizes might be sufficient to predict these measures accurately. Alternatively, if these measures are broadly distributed in the population, then larger sample sizes are needed to predict these measures accurately.

For example, suppose a group of forestry students wished to determine the average tree height on a Christmas tree farm and in an adjacent forest. All the trees on this Christmas tree farm are 4-year-old Douglas firs, whereas the trees in the forest are of various ages and species. The students could likely measure relatively few trees in the Christmas tree farm and have an accurate idea of the average tree height, whereas they would likely have to measure many more trees in the forest to determine the average tree height there.

In experimental studies, the more variable data are across subjects, the more subjects will be needed to detect a given effect. One means of reducing variability across subjects and thereby reducing the sample size required to detect an effect is to use a within-subject design. Within-subject designs, or repeated testing on

the same subjects across the different phases of the experiment, reduces variability across subjects by allowing each subject to serve as his or her own control. Care must be taken to control for possible carryover effects from prior testing that might influence later measures.

For example, let us suppose a researcher wishes to test the effects of a novel drug on performance on a memory task. Under baseline conditions, there is a fair amount of variability in performance across subjects, but each subject scores about the same each time he or she performs the task. Using a within-subjects design and comparing each subject under placebo and drug conditions helps control for variability between subjects and allows the researcher to use a smaller sample size than would be necessary in a between-subject design with separate placebo and drug groups.

Statistical Criteria

A larger sample size will be needed to detect a significant finding as the alpha level (p value criteria for determining significance) becomes more conservative (i.e., going from maximum acceptable p value of .05 to .01 or .001). This is a potential issue when alpha corrections are needed because of multiple statistical comparisons. A smaller sample size is necessary for one-tailed than two-tailed statistical comparisons. However, one-tailed statistical comparisons are only appropriate when it is known a priori that any difference between comparison groups is possible in only one direction.

Sample Size Estimation

There are several commercially available software programs for estimating required sample sizes based on study design, estimated effect size, desired statistical power, and significance thresholds. In addition, free estimation programs might be found through a search using an Internet search engine.

SAMPLE SIZE PLANNING

Sample size planning is the systematic approach to selecting an optimal number of participants to include in a research study so that some specified goal or set of goals can be satisfied. Sample size planning literally addresses the question “What size sample should be used in this study?” but an answer to the question must be based on the particular goal(s) articulated by the researcher. Because of the variety of research questions that can be asked, and the multiple inferences made in many studies, answering this question is not always straightforward. The appropriate sample size depends on the research questions of interest, the statistical model used, the assumptions specified in the sample size planning procedure, and the goal(s) of the study. In fact, for each null hypothesis significance test performed and/or confidence interval constructed, a sample size can be planned so as to satisfy the goals of the researcher (e.g., to reject the null hypothesis and/or obtain a sufficiently narrow confidence interval). Each of the possible sample size planning procedures can suggest a different sample size, and these sample sizes can be very different from one another.

The most common approach when planning an appropriate sample size is the *power analytic approach*, which has as its goal rejecting a false null hypothesis with some specified probability. Another approach, termed *accuracy in parameter estimation* (AIPE), has as its goal obtaining a sufficiently narrow $(1 - \alpha)\%$ confidence interval for a population parameter of interest, where $1 - \alpha$ is the desired confidence interval coverage, with α being the Type I error rate. Notice that the two perspectives of sample size planning are fundamentally different in their respective goals, with the former being concerned with rejecting a null hypothesis and the latter with obtaining sufficiently narrow confidence intervals. Perhaps not surprisingly, depending on the specific goals, the implied sample size from the two perspectives can be very different. Although other approaches to sample size planning exist, the power analytic and the AIPE approaches serve as broad categories for conceptualizing the goals of sample size planning.

In null hypothesis significance testing, where an attempt is made to test some null hypothesis, not having an adequate sample size can lead to a failure to reject a false null hypothesis—one that should in fact be rejected. When a false null hypothesis is not rejected, a Type II error is committed. In such situations, the failure to find significance oftentimes renders the study inconclusive because it is still uncertain whether the null hypothesis is true or false. Conversely, if the goal of the research study is to reject some specified null

hypothesis, then it is not generally a good use of time and resources to use a larger than necessary sample size. Furthermore, if the goal of the research study is to reject some specified null hypothesis and a power analysis suggests a sample size that would be exceedingly difficult to obtain given available resources, a researcher might decide to conduct a modified version of the originally proposed study or decide that such a study, at present, would not be a good use of resources because of the low probability of success.

A recent emphasis in the methodological literature on effect sizes and confidence intervals has made the dichotomous results of null hypothesis significance testing (reject or fail to reject) less of the focus of the research study than they once were. The AIPE approach to sample size planning attempts to overcome large confidence interval widths by planning an appropriate sample size, where the expected confidence interval width is sufficiently narrow or where there is some desired degree of assurance that the confidence interval width will be no larger than specified (e.g., sample size so that there is 99% assurance that the 95% confidence interval will be sufficiently narrow). Similar in spirit to the AIPE approach is one where an appropriate sample size is planned so that an estimate will be sufficiently close to the population parameter with some specified probability. Still others suggest that power and accuracy should be considered together, where there is some specified probability of simultaneously rejecting some false null hypothesis and obtaining a confidence interval that is sufficiently narrow.

The proverbial question “What size sample should I use?” has been repeatedly asked by researchers since inferential statistics became a research tool. However, an appropriate answer depends on several factors and is not always easy to determine. The sample size can be planned for any and all parameters in a model and from multiple approaches. Thus, for research questions that have more than a single parameter, as most research questions do, an appropriate sample size must be based on the question of interest, which is in turn based on one or more parameters. Coupling multiple parameters with different approaches adds to the potential complexity of sample size planning. Regarding multiple parameters, one issue often overlooked is that if several parameters have sufficient statistical power or narrow expected confidence interval width, then there is no guarantee that the entire set of parameters will simultaneously have sufficient statistical power or narrow expected confidence interval width.

An appropriate sample size thus depends on the parameter(s) of interest, the goal of the research study, and the characteristics of the population from which the data are sampled. If there is more than one question

of interest, then there will likely be more than one appropriate sample size. In such situations, choosing the largest of the planned sample sizes is advised.

SAMPLING

Sampling occurs when researchers examine a portion or sample of a larger group of potential participants and use the results to make statements that apply to this broader group or population. The extent to which the research findings can be generalized or applied to the larger group or population is an indication of the external validity of the research design. The process of choosing/selecting a sample is an integral part of designing sound research. An awareness of the principles of sampling design is imperative to the development of research with strong external validity. In theory, a sound sampling method will result in a sample that is free from bias (each individual in the population has an equal chance of being selected) and is reliable (a sample will yield the same or comparable results if the research were repeated).

A sample that is free from bias and reliable is said to be representative of the entire population of interest. A representative sample adequately reflects the properties of interest of the population being examined, thus enabling the researcher to study the sample but draw valid conclusions about the larger population of interest. If the sampling procedures are flawed, then the time and effort put into data collection and analysis can lead to erroneous inferences. A poor sample could lead to meaningless findings based on research that is fundamentally flawed. Researchers use sampling procedures to select units from a population. In social science research, the units being selected are commonly individuals, but they can also be couples, organizations, groups, cities, and so on.

This entry begins by detailing the steps in the sampling process. Next, this entry describes the types of sampling. The entry ends with a discussion of evaluating sampling and determining sample size.

Steps in the Sampling Process

The sampling process can be diagrammed as shown in Figure 1.

Identifying the population or entire group of interest is an important first step in designing the sampling method. This entire population is often referred to as the *theoretical* or *target population* because it includes all of the participants of theoretical interest to the researcher. These are the individuals about which the researcher is interested in making generalizations. Examples of possible theoretical populations are all high school principals in the United States, all couples over age 80 in the world, and all adults with chronic fatigue syndrome. It is hardly ever possible to study the entire theoretical population, so a portion of this theoretical population that is accessible (the *accessible population* or *sampling frame*) is identified. Researchers define the accessible population/sampling frame based on the participants to which they have access. Examples of accessible populations might be the high school principals in the state of Colorado, couples over age 80 who participate in a community activity targeting seniors, or patients who have visited a particular clinic for the treatment for chronic fatigue syndrome. From this accessible population, the researcher might employ a sampling design to create the *selected sample*, which is the smaller group of individuals selected from the accessible population. These individuals are asked by the researcher to participate in the study. For example, one might sample high school principals by selecting a random sample of 10 school districts within the state of Colorado. In other cases, the accessible population might be small enough that the researcher selects

Figure 1 Sampling Process Diagram

all these individuals as the selected “sample.” For example, a researcher studying couples older than age 80 who participate in a particular community activity could choose to study all the couples in that group rather than only some of them. In this case, the accessible population and the selected sample are the same. A third example of an accessible population could be if the patients treated during a certain 3-month time period were chosen as the selected sample from the accessible population of all individuals seeking treatment for chronic fatigue syndrome at a particular clinic.

Finally, the researcher has the *actual sample*, which is composed of the individuals who agree to participate and whose data are actually used in the analysis. For example, if there were 50 older couples at the community activity, perhaps only 30 (a 60% response rate) would send back the questionnaire.

The advantages to using a sample rather than examining a whole population include cost-effectiveness, speed, convenience, and potential for improved quality and reliability of the research. Designing a sound sampling procedure takes time and the cost per individual examined might be higher, but the overall cost of the study is reduced when a sample is selected. Studying a sample rather than the entire population results in less data that need to be collected, which can thereby produce a shorter time lag and better quality data. Finally, by examining a sample as opposed to an entire population, the researcher might be able to examine a greater scope of variables and content than would otherwise be allowed.

Although there are advantages to using sampling, there are some cautions to note. The virtues mentioned previously can also end up being limitations if the sampling procedures do not produce a representative sample. If a researcher is not prudent in selecting and designing a sampling method, then a biased and/or unreliable sample might be produced. Knowledge of what biases might potentially result from the choice of sampling method can be elusive. The errors can be especially large when sample observations falling within a single cell are small. For example, if one is

interested in making comparisons among high school principals of various ethnic groups, then the sampling process described previously might prove problematic. A random sample of 10 Colorado school districts might produce few principals who were ethnic minorities because proportionally there are relatively few large urban districts that are more likely to have minority principals. It is possible that none of these districts would be randomly selected.

Types of Sampling

When each individual in a population is studied, a census rather than a sample is used. In this instance, the accessible population contains the sample individuals as does the selected sample. When sampling methods are employed, researchers have two broad processes to choose from: probability sampling and nonprobability sampling. If using probability sampling, the researcher must have a list of and access to each individual in the accessible population from which the sample is being drawn. Furthermore, each member of the population must have a known, nonzero chance of being selected. Nonprobability sampling, in contrast, is used when the researcher does not have access to the whole accessible population and cannot state the likelihood of an individual being selected for the sample.

Probability Sampling

Probability sampling is more likely to result in a representative sample and to meet the underlying mathematical assumptions of statistical analysis. The use of some kind of random selection process increases the likelihood of obtaining a representative sample. Simple random sampling is the most basic form of probability sampling in which a random number table or random number generator is used to select participants from a list or sampling frame of the accessible population. Stratified random sampling enables the researcher to divide the accessible population on some important characteristic, like geographical region. In this way, each of these stratum, or segments of the

population, can be studied independently. Other types of probability sampling include systematic sampling and cluster sampling. The earlier example involving the selection of high school principals used a two-stage cluster sampling procedure, first randomly selecting, for example, 10 school districts then interviewing all the principals in those 10 districts. This procedure would make travel for the observation of principals much more feasible, while still selecting a probability sample.

Nonprobability Sampling

Probability samples, although considered preferable, are not always practical or feasible. In these cases, nonprobability sampling designs are used. As the name would imply, nonprobability sampling designs do not involve random selection; therefore, not everyone has an equal chance of selection. This does not necessarily lead to a sample that is not representative of the population. The level of representativeness, however, is difficult to determine.

A convenience sampling design is employed when the researcher uses individuals who are readily available. In quota sampling, quotas are set for the number of participants in each particular category to be included in the study. The categories chosen differ depending on what is being studied but, for example, quotas might be set on the number of men and women or employed or unemployed individuals.

Evaluating Sampling

A variety of steps in the sampling process might lead to an unrepresentative sample. First is the researcher's selection of the accessible population. Most often, the accessible population is chosen because it is the group that is readily available to the researcher. If this accessible population does not mirror the theoretical population in relation to the variables of interest, the representativeness of the resulting sample is compromised. The researcher's choice of sampling design is another entry point for error. It is not very likely that a nonprobability sample is representative of the population, and it is not possible to measure the extent to which it differs from the population of interest. A poor response rate and participant attrition can also lead to an unrepresentative sample. The effects of these nonresponses can be dramatic if there are systematic differences between those individuals who did and did not respond or drop out. Often, there is no way to know to what extent the resulting sample is biased because these individuals might differ from those who responded in important ways.

Sample Size

There is no single straightforward answer in relation to questions regarding how large a sample should be to be representative of the entire population of interest. Calculating power is the technically correct way to plan ahead of time how many participants are needed to detect a result of a certain effect size. The underlying motivation behind selecting a sampling method is the desire for a sample that is representative of the population of interest. The size of the selected sample depends partly on the extent to which the population varies with regard to the key characteristics being examined. Sometimes, if the group is fairly homogeneous on the characteristics of interest, one can be relatively sure that a small probability sample is representative of the entire population. If people are very similar (as in a selected interest group, individuals with a certain syndrome, etc.), one might suspect the sample size would not need to be as large as would be needed with a diverse group. The level of accuracy desired is another factor in determining the sample size. If the researcher is willing to tolerate a higher level of error for the sake of obtaining the results quickly, then he/she might choose to use a smaller sample that can be more quickly studied. A researcher must also consider the research methodology chosen when determining the sample size. Some methodologies, such as mailed surveys, have lower typical response rates. To obtain an actual sample of sufficient size, a researcher must take the anticipated response rate into consideration. Practical considerations based on time and money are probably the most common deciding factors in determining sample size.

SAMPLING DISTRIBUTIONS

Sampling distributions are the basis for making statistical inferences about a population from a sample. A sampling distribution is a set of samples from which some statistic is calculated. The distribution formed from the statistic computed from each sample is the sampling distribution. If the statistic computed is the mean, for example, then the distribution of means from each sample form the sampling distribution of the mean. One problem solved by sampling distributions is to provide a logical basis for using samples to make inferences about populations. Sampling distributions also provide a measure of variability among a set of sample means. This measure of variability will, in turn, allow one to estimate the likelihood of observing a particular sample mean collected in an experiment to test a hypothesis.

At the simplest level, when testing a hypothesis, one is testing whether an obtained sample comes from a known population. If the sample value is likely for the known population, then it is likely that the value must come from the known population. If the sample value is unlikely for the known population, then it likely does not come from the known population, and it can then be inferred that it comes from a different unknown population instead. If some treatment is performed, such as giving a drug to improve patient recovery time, then the average recovery time from a sample of the treated group will allow a test of the idea that the treatment had some effect (here on recovery time). Does giving patients this new drug in effect create a new and different population—a population using the drug? If the average recovery time of the treated group is very similar to, or likely for, the known population of patients that do not take the drug, then the treatment likely had no effect. If the average recovery rate is very different from, or very unlikely for, the known population of patients not taking the drug, then the treatment must have had an effect and created a new population of patients with different recovery times. Thus, some way to judge how likely a value is for the known population is needed.

The common formula used to find the probability or the likelihood of a value for a known population (solving z -score problems) is

$$z = \frac{X - \mu}{\sigma}.$$

In the previous formula, the standard deviation sigma (σ) provides information about how much variability exists in the population. Knowing how much variability exists in the population (the width of the distribution of scores) allows one to know how likely a single x value is for that population. Because most values in a distribution will lie close to the mean, less likely values will fall farther from the mean. The wider the distribution of scores, the less pronounced any specific difference between a value and the mean will be. For example, if the difference between an x value and the population mean remains constant (in the numerator), then that difference will be much more likely if the population has a very wide distribution (large denominator) compared with its likelihood in a very narrow distribution (small denominator). So, any factor, like a decreased spread in the distribution of scores, which increases the relative difference between a value and the mean will lower the estimate of how likely the value is for the distribution.

However, when testing a hypothesis, it is never based on a single x value. Instead, a sample of values is used from which the average is computed. If the average or mean value tested is very different from the known population, then it can be assumed that the population the sample represents is not the same as the known population. The problem in using the previous formula is that sigma gives information about how much individual values vary within a population but provides nothing about how much *sample means* vary. Sampling distributions provide an explanation of how to measure variability in samples and, thus, the probability of observing a particular sample mean.

Sampling Distribution of the Mean

Sampling distributions are theoretical and not actually computed. However, examining the process of computing one is necessary. There are many types of sampling distributions, and a sampling distribution for any statistic can be formed. For the current discussion, the sampling distribution of the mean is most relevant. To form a sampling distribution, a researcher will do the following:

1. Sample repeatedly and exhaustively from the population.

2. Calculate the statistic of interest (the mean) for each sample.
3. Form a distribution of the set of means obtained from the samples.

The values taken from the population to form a sample can be any specific size, but every possible sample of that size from the population must be taken. Then, an average of each sample is computed. The set of means obtained from each sample will form a new distribution, which is called a sampling distribution. In this case, where the mean is computed as the statistic, it will be the sampling distribution of the mean. Every possible combination of values from the population is sampled to form a true sampling distribution. Because most populations are very large, it is impractical actually to go through the process of forming a sampling distribution, which is why they remain theoretical.

Information Gained

The first important fact learned from the sampling distribution of the mean is that the mean of the population and the mean of the sampling distribution of means will have exactly the same value. That is, the average of the entire population of single x values is exactly the same as the average value obtained if each sample mean from the sampling distribution of means is averaged together. This fact is important to hypothesis testing because when testing a hypothesis based on a sample, even though a single sample will not likely yield a mean exactly the same as that of the population, on average it will be exactly the same. Thus, it is certain that repeated experiments will yield samples that will on average be the same as the population. Using a sample to make an inference about a population is therefore a logical and reasonable proposition.

The next important piece of information obtained from the sampling distribution of the mean is a measure of variability among sample means. Recall that some way to measure how much variability exists in a set of sample means is needed so that there will be some way to gauge how likely it is to obtain a particular sample mean collected in an experiment. If the mean value obtained in a sample is unlikely for the known population, then the population the value comes from is probably different from the known population. If the mean value obtained in the sample is likely or similar to the known population, then it is likely there is no difference between the population the value comes from and the known population. If there is a large amount of variability from sample to sample, then an individual sample mean obtained to test a hypothesis will have to be

much more different from the known population to stand out distinctively and be considered unlikely for that population than if there is little variability from sample to sample. The standard deviation, just as with other distributions, will be the measure used to indicate the spread or dispersion of a distribution. Just as with the standard deviation of a population of individual values in which the amount of variability that exists is measured by how much individual values deviate from the average, variability in the set of sample means will be computed the same way. When measuring the average deviation of a set of sample means in a sampling distribution, the amount of variability that exists from sample to sample is being measured. This measure of the standard deviation of a distribution of sample means is called the *standard error* and is symbolized as $\sigma_{\bar{x}}$.

Because the sampling distribution of the mean is theoretical, there is no need to calculate the standard error every time an inferential test is conducted. Instead, an estimate is made from the population or the sample. The formula to estimate the standard error from the population is

$$\sigma_{\bar{x}} = \sigma / \sqrt{n}.$$

The previous formula can be used if the population standard deviation is known. If so, it forms the denominator for a z -score hypothesis test:

$$z = \frac{\bar{X} - \mu}{\sigma_{\bar{x}}}.$$

If the population standard deviation is not known, which is usually the case, then the population standard deviation must be estimated from the obtained sample. Although the standard deviation estimated from a sample is calculated slightly differently than when all the population values are known, the computation of the standard error is essentially the same. In such cases, the standard error is usually represented with Roman instead of Greek letters. So, the standard error is represented as $S_{\bar{x}}$ and is computed with the formula

$$S_{\bar{x}} = S / \sqrt{n}.$$

In addition, when using the sample to estimate the standard deviation, one is no longer computing a z test but a t test instead:

$$t = \frac{\bar{X} - \mu}{S_{\bar{x}}}.$$

Notice that the denominator is an estimate of the standard error, and it is the same whether computing a z test or a t test. The distance a sample mean falls from the mean of the population is mediated by how much variability exists from sample to sample. If it is

relatively unlikely to observe a certain sample ($p < .05$ for $\alpha = .05$), then one can conclude that the sample did not come from the known population.

Finally, sampling distributions also yield information about how large a sample needs to be to test a hypothesis. The shape of the sampling distribution of the mean will always be normal *regardless* of the shape of the population distribution. Whether the population distribution has a normal, positively or negatively skewed, or unimodal or bimodal in shape, the sampling distribution of the mean will always have a “normal” (unimodal and symmetric) shape. That is because when a distribution of sample means is formed, each value in the distribution is derived from a sample that contains a variety of scores from the population. Because each value in the sampling distribution is an average of these values from the population, most of the scores will be close to the mean of the population and create unimodal and symmetric distribution, even if the values in the population of single x values do not.

Recall that when values are used to form a sampling distribution, samples of any size can be used. However, the larger the number of values in a sample taken from the population to form the sampling distribution, the more “normal” the sampling distribution will be. That is because there will be a larger variety of values from the population in any individual sample, and it is more than likely the average from each sample will approximate the average value of the entire population. Thus, when 30 values in a sample are collected, enough variety is contained in the sample for those values to average out very close to the average of the population. However, the larger the number of values one takes in a sample, the closer one gets to the average of the population. Because an estimate of the standard error is usually made from a sample, the sample size needs to be around 30 to approximate the value that would be obtained if the standard error was computed from the population. Thus, the minimum number of values needed to approximate the population with a sample is close to 30, and it is best to have this minimum number in any sample used for hypothesis testing.

SAMPLING ERROR

Sampling error addresses how much, on average, the sample estimates of a study characteristic or variable, such as years of education, differ from sample to sample. Sampling error is essential in describing research results, how much they vary, and the statistical level of confidence that can be placed in them. Sampling error is also critical in tests of classic statistical significance. This entry provides basic definitions of concepts inextricably related to sampling error, describes when it is appropriate to calculate sampling error, and outlines when complications might occur in these calculations.

Populations and Samples

Which candidate do voters prefer in an upcoming election? What is the average level of formal education among American adults at least 25 years old? Considerable research tries to ascertain the value of some characteristic in a well-defined population. Researchers call the value of a selected characteristic in the population, such as a preference for “Candidate X,” a *population parameter*.

A *population* is the entire collection of cases, elements, or people that the researcher plans to study, such as all U.S. registered voters in November 2008. Notice the precision in the example population definition—it is specific to a particular quality such as voter status, location, and time. If a population is small, cooperative, and accessible, then collecting information is straightforward. For example, a small county has an address list of all registered voters. Such a list is called a population frame, and researchers ensure that it is as complete as possible. Collecting information from all population elements is called a census.

Most often, however, the population is too large, geographically dispersed, or unwieldy to collect information efficiently from every single element. When the United States conducts its decennial population census,

it can take a year to collect the information; even with such a massive effort, the U.S. Census undercounts some population segments, spending additional time making corrections. Thus, much research gathers information from a *sample* (i.e., a specified subpart or subset of the population). The value of a selected characteristic in a sample is called the *sample estimate* or the *sample statistic*. For example, surveys are gathered about voter preferences using samples prior to elections. Sampling error forms an integral part of generalizing from a sample to the larger population because the exact population value is typically unknown.

Many studies predict the population parameter from a sample estimate. However, because sample estimates rely on only a subset of population cases, the estimates will vary across the samples. If the sample is carefully selected using probability methods comparable with a lottery, most estimates will be close to the population parameter, but a few will deviate sharply from the population value. The study of this sample variability comprises much of the study of sampling error.

Types of Error in Parameter Estimation

Research practitioners distinguish two major sources of error in estimating population parameters. First is systematic error or *bias*, which is often hidden and thus uncontrolled. An example is the scale that always weighs its user 5 lb too light. Poundage loss or gain is reflected in the scale results—but always 5 lb under the true weight. Given a strong focus on sampling error, bias is often critically neglected. Strategies used to minimize bias include careful measurement (e.g., a correctly calibrated scale), using several different measures, and a probability sample.

The second major source of error in estimation is sampling error, or the average estimated variability of results from sample to sample. It is random and can sometimes be estimated in advance of the study if the researcher has sufficient information about the population. Random error means exactly that: There are no systematic deviations from the population parameter across a potential range of samples. Fluctuations in one direction from a sample mean or average in the long run over many samples are assumed to cancel fluctuations in a different direction from other samples. The results from any single sample, of course, could deviate in *any* direction from the population value. By definition, sampling error should only be calculated on probability samples because the laws of probability are used in its estimates.

Basic Types of Samples

Probability samples, in which each element or case has a known, nonzero chance of selection from a well-defined population, differ from nonprobability samples, in which the chances of selection are unknown. Typically, nonprobability samples have unknown chances of selection because human judgment has been substituted for probability selection methods. For example, students gathering data for a project might survey all customers visiting a convenient grocery store. Many magazines gather information from self-selected readers who mail in a completed questionnaire. Neither sample represents its larger population of grocery customers or magazine readers.

Effects of Sample Type on Sampling Error

Novice researchers are most familiar with simple random samples (SRS); not only does each element have an equal chance of selection, but also each combination of elements is equally probable. Think of a state lottery in which each winning number in a sequence is mechanically and separately drawn making any number progression possible. SRS calculations are the basic formulas used for sampling error in most statistical computer programs, such as the Statistical Package for the Social Sciences (SPSS, an IBM product). Calculation formulas for sampling error on other equal probability samples, such as cluster samples, in which several adjacent cases are selected at once (as, for example, when a researcher collects data from an entire classroom), are more complex.

Not all probability samples employ equal selection of sample elements. Some employ unequal selection: For example, to obtain sufficient women physicists in a study of university faculty, a researcher might “oversample” females, giving them greater chances of entering the study than men. Again, formulas to calculate sampling errors in unequal probability samples are more complicated.

Samples drawn from large, dispersed populations, especially where an initial complete frame is unavailable, often use multistage designs. In an area sample of households, researchers might first select states, then counties or parishes, blocks within counties, dwelling units within blocks, and respondents within dwelling units. Calculating sampling errors for multiple-stage designs is more complicated than those for a single-stage design.

Sampling Error and Sampling Distributions

An important statistical construct behind estimating sampling error is the *sampling distribution*, which is a (usually hypothetical) set of sample estimates from a theoretically infinite number of samples of the same size and type gathered within about the same time period. When pollsters draw many samples from a pool of registered voters during an election season, the data actually begin to approximate a sampling distribution: Suppose many samples were drawn from registered voters using SRS of size 1,600, with each respondent indicating his or her candidate choice. Suppose 40% preferred Candidate X in each of five samples, 30% chose her in one sample, 45% chose her in each of three samples, and so on. We then could create a graph with Candidate X preference percentage along the horizontal (x) axis and the frequency with which each sample estimate occurred along the vertical (y) axis. Given many such samples and many respondents in each one of those samples, the distribution of sample percentage estimates should resemble the familiar bell-shaped or normal curve. The average or mean percentage of all the sample results (40% in this example) is considered an *unbiased estimator* of the population parameter—what the researchers would have obtained had they been able to contact all U.S. registered voters within a short time period. It is critical to remember in estimating sampling error that the unit in a sampling distribution is a single sample result rather than an opinion from an individual respondent.

Confidence Intervals and Standard Errors

Considerable research predicts the population value from a sample statistic. It is helpful to approximate how much estimates can be expected to vary across samples. If the characteristic or variable of interest is numeric (e.g., years of age or dollars of income), then positive and negative error limits, which are called *confidence intervals*, can be placed around a single sample statistical estimate. Confidence intervals can only be constructed if the characteristic is an actual number or percentage. Most surveys or polls report confidence intervals when they explain that study results can vary by a certain amount (e.g., “40% of those interviewed prefer Candidate X—plus or minus 5%”). Thus, support for Candidate X could range from 35% to 45%—in most samples—typically 95 of 100 probability samples. Four main components comprise the confidence interval, as follows:

1. The result from one sample (e.g., 40% choosing Candidate X for president).
2. The variability around the mean, percentage, or average within that single sample called the *standard deviation*.
3. The size of the sample; recall that each sample size in the sampling distribution is the same (e.g., 1,600).
4. How confident the researcher wishes to be in his or her estimate. Sample estimates vary; some are very close to the population parameter (say, 39%), and a few are very different (e.g., a sample in which only 16% support Candidate X). The typical choice is to construct the interval such that 95% of the samples drawn produce estimates relatively close to the population parameter.

The estimate of average variability around the population parameter is called the *standard error* or sometimes the *standard error of the estimate*. The standard error is a measure of variability for the sampling distribution (i.e., how much we expect the results to vary on the average from sample to sample and from the “average sample” to the population parameter). If the sampling distribution approximates a normal curve, which it usually does with samples that have large casebases, by definition 95% of the sample estimates will be within two standard errors on either side of the estimated population parameter. In contrast, 5% of the samples will deviate considerably from the actual population parameter. Such an erroneous estimate can occur even with a probability sample. Based on the laws of chance, every now and then, there is a totally unrepresentative sample.

The results from large samples vary less from one sample to another than results from small samples: Larger samples have smaller sampling errors, thus producing more stable predictions. In fact, one way to minimize (thus partially control) sampling error is to take much larger samples. Samples with very little internal variability (small standard deviations) also differ less from sample to sample. So either large samples or samples with low internal variability produce estimates that deviate less across each another, have smaller confidence intervals, and tend to approximate the estimated population parameter more closely.

Putting it all together, the generic calculation formula for the 95% confidence interval (CI) around the mean is

$$CI = \bar{X} + 1.96 \times \sigma_{\bar{X}},$$

where $\bar{X}$ is a sample mean, +1.96 is the number of estimated standard error of the mean units on either side of mean (−1.96 to +1.96 standard errors incorporate about 95% of sample results), and $\sigma_{\bar{X}}$ is the estimated standard error of the mean.

Although it is somewhat cumbersome to do, the confidence interval can be estimated with a calculator, and virtually all statistical computer programs calculate it in seconds.

Some Other Uses of Sampling Error

Sampling error is important in creating estimates of the population value of a particular variable, how much these estimates can be expected to vary across samples, and the level of confidence that can be placed in the results. Furthermore, estimates of sampling error are involved in tests of statistical significance for most basic classic statistics. Some form of sampling error serves as a denominator in t tests for the difference between means from two separate samples, in analysis of variance and in regression statistics. Sampling error reminds us that it is not sufficient simply to “eyeball” differences in means or percentages across different groups because these differences might simply reflect chance sampling fluctuations rather than “real” differences. The study of sampling error reaffirms that sample statistics are just that: estimates of the population value from particular collections of data.

SAS

SAS, originally called the Statistical Analysis System, is a software suite that runs on most computers with a Windows, macOS, Linux, or Unix operating system. Growing out of a project aiming at analyzing agricultural data at North Carolina State University in the 1960s, SAS has evolved and developed into a software suite that consists of more than 150 products. SAS is capable of performing data entry, retrieval, management, and mining; graphics generation and reporting; statistical analysis; business planning, forecasting, and

decision-making; operation research and project management; and quality improvement. Although SAS offers a point-and-click front end (the windows-based graphical user interface) to users not familiar with the SAS language, SAS programming provides more flexibility, efficiency, and options in statistical analysis. The first limited release of the SAS system, SAS 71, occurred in 1971, while the more recent version, SAS 9.4M7, was released in October 2020.

Through more than 40 years of analytics innovation, SAS continues to provide state-of-the-art technologies for data analysis and management, such as artificial intelligence/machine learning, cloud computing, customer intelligence, fraud and security intelligence, and Internet of Things. This entry reviews the advantages and disadvantages of SAS.

Components

SAS consists of a number of components that may require separate licenses and installation. A list, though far from being complete, includes the following: Base SAS (the core of SAS), Enterprise Miner (a data mining tool), SAS/ACCESS (for the transparent sharing of data with non-native data sources), SAS/AF (applications facility), SAS/CONNECT (for communication between different platforms), SAS/ETS (for econometric and time series analysis), SAS/GRAPH (for charting on graphical media), SAS/INSIGHT (a dynamic data mining tool), SAS/IML (an interactive matrix language), SAS/OR (for operations research), SAS/QC (quality control tools), SAS/SHARE (a data server which enables multiple users to have simultaneous access to SAS files), and SAS/STAT (for statistical analysis).

Features

SAS has many features, making it a powerful tool for data management and analysis. It can read, write, and process data in different formats. Its system of formats and informats, which are used to control representation and categorization of data, enables users to create customized user formats. SAS also provides interaction with the operating system. For example, in Windows, through the Dynamic Data Exchange, users can connect SAS results with Microsoft Excel.

SAS supports implementation of structured query language, which is a standardized, widely used language that retrieves and manipulates data in relational tables and databases. Structured query language provides an alternative to other SAS procedures or the DATA step and is an easy and flexible way to query and combine data.

SAS/ACCESS modules allow communication with databases. Database tables, in most cases, can be treated as if they were native SAS data sets. As a result, data from different platforms can be combined without knowledge of the details and distinctions between data sources.

It supports dynamic data-driven code generation through the SAS macro language, which can make the SAS programs more dynamic and reusable. Large programs can be simplified by creating functions with parameters that can be evoked multiple times. Macros and other SAS commands can be stored in an external file, which can be shared and used easily by other users. The macros, to some extent, are similar to the packages or toolbox in other statistical software and minimize the tedious work on programming and significantly facilitate statistical planning, research, and preparation of results.

The Output Delivery System, which is designed to overcome the limitations of traditional SAS output, can deliver the output in various formats, such as RTF, PDF, HTML, XLS, XML, and SAS data sets. Output Delivery System provides high-quality, professional-looking, and detailed presentation output from SAS. Various styles available in Output Delivery System also enhance presentation output by controlling, for example, the report's content, overall color scheme, or font.

The Interactive Matrix Language (SAS/IML) gives users access to powerful and flexible programming in a dynamic, interactive environment. Results can be seen immediately; alternatively, statements can be stored in a module and executed later. SAS/IML makes possible easy and efficient programming with the many features for manipulation of arithmetic and characteristic expressions. As a part of the SAS system, it also gives users access to SAS data sets or external files with the rich SAS commands for data management.

The release of SAS 9.4M6 in 2019 added support of creating a Python object or executing a Python function using PROC FCMP or the DATA step.

Applications

Partly due to its powerful capability to import, export, and manipulate data sets of various formats, SAS is widely used for statistical analysis in many fields, such as banking, insurance, health care, life sciences, and manufacturing. SAS continues to be the standard statistical analysis software used for the submission of reports of clinical pharmaceutical trials to the U.S. Food and Drug Administration.

SAS is used at more than 83,000 sites in 147 countries. Approximately 14,000 SAS employees in more

than 50 countries provide local support for global implementations.

User Groups

SAS has various in-house, local, regional, and virtual user groups, which promote communication about understanding and using the software more productively. These SAS user groups make available some of the resources and the expertise of SAS programmers to the new users of SAS. SAS Users Group International is a nonprofit organization open to all SAS software users throughout the world. SAS Users Group International plans and sponsors an annual international conference to exchange ideas and explore ways of using SAS. In 2007, SAS Users Group International was changed to SAS Global Forum, which consists of more than 150 sessions as of 2020.

There are regional user groups, in which SAS users meet annually at multiple-day conferences. There are also virtual user groups consisting of SAS users who are in a specific industry or share other similarities.

Experimental Design Using SAS

The construction of optimal experimental designs requires powerful algorithms. SAS provides good support for experimental design. The ADX interface (available in SAS/QC) provides an easy-to-use and intuitive interface, data entry, and facility and interactive graphics throughout the entire experimental design process. SAS/QC provides two procedures for experimental design, FACTEX and OPTEX, to construct factorial and optimal designs, respectively. In addition, there also exists a collection of macros that can be obtained as a programming interface to tackle common experimental design tasks. For example, SAS macros and external procedures are available to ease implementation of multiphase optimization strategy (MOST), a research framework to optimize interventions using a factorial design; and sequential, multiple assignment, randomized trial (SMART), an innovative research design for building time-varying adaptive interventions.

Sample size requirements can be obtained easily using the POWER or GLMPOWER procedures. The PLAN procedure can be used to construct designs and randomization plans for factorial experiments, especially nested and crossed experiments and randomized block designs. The SEQDESIGN procedure provides various methods to compute the boundary values for a group sequential design. These procedures, together with the ADX interface, provide a rich set of design

tools for both proficient SAS programmers and those who are new to SAS programming.

Disadvantages

Although SAS has many features and is powerful for both data manipulation and analysis, it has some disadvantages when compared with other statistical software. First, it is not free, and the licensing is expensive while there exist free alternatives, such as R, an open-source software. Second, SAS requires programming, which takes time to learn, to fully explore the many options it provides. Its graphical output is not as elegant as other statistical software, such as R. Although SAS can also be used to perform machine learning, it is less flexible and has less frequent updates, compared to some other software such as Python.

theoretical saturation by Barney Glaser and Anselm Strauss in their 1967 book *The Discovery of Grounded Theory*. They defined the term as the point at which “no additional data are being found whereby the [researcher] can develop properties of the category” (p. 61). Their definition was specifically intended for the practice of building and testing theoretical models using qualitative data and refers to the point at which a theoretical model being developed stabilizes.

As the use of qualitative research spread across academic fields and began to be employed outside of a grounded theory context, the broader terms *data saturation*, *thematic saturation*, or simply *saturation* were increasingly adopted. These terms reflect a wider application of the concept that goes beyond building theoretical models. In this broader sense, *saturation* refers to the point in qualitative data collection and analysis when new incoming data provide limited or no new information relevant to the research objectives. A data collector will intuitively recognize this point when they begin hearing similar concepts over and over again from participants. A data analyst will recognize it when incoming data no longer changes the content or structure of their thematic codebook. This entry discusses factors that affect saturation and the problem of determining the saturation point prior to starting research.

Factors That Affect Saturation

The following four factors are common determinants on the rapidity at which saturation is reached within a data set:

1. *The degree of instrument structure.* The more structure embodied in a data collection instrument or line of questioning, the sooner saturation will be reached. This means that for studies using a highly unstructured interview or focus group guide, or no guide at all, saturation will take a longer time to reach because the questions are constantly changing.
2. *The degree of sample homogeneity.* The more homogeneous the sample, the quicker saturation is achieved. People who share cultural backgrounds, socioeconomic traits, and/or lived experiences are more likely to perceive the world, and express those perceptions, in similar ways. This homogeneity of experience leads to less variability in responses and reaching saturation relatively early in the process.
3. *The complexity and focus of the study topic.* For more complex and intricate topics, it will take longer to reach saturation than for simpler and more focused topics. A highly targeted inquiry on a simple

SATURATION

Saturation is broadly defined as the stage in qualitative research where no new, relevant information emerges from additional interviews. Saturation has become the conceptual yardstick by which sample sizes for qualitative inquiry are judged. The concept of saturation was first introduced into the field of qualitative research as

subject matter, in contrast, conceptually constrains the range of likely responses, thereby resulting in saturation after fewer data collection events.

4. *Study purpose.* Finding high-level common themes across a sample will generally require fewer sampling units than identifying the maximum range of responses/themes within a sample. If a study is focused on finding significant issues, a small sample is often sufficient because these are typically highly salient and top of mind for individuals. And, they are more likely to be shared across a group or population. Conversely, if the objectives of a study require the comprehensive documentation of all the idiosyncrasies exhibited within a group or population of interest, it will require a much larger sample to ensure this range is captured.

Using Saturation to Estimate Sample Sizes for Qualitative Inquiry

A notable problem with the concept of saturation is that, as conceptualized, it can only be determined during or after data analysis. Yet in many research contexts, sample size specification is required before a study is implemented, often by funders and ethics committees. Applied qualitative researchers needed some guidance to estimate qualitative sample sizes *before* data collection begins.

Scholars have increasingly worked on this problem and, in recent years, have conducted systematic, empirically based studies to assess saturation points across qualitative data sets. Collectively, findings from these studies indicate that the majority of concepts and themes—as well as the most commonly expressed themes—are discoverable in the first six qualitative interviews. The caveat with these studies, however, is that their samples were relatively homogenous and topics of inquiry rather focused. For cross-cultural studies and/or research that has a heterogenous sample or a complex study topic, larger samples will likely be needed.

The empirical work on saturation has recently extended to focus groups. Several methodological studies conducted since 2010 have shown that the majority of themes were discoverable—that is, saturation was reached—within two to three focus groups. More than 90% of themes were discoverable after three to six groups.

Despite the progress made to date, more empirical research is needed to better understand saturation points across different research contexts, for both individual interviews and focus groups. Qualitative

researchers are now looking for more valid and reliable ways to operationalize and determine if and when saturation was reached *after* a study is completed. A new line of scholarly inquiry is endeavoring to do just that.

SCATTERPLOT

A scatterplot is a graphic representation of the relationship between two or three variables. Each data point is represented by a point in n space, where n is the number of variables. The most common type of scatterplot involves two variables, with data indicated by its bivariate coordinates, usually denoted by X and Y . Trivariate plots are also common. Representing data in more than three dimensions requires multiple bivariate and/or trivariate plots. So basically, all scatterplots fall into two types: bivariate and trivariate.

Manipulated data points are used to present a bivariate scatterplot in Figure 1 and a trivariate plot in Figure 2.

Scatterplots in Data Analysis

Scatterplots can be used to represent variables that have linear, nonlinear, or no relationship. Often scatterplots can be used to provide researchers with the information necessary to decide whether they should fit a linear model to their data. This is particularly important if they plan to use a statistical technique that assumes linearity, such as an ordinary least squares regression. Looking at the scatterplot in Figure 3 would lead a researcher to understand that fitting a linear model would be misleading.

Correlation and Regression

Correlation is a good way to examine the linear relationships between two variables, for example, a person's weight and height, or a student's high school

grade point average, and his SAT/ACT score. The strength of the relationship between two variables is usually described in terms of the correlation coefficient (also known as the Pearson correlation coefficient), which ranges from -1 to 1 . A scatterplot is often used to provide researchers the graphic view of what tends to happen to one score when another score increases/decreases.

When a set of variables is at hand, it is fairly easy to draw the scatterplot by plotting one score on the vertical axis and the other on the horizontal axis. Figures 4 through 7 provide examples of variable pairs with correlations of -0.8 , -0.3 , 0.3 , and 0.8 , respectively.

A positive correlation describes the situation in which an increase in variable X is associated with an increase in variable Y , whereas a negative correlation implies that an increase in variable X is associated with a decrease in variable Y . But a correlation of 0.8 is not stronger than a correlation of -0.8 . It is the magnitude that matters. They simply work in opposite directions.

In certain extreme situations, all of the dots fall on a straight line. This is called a perfect correlation. Figures 8 and 9 show perfect positive and perfect negative correlations, respectively.

The line interpolating all the dots in Figures 8 and 9 is considered as the line of best fit. In a real-world data analysis, the line of best fit does not necessarily go through all the dots in a scatterplot. Essentially, the line of best fit means that a line is closest to most of the dots or a line is as close to most of the dots as

Figure 1 Bivariate Scatterplot

Figure 2 Trivariate Scatterplot

Figure 3 Nonlinear Model With Zero Correlation

Figure 4 Bivariate Linear Relation With Positive Correlation = 0.3

possible. The vertical distances between the line and those dots are called residuals. In statistics, the least squares method is used to get a regression line, which minimizes the sum of the squared residuals. Generally, the line of best fit is also referred to as the regression line.

Before a regression analysis is implemented, a scatterplot is helpful in judging whether the regression line is appropriate to depict the relationship between two variables. Standard statistical software, like SAS, SPSS, R, and S-Plus, can generate a scatterplot with the regression line. Figure 10 shows a scatterplot and the corresponding regression line. This graphic representation indicates it makes sense to use the score from variable X to predict the score in variable Y.

Figure 5 Bivariate Linear Relation With Negative Correlation = -0.3

Figure 6 Bivariate Linear Relation With Positive Correlation = 0.8

Test for Normality

Normality assumption is required by most statistical procedures. Statisticians usually use a normal quantile-quantile (Q-Q) plot to check the normality of a variable. Figure 11 is the example of a Q-Q Plot.

The Q-Q plot is a type of bivariate plot that can be used to identify commonly encountered departures from normality as shown in Table 1.

Time-Series Analysis

Scatterplots are also used in time-series analysis. It is assumed that the noise series for an

Figure 7 Bivariate Linear Relation With Negative Correlation = -0.8

Figure 9 Perfect Negative Correlation

Figure 8 Perfect Positive Correlation

Figure 10 Scatterplot and Corresponding Regression Line

autoregressive-moving average model must be stationary, which means that both the expected values of the series and its autocovariance function are independent of time. These scatterplots with needles are called autocorrelation functions (ACFs) because they show the degree of correlation with past values of the series as a function of the number of periods in the past (that is, the lag) at which the correlation is computed. A scatterplot of this series and its autocorrelation function is the standard way to check for nonstationarity. The autocorrelation plot shows how values of the series are correlated with past values of

Figure 11 Q-Q Plot

Table I Commonly Encountered Departures From Normality

<i>Description of Point Pattern</i>	<i>Possible Interpretation</i>
Some points do not fall on a line	Outliers in the data
Left end of pattern is below the line; right end of pattern is above the line	Long tails at both ends of the data distribution (platykurtosis)
Left end of pattern is above the line; right end of pattern is below the line	Short tails at both ends of the distribution (leptokurtosis)
Curved pattern with slope increasing from left to right	Data distribution is skewed to the right
Curved pattern with slope decreasing from left to right	Data distribution is skewed to the left
Staircase pattern (plateaus and gaps)	Data have been rounded or are discrete

Figure 12 Stationary Series

the series. A series is considered nonstationary if a visual inspection of the autocorrelation function plot indicates that the ACF decays very slowly. If the series is nonstationary, then the next step is to transform it to a stationary series by differencing. Figure 12 shows an example of a stationary series because the ACF decays very drastically. Actually, this series was generated by a random number generator.

SCHEFFÉ TEST

The Scheffé test is one of the oldest multiple comparison procedures in use today. It is important to recognize that it is a frequently misused procedure and that it is also a valuable test when used as Henry Scheffé intended it. Unlike competitors such as Tukey’s Honestly Significant Difference test, the Scheffé test is specifically designed for the situation in which post hoc comparisons involve more than pairwise differences. For example, it could be used to compare the mean of two groups to the mean of two other groups on the basis of interesting differences that appeared after the data had been collected.

This entry begins by describing the background and development of the Scheffé test. Next, this entry details the test statistic, its role in variance heterogeneity, and its relation with the Bonferroni correction and a priori tests. Last, the entry discusses how the Scheffé test is implemented in computer programs and its future in the field.

Background

Like much in statistics, it all started with John Tukey. In a series of oral presentations beginning in about 1950 and culminating in what might be the most cited unpublished manuscript in statistics, Tukey developed the concept of error rates, focusing on the per comparison and familywise rates. Scheffé developed his procedure at the time that Tukey was speaking about his own ideas on multiplicity and, in a footnote to his paper, Scheffé explicitly gave credit to Tukey for the familywise error rate concept that was the basis for his test. The reason for focusing on the familywise error rate as the basis for a test is that it holds the error rate constant at α for the set of all possible contrasts, whether those contrasts had

been planned a priori or whether they were reached after examining the data. Scheffé's test was intended specifically as a post hoc test and is most appropriately used that way. It is also a simultaneous inference procedure because intervals or tests are computed simultaneously rather than in a stepwise or layered fashion.

The Test Statistic

Unlike most multiple comparison procedures, Scheffé's test was built on the standard F distribution. Although his derivation of the method is complex, a very clear explanation can be found in the text by Scott Maxwell and Harold Delaney. The basic idea is to find the distribution of the F_{maximum} statistic, which is the maximum possible F for *any* contrast on a set of means. Maxwell and Delaney show that the distribution of F_{maximum} is

$$F_{\text{maximum}} = (k-1)MS_{\text{Bet}} / MS_{\text{error}} \\ = (k-1)F_{.05; k-1, N-k},$$

where k is the number of groups, MS_{Bet} and MS_{error} are the between groups and error mean squares, and N is the total number of observations. The distribution of all possible contrasts (pairwise or complex) will have an F_{maximum} distribution under the null hypothesis and can be tested against $(k-1)F_{.05; k-1, N-k}$. Using that critical value, the familywise error rate will be, at most, α . If the omnibus null hypothesis is rejected, then at least one contrast will equal F_{maximum} . Although the Scheffé test is not a protected test like Fisher's least significant difference test, which requires a significant omnibus F before any comparisons are made, there is no point in using Scheffé's test unless the omnibus F is significant. If it is not significant, there can be no significant contrasts. In contrast, just because a significant omnibus F indicates that there will be at least one significant contrast, it does not guarantee that the contrast will be of any interest to researchers.

Scheffé's test has been controversial from the beginning. Scheffé and Tukey long debated the relative merits of F and Studentized range statistics as the basis for statistical decisions, and the lower power of Scheffé's test for all pairwise contrasts is well known. The Studentized range statistic is the difference between the largest and smallest means in a set divided by the square root of MS_{error} / n , where n is the size of any one sample. This statistic has its own distribution that is different from the standard F distribution. In a footnote to his original paper, Scheffé specifically said that if one were only interested in pairwise comparisons between all means, the Tukey test should be used instead because the confidence intervals would be shorter. The advantage of Scheffé's test is that it allows researchers to examine any contrast, whether it was arrived at

before the data were collected or after interesting mean differences appeared in the data. Currently, Scheffé's test is the only post hoc procedure that allows one to examine complex contrasts.

As an example of a complex contrast and its confidence interval, suppose that a study was conducted comparing five different forms of therapy and two of them seemed to be considerably more effective than the other three. It would be sensible to wish to compare the mean for those two treatments against the mean of the other three. The means are [210, 205, 190, 180, 185], with $MS_{\text{error}} = 264$ and the size of each sample (n_j) is 5. The overall F is 3.116, which is significant at $\alpha = .05$. The contrast of the first two groups against the last three groups is denoted as

$$\psi = (\Sigma c_j \bar{X}_j),$$

where $c_j = [1/2, 1/2, -1/3, -1/3, -1/3]$. (The simplest way for the researcher to arrive at the necessary coefficients is to break the design into the two subsets he or she wishes to compare, and then to take as the coefficients for members of each subset the reciprocals of the number of groups in that subset, making one subset negative.)

The F for this contrast would be

$$\psi = (\Sigma c_j \bar{X}_j) = \frac{1}{2}(210) + \frac{1}{2}(205) - \frac{1}{3}(188) - \frac{1}{3}(187) \\ - \frac{1}{3}(180) = 22.5, \\ F = \frac{n\psi^2}{\Sigma c_j^2 MS_{\text{error}}} = \frac{n(\Sigma c_j \bar{X}_j)^2}{\Sigma c_j^2 MS_{\text{error}}} \\ = \frac{5(22.5)^2}{.833 \times 264} = 11.51.$$

The critical value for this or any similarly calculated contrast would be $(k-1)F_{.05; k-1, N-k} = (4)2.87 = 11.47$, which would cause the rejection of the null hypothesis and the conclusion that the first two therapy conditions are significantly better than the other three conditions. To learn more about this contrast, confidence limits on the mean difference between the two sets of treatments can be calculated.

$$CI_{.95} = \psi \pm \sqrt{(k-1)F_{.05; k-1, df} \frac{\Sigma c_j^2 MS_{\text{error}}}{n}} \\ = 22.5 \pm \sqrt{11.466} \sqrt{\frac{.833 \times 264}{5}} \\ = 22.5 \pm (3.386)(6.633) \\ = 22.5 \pm 22.466 \\ = 44.966 - 0.034.$$

Although both ends of the confidence interval are positive, it is a very wide interval with a lower end very close to 0.00. Any number of intervals can be formed in this way and the probability that all intervals would simultaneously include the corresponding parameter is α .

The post hoc contrast that was just tested, and its associated confidence interval, could not be tested by other standard multiple comparison techniques in a way that would control the familywise error rate. But two qualifications need to be made for the last statement. First, Tukey would have argued that you would accomplish nearly the same thing, and perhaps something better, by making pairwise comparisons among all five means. However, Tukey's test would show all groups to be a homogeneous set, which is not particularly helpful. The second argument is that the price you pay for being able to run this, or any other, contrast is extremely high relative to the price you would pay for alternative approaches. For example, with five subjects in each of the five groups, Scheffé's test would require an F of

$$(k-1)F_{.05;4,20} = 4 \times 2.866 = 11.46,$$

whereas the comparable value for all pairwise Tukey HSD tests is

$$F = (q_{.05;5,20} / \sqrt{2})^2 = (4.23 / 1.414)^2 \\ = 2.991^2 = 8.946.$$

Clearly, the Tukey would be more powerful if one was willing to substitute pairwise comparisons for the contrast that was tested with Scheffé's test.

Variance Heterogeneity

The Scheffé test, like other tests involving the analysis of variance on means, assumes that error is normally distributed and homogeneous across groups. If this condition is not met, then the original test can be improved by applying what is known as the Brown-Forsythe procedure. In this case, the denominator of F is modified to adjust the estimate of error. The degrees of freedom (df) also need to be modified as shown:

$$F = \frac{(\sum c_i \bar{X}_i)^2}{\sum (c_i^2 / n_i) s_i^2}$$

and

$$df = \frac{\left(\sum_1^k c_i^2 s_i^2 / n_i \right)^2}{\sum_1^k (c_i^2 s_i^2 / n_i)^2 / (n_i - 1)}.$$

Similarly, the confidence intervals can be defined as

$$CI = \psi \pm \sqrt{(k-1)F_{.05;k-1,df}} \sqrt{\sum_1^k \left[(c_i^2 / n_i) s_i^2 \right]}.$$

Just as with homogeneous variances and equal sample sizes, these intervals will have a probability of α of *simultaneously* including the relevant parameter, which is one of the reasons that they are often called Simultaneous Test Procedures or Simultaneous Inference Procedures.

The Bonferroni as an Alternative Approach

One alternative that might immediately come to mind would be to apply a Bonferroni correction to evaluate several contrasts that might need to be tested. However, this is not a legitimate alternative when considering post hoc tests. (Using this correction, the researcher simply divides the desired familywise error rate by the number of contrasts run and uses that value of the critical p value for each contrast.) The Scheffé test would allow an infinite number of contrasts to be tested, so as a post hoc procedure, the adjusted p value for the Bonferroni would be α/∞ , which is undefined. Certainly that is not going to work. Thus, when making complex post hoc contrasts, holding the familywise error rate at α , Scheffé test is going to be the only choice.

A Priori Tests

It would be possible to apply Scheffé's procedure when several a priori contrasts need to be tested, and there might be situations in which that would be a practical approach. However, it is not likely that there would be enough a priori contrasts to warrant taking this step. For example, consider the study of five different therapies that were just examined. If two of those therapies were control treatments, then it would be reasonable to wish to compare the control treatments with the others using the contrast given previously. It would also be reasonable to compare the two controls with each other and perhaps planning pairwise comparisons among the three active treatments. But that would only come to five contrasts. The researcher might come up with one or two others that he or she would like to test, so perhaps there are seven contrasts. If Scheffé's test was used, the critical value of F would be 11.46, as

shown previously. Alternatively, if a Bonferroni correction was applied to the tests, it would require a significance level of $\alpha = .05/7 = .007$, which is equivalent to an F of only 4.807. Certainly, the researcher would rather work against a critical value of 4.807 than one of 11.46. Thus, the Bonferroni correction for the seven a priori contrasts is considerably more powerful than the Scheffé test, which would allow many more contrasts to be made that are not likely to be of interest. In fact, the researcher would have to run 18 contrasts for the Scheffé test to be more powerful than the Bonferroni in this situation, and it would be difficult to imagine any way the researcher could think of 18 sensible contrasts among five means.

Implementing Scheffé's Test in SAS and SPSS

Both SAS and SPSS, an IBM product, offer the Scheffé test as a post hoc test but only for pairwise comparisons. As noted earlier, the Scheffé should not be used for only pairwise tests. However, both programs allow the user to specify contrasts, although the user will have to calculate the critical value himself or herself, which is hardly a problem. SPSS allows the user to specify contrasts for the "One-way ANOVA" procedure, and SAS allows the user to define contrasts under "Proc GLM." Neither program will print out confidence intervals, so the user needs to do that by hand.

The Changing Landscape

When Tukey started working on multiple comparison procedures, he largely set the field moving in the direction of familywise error rates, which is where Scheffé's test fits. But the problem with the familywise error rate approach is that it is an extreme case. If a family consists of a large number of contrasts (pairwise or not), then any error is considered a failure of the entire set—the confidence intervals no longer cover *all* parameters. That is why the critical values are as large as they are. In the last decade of Tukey's life, he began to take an interest in Benjamini's False Discovery Rate, which aims to control the *number* of false discoveries (Type I errors) that a procedure will make, rather than focusing on allowing no errors. As the field moves further in that direction, tests such as Scheffé's, and perhaps even Tukey's, are likely to play a smaller role.

SCIENTIFIC METHOD

The term *method* derives from the Greek *meta* and *odos* meaning *following after*, suggesting the idea of order. Applied to science, method suggests the efficient, systematic ordering of inquiry. Scientific method, then, describes a sequence of actions that constitute a strategy to achieve one or more research goals. Relatedly, scientific *methodology* denotes the general study of scientific methods and forms the basis for a proper understanding of those methods.

Modern science is a multifaceted endeavor. A full appreciation of its nature needs to consider the aims it pursues, the theories it produces, the methods it employs, and the institutions in which it is embedded. Although all these features are integral to science, science is most illuminatingly characterized as method. Method is central to science because much of what we have learned from science has been acquired through use of its methods. Our scientific methods have been acquired in the course of learning about the world; as we learn, we use methods and theorize about them with increased understanding and success.

In this entry, scientific method is contrasted with other types of method. Then, some criticisms of the idea of scientific method are considered. Thereafter, four major theories of scientific method are outlined and evaluated. Finally, the place of methods in science is addressed.

Four Methods of Knowing

The American philosopher and scientist Charles Sanders Peirce maintained that there are four general ways of establishing beliefs. The poorest of these, the *method of tenacity*, involves a person stubbornly clinging to a familiar idea when challenged. The belief is sustained by an attitude of tenacity and unquestioned acceptance.

The *method of authority* maintains that ideas are held to be true simply because they are the ideas of a person who is deemed an expert or perceived to be in a position of power. Peirce noted that this method is superior to the method of tenacity, because some beliefs can be fixed by adopting the method. The *a priori method*, which is better than both of the methods just mentioned, involves an appeal to the powers of reason independent of scientific observation. It involves accepting beliefs on the grounds that they are intuitive, self-evident, and based on reason rather than experience. The *method of science* is the method that Peirce himself advocated. It is superior to the other three methods because it establishes belief by appeal to an external reality and not to something merely human. Unlike the other methods, which are prescientific, the method of science has the characteristic of self-correction because it has built-in checks along the way. For Peirce, only this method has the ability to lead eventually to the truth.

Criticisms of the Idea of Scientific Method

Despite the importance of method in science, the idea that there is a scientific method characteristic of scientific inquiry has been the subject of many criticisms. Perhaps the most frequently voiced criticism of scientific method is that there is no such thing as *the* scientific method; that is, there can be no fixed universal account of scientific method appropriate for all disciplines and at all times. This criticism should be readily accepted because it speaks against an unrealistic view of scientific method.

Another prominent criticism of scientific method was proposed by Karl Popper, who often remarked that scientific method does not exist. By this he meant that there is no method of discovering a scientific theory, that there is no method of verification, and that there is no method for establishing whether a hypothesis is probably true or not. However, these claims are part of Popper's preference for a falsificationist construal of the hypothetico-deductive method. These claims might, or might not, be part of other conceptions of scientific method. For example, advocates of an inductive conception of scientific method will not accept the first claim; those who accept the idea of confirmation, as distinct from falsification, will argue against the second claim; and Bayesian methodologists will reject the third claim.

In a book, which was provocatively entitled *Against Method*, Paul Feyerabend presented a different criticism of scientific method. He argued that there are no methodological rules that are part of scientific method that have not been broken at some time or other in the

interests of genuine scientific progress. Thus, for Feyerabend, the only rule that does not inhibit progress is the rule "anything goes." Feyerabend's argument has been endorsed by several commentators who are critical of appeals to the importance of scientific method. However, it should be noted that Feyerabend's criticism strictly speaks against the fixity of methodological rules only. There is nothing in Feyerabend's writing that would counsel against the flexible use of a variety of different methodological rules that are revisable in the light of experience, reason, and other sources of justification.

None of the three criticisms just considered addresses contemporary issues in scientific methodology.

Four Theories of Scientific Method

Modern scientific methodology has given considerable attention to the following four general theories of scientific method: (1) inductive method, (2) hypothetico-deductive method, (3) Bayesian hypothesis testing, and (4) inference to the best explanation.

Inductive Method

The idea that scientific method involves inductive reasoning goes back at least to Aristotle, and was given a heavy emphasis by Francis Bacon and John Stuart Mill. Inductive reasoning takes different forms. For example, it is to be found in the fashioning of statistical generalizations, in the Bayesian assignment of probabilities to hypotheses, and in the reasoning involved in moving from data to hypotheses in the hypothetico-deductive method.

The most popular inductive approach to scientific method is sometimes called *naïve inductivism*. According to this account of method, science begins by securing observed facts, which are collected in a theory-free manner. These facts provide a firm base from which the scientist reasons upward to hypotheses, laws, or theories. The reasoning involved takes the form of enumerative induction and proceeds in accordance with some governing principle of inductive reasoning. As its name suggests, enumerative induction is a form of argument in which the premises enumerate several observed cases from which a conclusion is drawn, typically in the form of an empirical generalization. However, enumerative induction can also take the form of a prediction about something in the future or a retrodiction about something in the past. The governing principle for an enumerative induction to a generalization can be stated informally as follows: "If a proportion of As have been observed under appropriate conditions to possess property B, then infer the same proportion of

all As have property B.” This inductive principle can be taken to underwrite the establishment of statistical generalizations.

The naïve inductive method has been criticized in various ways, although the criticisms are mostly directed at extreme versions of the method—versions making the claim that observed facts can be known infallibly, that observations are made in an entirely theory-free manner, or that empirical generalizations can be secured through the use of a strongly justified principle of induction. However, the so-called naïve inductive method can be defended in a moderate form: Observed facts can be established reliably, if fallibly; theory has to be used to guide observations, and theoretical terms can be used to report observational statements without threatening the reliability of those statements; and principles of induction can be given an adequate justification on pragmatic grounds.

In the behavioral sciences, the radical behaviorism of Burrhus F. Skinner is a prominent example of a research tradition that makes use of a nonstatistical inductive conception of scientific method. The major goals of radical behaviorist research are first to detect empirical generalizations about learning, and then to systematize those empirical generalizations by assembling them into nonexplanatory theories. Murray Sidman’s *Tactics of Scientific Research* is an instructive radical behaviorist account of the methodology of phenomena detection.

The Bayesian approach to hypothesis testing can be regarded as a sophisticated variant of inductive method. It is considered later as an account of scientific method in its own right.

Hypothetico-Deductive Method

The most popular account of method in science is the hypothetico-deductive method, which has been the method of choice in the natural sciences for more than 150 years. The method has come to assume hegemonic status in the behavioral sciences, which have often placed a heavy emphasis on testing hypotheses in terms of their predictive success. Relatedly, the use of traditional statistical significance test procedures is often embedded in a hypothetico-deductive structure.

The hypothetico-deductive method is characteristically described in one of two ways: On one account, the scientist takes a hypothesis or a theory and tests it indirectly by deriving from it one or more observational predictions, which are amenable to direct empirical test. If the predictions are borne out by the data, then that result is taken as a confirming instance of the theory in question. If the predictions fail to square with the data, then that fact counts as a disconfirming

instance of the theory. The second account is from Karl Popper, who construes the hypothetico-deductive method in falsificationist terms. On this rendition, hypotheses are viewed as bold conjectures, which the scientist submits to strong criticism with a view to overthrowing or refuting them. Hypotheses that successfully withstand such criticism are said to be corroborated, which is a noninductive notion of support.

Even though the hypothetico-deductive method is used by many scientists and has been endorsed by prominent philosophers of science, it has received considerable criticism. Leaving aside Popper’s less influential falsificationist account of the hypothetico-deductive method, the major criticism of the hypothetico-deductive method is that it is confirmationally lax. This laxity arises from the fact that any positive confirming instance of a hypothesis obtained through its use can confirm any hypothesis that is conjoined with the test hypothesis, irrespective of the plausibility of that conjunct. Another criticism of the hypothetico-deductive method is that it submits a single hypothesis to critical evaluation without regard for its performance in relation to possible competing hypotheses. Yet another criticism of the method is that it mistakenly maintains that hypotheses and theories arise through free use of the imagination, not by some rational, methodological, or logical means.

Criticisms such as these have led some methodologists to recommend that the hypothetico-deductive method should be abandoned. Although this might be a reasonable recommendation about the method as it is standardly conceived, it is possible to correct for these deficiencies and use the method to good effect in hypothesis testing research. For example, one might overcome the confirmational defects of the orthodox hypothetico-deductive method by employing a Bayesian approach to confirmation within a hypothetico-deductive framework. With or without a commitment to the Bayesian approach, one could use the hypothetico-deductive method to test two or more competing hypotheses deliberately in relation to the evidence, rather than one hypothesis in relation to the evidence. Furthermore, in testing two or more hypotheses, one might supplement the appeal to empirical adequacy by invoking criteria to do with explanatory goodness.

Bayesian Method

Although the Bayesian approach to evaluating scientific hypotheses and theories is looked on more favorably in philosophy of science than the hypothetico-deductive alternative is, it remains a minority practice in the behavioral sciences.

For the Bayesian approach, probabilities are considered central to scientific hypothesis and theory choice. It is claimed that they are best provided by probability theory, which is augmented by the allied philosophy of science known as *Bayesianism*. In using probability theory to characterize theory evaluation, Bayesians recommend the assignment of posterior probabilities to scientific hypotheses and theories in the light of relevant evidence. Bayesian hypothesis choice involves selecting from competing hypotheses the one with the highest posterior probability, given the evidence. The vehicle through which this process is conducted is Bayes' theorem. This theorem can be written in a simple form as: $\Pr(H/D) = \Pr(H) \times \Pr(D/H) \div \Pr(D)$. The theorem says that the posterior probability of the hypothesis is obtained by multiplying the prior probability of the hypothesis by the probability of the data, given the hypothesis (the likelihood), and dividing the product by the prior probability of the data.

Although Bayes' theorem is not controversial as a mathematical theorem, it is controversial as a guide to scientific inference. With respect to theory appraisal, one frequently mentioned problem for Bayesians is that the probabilistic information required for their calculations on many scientific hypotheses and theories cannot be obtained. It is difficult to know how one would obtain credible estimates of the prior probabilities of the various hypotheses and evidence statements that comprised, say, Charles Darwin's evolutionary theory. Not only are the required probabilistic estimates for such theories hard to come by, but also they do not seem to be particularly relevant when appraising such explanatory theories.

The problem for Bayesianism presented by scientific theory evaluation is that scientists naturally appeal to qualitative theoretical criteria rather than probabilities. It will be described in the next section that scientific theories are often evaluated qualitatively by employing explanatory reasoning rather than probabilistic reasoning.

Inference to the Best Explanation

In accordance with its name, inference to the best explanation (IBE) is founded on the belief that much of what we know about the world is based on considerations of explanatory worth. In contrast to the hypothetico-deductive method, IBE takes the relation between theory and evidence to be one of explanation, not logical entailment, and by contrast with the Bayesian approach, it takes theory evaluation to be a qualitative exercise that focuses explicitly on explanatory criteria, not a quantitative undertaking in which one assigns probabilities to theories. Given that a primary

function of many theories in science is to explain, it stands to reason that the explanatory merits of explanatory theories should count in their favor, whereas their explanatory failings should detract from their worth as theories. The major point of IBE is that the theory judged to be the best explanation is taken as the theory most likely to be correct. There is, then, a two-fold justification for employing IBE when evaluating explanatory theories: It explicitly assesses such theories in terms of the important goal of explanatory power, and it provides some guide to the approximate truth of theories.

The cognitive scientist Paul Thagard has developed a detailed account of IBE as a scientific method—one that helps a researcher to appraise competing theories reliably through the coordinated use of several criteria. This method is known as the *theory of explanatory coherence*. The theory comprises an account of explanatory coherence in terms of many constituent principles, a computer program for implementing the principles, and various simulation studies that demonstrate its promise as a method of IBE.

According to the theory of explanatory coherence, IBE is centrally concerned with establishing relations of explanatory coherence. To infer that a theory is the best explanation is to judge it as more explanatorily coherent than its rivals. The theory of explanatory coherence is not a general theory of coherence that subsumes different forms of coherence such as logical and probabilistic coherence. Rather, it is a theory of *explanatory coherence*, where the propositions hold together because of their explanatory relations.

Relations of explanatory coherence are established through the operation of seven principles. These principles are symmetry, explanation, analogy, data priority, contradiction, competition, and acceptability. The determination of the explanatory coherence of a theory is made in terms of the three criteria. Within the theory of explanatory coherence, each of these criteria is embedded in one or more of the seven principles.

Thagard determined that explanatory breadth is the most important criterion for choosing the best explanation. This criterion captures the idea that a theory is more explanatorily powerful than its rivals if it explains a greater range of facts.

The notion of simplicity that Thagard deems most appropriate for theory choice is a pragmatic criterion that is closely related to explanation; it is captured by the idea that preference should be given to theories that make fewer special or ad hoc assumptions. Thagard regards simplicity as the most important constraint on explanatory breadth; one should not sacrifice simplicity through ad hoc adjustments to a theory to enhance its consilience.

Finally, Thagard found that analogy is an important criterion of IBE because it can improve the explanation offered by a theory. Explanations are judged more coherent if they are supported by analogy to theories that scientists already find credible.

The four theories of scientific method just considered are commonly regarded as the major theories of scientific method. Although all the methods have sometimes been proposed as the principal claimant for the title of *the* scientific method, they are better thought of as restrictive accounts of method that can be used to meet specific research goals, not broad accounts of method that pursue a range of research goals.

The Importance of Method

Even though methodological discussions of scientific method are not fashionable, they are of vital importance to the well-being of science. For it is to scientific methods that scientists naturally turn for the cognitive assistance they need to investigate their subject matters successfully. The evolution and understanding of scientific methods is to be found in the domain of scientific methodology; this fact makes this interdisciplinary sphere of learning of major practical and educational importance.

SECONDARY DATA SOURCE

Secondary data sources are generally considered those not collected directly by the researcher through empirical methods. Secondary data sources are most common in qualitative research designs where the researcher seeks to provide additional evidence to further corroborate research results, explain the context of the research site, or provide in-depth descriptions of how the phenomena were experienced by study participants. Secondary data sources are also a source and method to ensure validity of qualitative studies through triangulation of multiple data sources. In quantitative research design, secondary data sources are often pre-existing data sets that are collected and compiled by others and then accessed by the researcher. This entry discusses common and emerging types of secondary data sources before providing an example of how these data sources are used in a qualitative research design.

Common Types of Secondary Data Sources

Within qualitative research designs, the most common primary data sources are interviews and observations that are transcribed to create field notes. These data are collected by the researcher in the field ideally through prolonged engagement with research subjects. Secondary data sources are sometimes referred to as *artifacts* that the researcher discovers through the empirical data collection process. These data sources may not always be on the researcher's data collection plan or conceptual framework that guides the researcher's entry into the field to collect data. Astute qualitative researchers consistently look for possible sources of secondary data as they use their senses to understand the context of the research setting and phenomena that researcher participants experienced. Qualitative researchers should keep a list of potential secondary data sources throughout the data collection process that includes source, person who can grant access to data if needed, and whether the source is static or living.

Common sources of secondary qualitative data include preexisting documents such as books, newspapers, journals, government records, and other texts; audio and video files; and photographs. These data may be official archival or historical materials of a program, organization, or other entity where the research is being conducted whereby access is granted by a gatekeeper. Likewise, these data sources may be shared with the researcher by study participants who consent to an interview or observation. These data sources may be in hard copy or electronic formats.

Secondary data sources in hardcopy format can be digitized so that the artifact can be imported into a qualitative data analysis software program.

Within quantitative research design, secondary data sources are typically considered preexisting data sets that are made available to the researcher. This might include assessment and survey data compiled and tabulated by government agencies, educational institutions, research firms, or organizations. These quantitative secondary data sources should include access to a data dictionary that includes, among other entries, an operational definition of variables, scales of measurement, and relationship to other variables. Quantitative secondary data sets may be publicly accessible or require the researcher to obtain a license to access.

Emerging Types of Secondary Data Sources

The internet has made traditional secondary data sources that have been digitized more accessible to researchers. Likewise, the internet has also caused new forms of secondary data sources to emerge. Common forms of emerging secondary data sources include web pages, personal blogs, and discussion boards. These emerging secondary data sources can also be publicly accessible to anyone who is surfing the web and who is willing to mine the data for empirical evidence that is openly viewable.

Social media applications (e.g., Facebook, Twitter, Instagram, LinkedIn) are also providing an abundance of data to researchers. Secondary data available through these applications include posts that originated on social media sites, shared messages and other content, and reactions to content. Perhaps one of the richest sources of social media data is the interaction and discourse that can occur within the social media platform. However, these data sources are often limited to users of these applications unless access is granted to the researcher who is often considered an outsider.

Example

A research team decides to conduct a case study of a community-based organization that operates after-school and summer programs for youth along with a parent education program. The research team gathers initial information about the organization's structure, history, and services offered. A meeting was held with leadership of the community-based organization to determine accessibility to the community-based organization's employees and participants to collect data for the case study. Proper human subjects' approvals are obtained and data collection begins. The research team

interviews employees, youth participants, and their parents. The team also observes program activities where youth and parents are engaged. These data, collected by the researchers, become the primary data source for the case study.

Through the process of collecting primary data sources, the research team becomes aware of several secondary data sources that might be available. Those data sources include copies of the current and previous strategic plans, program curricula, and a facilitator training manual. The research team also learns that the community-based organization has a data set of all participants for the past 10 years. That data set includes demographic needs related to academic support, program attendance, family support needs, and other longitudinal data points collected from youth participants and parents. The community-based organization also provides the research team with a data set that includes results of participant satisfaction surveys from youth participants and parents. Reflective essays of the youth participants are also available that chronicle how participants have changed their mindsets about school while enrolled in the community-based organization program.

All these various secondary data sources enhance the research team's effort to conduct the case study of the community-based organization. These data sources show patterns of the organization's program, explain important contextual details about the program, and most importantly corroborate how the phenomena are experienced by the youth participants and parents. These secondary data sources are also a valuable resource for data validation, especially triangulation of evidence from multiple sources.

SELECTION BIAS

Selection bias refers to a situation in which data are not representative of the underlying population of interest. In particular, selection occurs when unobserved factors that determine whether an observation is in the data set also help determine the value of the quantity of interest. For example, in a study of willingness to volunteer, it would make little sense to only select those participants who volunteer to participate. An analysis of data that suffer from selection generally produces biased estimates and renders statistical inference problematic. Solutions to the problem commonly involve modeling the selection process and the outcome of interest at the same time to account for how selection influences the observed values.

Types of Missing Data

Selection bias generally refers to a particular type of missing data: nonrandom missingness. Also referred to as nonignorable missingness, it is one of three types of missing data, which include missing at random and missing completely at random. Data that are missing completely at random are missing in a way that is completely unrelated to any information in the data set—observations or values of variables are missing with equal probability. Data that are missing at random have values that are missing in a way that is related to the observed values of other variables in the data set—the probability that a value is missing can be predicted with observed variables alone. Data exhibit nonignorable missingness when the value of the missing variable helps explain its missingness above and beyond what can be explained with the information contained in observed variables. Of course, this also means that values of variables included in the data set help determine their inclusion as well.

In its common usage, selection refers to a specific type of nonignorable missingness. A typical situation involves no missing data for all covariates Z , but missing values of the quantity of interest Y . The values of Y might be missing for a variety of reasons. For example, schools might withhold tests from students who might score relatively low, rendering observation of their scores impossible, or respondents might refuse to answer survey questions about sensitive activities. In general, nonrandom sample selection occurs when observation of Y for an individual (or other unit of analysis) depends on unobserved information that helps determine its value.

The best way to avoid nonrandom sample selection is by careful study design and implementation. In

survey contexts, allocating effort on additional follow-ups to avoid unit and item nonresponse can reduce or eliminate selection. Phrasing questions in ways that reduce sensitivity can help as well (perhaps by substituting scales in place of exact responses). In program evaluation, the focus should be on ensuring random assignment and high compliance rates. In real-world situations, however, these remedies might be impossible, often leaving only statistical approaches to correct for selection.

Consequences

Even though the value of Y might depend on a combination of observed factors, which are measured in Z , and unobserved factors, the critical element that determines the consequences of selection is whether observation of Y depends, at least in part, on unobserved factors. Selection that depends only on observed factors does not lead to unrepresentative values of Y given the observed covariates, although if one is interested in the average for the entire population, then one should remember to make adjustments to account for differences in the distribution of covariates between the selected sample and the population of interest.

Selection that does depend on unobserved factors leads to unrepresentative values of Y , even for observations with the observed covariates: The value of Y will be systematically too large or too small, so estimates of the average value of Y will be biased. This leads to the most common misperception about sample selection: Researchers often assert that despite the presence of selection, their estimates are representative of the sample being studied, although perhaps not of the population of interest. When the value of the unobserved component is related to the observation of Y , then the mean of the unobserved component of Y is not zero among the set of individuals for whom the outcome of interest is observed. Thus, the observed value departs from the expected value, and estimates based on those values are almost always wrong.

When moving from estimation of averages for the quantity of interest to regression models that attempt to relate Y to a set of observed covariates Z , additional complications arise. The consequences depend on whether the observed factors included in the model are correlated with the unobserved factors that determine the observation and value of Y . When these factors are uncorrelated, then coefficient estimates from a linear regression model will be unbiased (although the intercept term will be biased because the mean of the errors is not zero). When these factors are correlated, then coefficient estimates will be biased.

In the linear regression context, selection can best be understood as a form of omitted variable bias, and it produces similar consequences. To illustrate this, consider that observation of Y depends positively on an observed factor Z and some unobserved random component u . When Z is large, Y is likely to be observed for almost any value of the random component, but when Z is small, Y will only be observed for large values of the random component. This induces a negative correlation between Z and u among individuals with observed values of Y because, on average, u must be larger as Z gets smaller to exceed the threshold for observation.

Now consider the relationship between unobserved factors e and observed factors X (possibly including Z), which explain Y (e.g., $Y = X\beta + e$). In the context of selection, u is correlated with e , because the unobserved factors that explain the value of Y also help explain whether Y is observed. Consider the case of a positive correlation: Because the values of u necessary to observe Y get larger as Z gets smaller, the values of e will tend to be larger for the associated observations as well. In the standard linear regression model, one assumes that e has mean zero. With selection, this might be true for the population of potential observations, but it is not true among the selected sample because of the correlation between e and u . Because Y is a linear function of its observed and unobserved components, the realized values of Y are larger than they should be.

Now assume that Z and X are related, either because both contain at least one factor in common or because there is a nonzero correlation between at least one variable in each. Because Z and u are correlated among the selection sample and u and e are correlated in the context of nonrandom sample selection, a correlation between Z and X will lead to a correlation between X and e . If Z and X are positively correlated, then in the current example, the negative relationship between Z and e will lead to a negative correlation between X and e . This violates the regression assumption that the errors are uncorrelated with the explanatory variables, which is also what happens with omitted variable bias and leads to biased estimates of the effect of X on Y .

Approaches for Eliminating Selection Bias

The omitted variable bias interpretation was described by James Heckman, who also proposed a solution to the problem. Heckman showed that by accounting for the fact that selection affects the distribution of the unobserved component of Y in the observed sample, one can generate accurate regression coefficients and

estimates of the conditional expected value of Y . The correction assumes that the two errors are distributed bivariate normal, and it is implemented by running a probit model of the selection process, then using the estimates to calculate the inverse Mills's ratio (the density divided by the cumulative distribution function evaluated at Z) for each individual in the selected sample. The inverse Mills's ratio is then included in the linear regression model as an additional right-hand side variable. This process cleans the errors of the part affected by the selection process and breaks the correlation between e and X , thereby avoiding bias in the coefficient estimates.

The two-step procedure described previously is unbiased but produces inaccurate standard errors because the uncertainty associated with the model of the selection process, and therefore the inverse Mills's ratio, is ignored. An alternative version of the Heckman estimator avoids this problem by estimating the two equations for selection and the outcome of interest simultaneously.

Selection Bias in Other Regression Models

The Heckman solution for linear regression has been extended to discrete outcomes for both probit and logit equations of interest, as well as for count and duration outcomes. Not all of these estimators lend themselves to correction through the inclusion of the inverse Mills's ratio in the equation of interest. Rather, one should rely on the simultaneous estimation approach to account for the selection process while analyzing the equation of interest.

A related problem occurs when the sample is truncated rather than censored. When censored, researchers observe everything except the outcome variable Y ; with truncation, researchers observe nothing for respondents that do not select in. Truncation makes it difficult to estimate the selection equation because there is no variation in selection status. Relying on the distributional assumptions about the errors, however, it is possible to estimate the parameters of the selection process simultaneously with the equation of interest, despite the lack of data on observations that do not select into the sample. These models tend to be difficult to estimate, although several authors have proposed methods to improve estimation.

Challenges in Selection

Although the previous corrections offer an opportunity to avoid the potential threat to inference caused by nonrandom sample selection, diagnosing and correction for it is not always straightforward. It is necessary

to specify correctly not only the equation of interest but also the selection equation. Variables incorrectly omitted from both equations can create selection bias, for example. Even with correct specification, estimating selection models, especially those with discrete dependent variables, can prove difficult: In many cases, the estimation process might fail to converge. Even if convergence is achieved, estimates might have large standard errors; particularly the estimate of the error correlation or the estimate of the correlation can be very close to its bounds.

A related issue arises in the form of identification. If the selection equation and the equation of interest contain exactly the same variables, then identification is achieved through the functional form assumption embodied in the specific distribution chosen for the error terms. Under certain conditions, this can be a fairly weak form of identification. When possible, researchers should include variables that influence selection but not the outcome of interest.

The sequential nature of selection estimators also complicates the interpretation of the estimation results. Variables included in both equations influence the outcome variable in two different ways: through the selection process and through the equation of interest. Furthermore, the effect depends on the value of other variables included in the selection equation. Care must be taken to account for both influences when calculating marginal effects or first differences, for example.

SEMI-INTERQUARTILE RANGE

The semi-interquartile range (semi-IQR) is a numerical measure of the spread of a quantitative data distribution. Quantitative data, as opposed to categorical variables, comprise numerical values for which arithmetic operations (e.g., adding, dividing) can be reasonably conducted. Data analysis begins by examining data with graphics and numerical summaries. A quantitative data

distribution is typically summarized by its center (e.g., mean or median) and its spread (e.g., standard deviation, IQR, semi-IQR). The *center* quantifies the average or middle value of the data distribution, and the *spread* communicates the variability or range in the data.

Numerical summaries of a data distribution are derived from two types of underlying distributions: parametric and nonparametric. Parametric distributions are probability distributions with known functional forms that accompany a fixed set of parameters (e.g., the uniform distribution of a variable X , $f(x) = \frac{1}{b-a}$ for $a \leq x \leq b$, has two parameters: a and b).

In contrast, nonparametric distributions do not follow any known function (i.e., $f(x)$ is unknown). The center and spread of data from parametric distributions are quantified by the mean and standard deviation (e.g., for the uniform distribution, the mean is $\frac{a+b}{2}$ and the variance is $\frac{(b-a)^2}{12}$). Alternatively, the center and spread of data from nonparametric distributions are typically quantified by the median, IQR, and semi-IQR. Unlike parametric measures, nonparametric measures of center and spread make no assumptions of the form of the distribution underlying the data.

Center and Spread

Suppose we have the following math achievement scores on nine students, arranged from smallest to largest: 67, 79, 80, 83, 87, 90, 90, 95, 98. These data are presented as a histogram overlaid with a normal distribution in Figure 1.

Parametric Numerical Summaries

If the data are assumed to follow the parametric normal distribution, the center is estimated by the average value or mean, $\bar{x} = 85.4$ (solid vertical line in Figure 1A), and the spread is quantified by the standard deviation, $s_x = 9.4$. The values of $\bar{x}$ and s_x are sample estimates of the population parameters of the normal distribution, where μ is the population mean and σ is the population standard deviation. If the data are normally distributed, then 68% of the data will lie within $\bar{x} \pm s_x$ or [76.0, 94.9], 95% of the data will lie within $\bar{x} \pm 2s_x$ or [66.6, 104.3], and 99.7% of the data will lie within $\bar{x} \pm 3s_x$ or [57.1, 113.7] (Figure 1A). The observed range is calculated by taking the difference between the minimum and maximum score, $98 - 67 = 31$. Observe that the minimum and maximum values of the intervals bounded by $\bar{x} \pm 2s_x$ and $\bar{x} \pm 3s_x$ exceeds the observed values in the data, [67, 98],

Figure 1 Histogram of Math Achievement Scores

Note: (A) Assuming a normal distribution, the mean is represented by the solid vertical line, and a standard deviation is represented by the width between two vertical reference lines. (B) Assuming a nonparametric distribution, the median is represented by the solid vertical line, and the other quartiles are represented by the dotted vertical lines. The IQR is represented by the longer horizontal line, spanning 50% of the distribution or the length of the box-and-whisker plot. The semi-IQR is represented by the shorter horizontal line, spanning 25% of the distribution or a half-width of the box-and-whisker plot.

suggesting that the mean and standard deviation may not be the best numerical summaries for these data. Numerical summaries based on parametric distributions are also sensitive to observations that are inconsistent with the assumed distribution. Stated differently, $\bar{x}$ and s_x are not robust to the presence of outliers.

Nonparametric Numerical Summaries

Without assuming a parametric distribution, the center of the data is represented by the median. The median divides the data into two parts, in which 50% of the data lies below, making the median the 50th percentile. In the example of nine math achievement scores, the median is the fifth rank ordered value of 87 (solid vertical reference line in Figure 1B). As opposed to standard deviation, other percentiles such as quartiles can represent the spread of the data. Consistent with nomenclature, quartiles divide the data into four parts. The first quartile (Q1) is the 25th percentile, the second quartile (Q2) is the median, the third quartile (Q3) is the 75th percentile, and the fourth quartile (Q4) is the 100th percentile or maximum value. These quartiles are represented by vertical lines in Figure 1B as well as the

box-and-whisker plot below the histogram. Percentiles and quartiles that are calculated directly from the data are always consistent with observed data, unlike the parametric measures of spread based on s_x .

In Figure 1B, the box-and-whisker plot depicts the 0th percentile and the four quartiles as a graphic. The hinges or edges of the box align with the first and third quartiles and represent the IQR. The line inside the box represents the median (87 points), and the whiskers extending from the box present the minimum and maximum observations in the data. When there are outliers, the whiskers do not extend to encompass the full range of the data but instead extend to 1.5 IQR. Because the data are left-skewed (and therefore asymmetric), the mean is closer to the left tail relative to the median, and the median is closer to Q3 compared to Q1. The IQR is calculated as:

$$\text{IQR} = Q3 - Q1. \quad (1)$$

In this example, the IQR is $90 - 80 = 10$; 50% of observed math achievement scores lie within 10 achievement score points. The semi-IQR is the half-width of the IQR:

$$\text{Semi IQR} = \frac{Q3 - Q1}{2} \quad (2)$$

and is also called the *quartile deviation* (cf. standard deviation). The semi-IQR in this example is $\frac{10}{2} = 5$, suggesting that 25% of the math achievement scores in the middle of the distribution span about five points. The semi-IQR tends to be robust to unique characteristics of the data because it is not calculated directly from percentiles that differ by 25%. For instance, the range between the 0th and 25th percentile from the example on math achievement scores is 13 points, whereas the range between the 12.5th and 37.5th percentile is four points. By computing a range for 25% of the data from the IQR, the semi-IQR is robust to idiosyncrasies (e.g., sparseness) in the data. The semi-IQR does not make parametric assumptions and is a relatively robust measure of spread that is not as sensitive as parametric measures.

SEMIPARTIAL CORRELATION COEFFICIENT

A semipartial correlation coefficient is the correlation between variable A and variable B after controlling for other variables' relationships with variable B. It is also called a part correlation. The semipartial correlation coefficient is useful to understand relationships between predictors in a multiple regression and the criterion variable. Because the correlation between one predictor and the criterion used in regression analyses is actually the semipartial correlation, we can see the independent relationship between each predictor and the criterion after controlling for other predictors' overlap with that predictor.

A squared, semipartial correlation coefficient can be used in connection with multiple regression analysis to measure the strength of the association between the dependent and an independent variable, taking into

account the relationships among all the variables. A squared semipartial correlation coefficient is also called a squared part correlation. To illustrate the squared semipartial correlation coefficient, consider data that include final mathematics grades (MA), student perception of teacher's academic support (TAS) in mathematics class, and positive affect (PA) in mathematics class. The sample size is $N = 200$. A multiple regression model for these variables is

$$MA = \alpha + \beta_1 PA + \beta_2 TAS + \epsilon, \quad (1)$$

where α denotes the intercept; β_1 and β_2 denote the regression coefficients (slopes) for PA and TAS, respectively; and ϵ denotes the residual. The sample squared multiple correlation coefficient for the model is $R^2 = .169$, where the subscript 2 indicates that there are two variables in the model and .169 means that 16.9% of the variance in MA is associated with the joint variability in PA and TAS. Suppose the researcher wants to know how much variance in MA is uniquely associated with TAS. The simple linear regression model

$$MA = \alpha + \beta PA + \epsilon \quad (2)$$

has $R_1^2 = .121$ and indicates that 12.1% of the variance in mathematics grades is associated with variability in PA. So starting with PA in the model, 12.1% of the total variance in mathematics grades is associated with variability in PA. When TAS is added to the model, 16.9% of the total variance in mathematics grades is associated with joint variability in PA and TAS. Consequently, 4.8% of the total variance in mathematics grades is uniquely associated with variability in TAS. The squared semipartial correlation coefficient for TAS is simply

$$\Delta R^2 = R_2^2 - R_1^2 = .169 - .121 = .048,$$

where ΔR^2 is read change in R^2 and measures the strength of the association between MA and TAS taking into account the relationships among all three variables. The squared semipartial correlation coefficient for PA can also be computed. The squared correlation coefficient for the model

$$MA = \alpha + \beta TAS + \epsilon \quad (3)$$

is $R_1^2 = .107$, and the squared semipartial correlation coefficient for PA is

$$\Delta R^2 = R_2^2 - R_1^2 = .169 - .107 = .062.$$

When the goal is to determine how strongly TAS and MA are associated taking into account the

relationships among all three variables, the roles of *TAS* and *MA* can be interchanged in Equations 1 and 2:

$$TAS = \alpha + \beta_1 PA + \beta_2 MA + \varepsilon, \quad (4)$$

$$TAS = \alpha + \beta PA + \varepsilon, \quad (5)$$

and $\Delta R^2 = .046$, so 4.6% of the variance in *TAS* is uniquely associated with *MA*. The choice between reporting the 4.8% associated with Equation 1 and the 4.6% associated with Equation 4 should be based on whether *MA* or *TAS* is substantively considered the dependent variable.

A semipartial correlation can also be expressed as a correlation between the dependent variable and a residualized version of an independent variable. Let the predicted value for the regression of *TAS* on *PA* be denoted by $\widehat{TAS}$. The predicted value is

$$\widehat{TAS} = a + bPA,$$

where *a* is the sample intercept and *b* is the sample slope for *PA*. The residual is $TAS - \widehat{TAS}$, which is uncorrelated with *PA* and can be interpreted as the part of *TAS* that is not associated with *PA*. The semipartial correlation between *MA* and *TAS* is the correlation between *MA* and $TAS - \widehat{TAS}$, which is often written as $r_{MA(TAS-PA)}$, and can be interpreted as the correlation between *MA* and the part of *TAS* that is not associated with *PA*. In a similar fashion, $r_{TAS(MA-PA)}$ can be formulated based on

$$\widehat{MA} = a + bPA$$

and

$$MA - \widehat{MA}.$$

The squared semipartial correlation coefficient can also be used in situations with more than two independent variables. In general, let there be *K* independent variables and let the squared multiple correlation coefficient for the *K* variables be denoted by R_K^2 , where the *K* subscript indicates a model with *K* independent variables. Now if one of the independent variables is removed from the model, the new model has *K* - 1 independent variables. The squared multiple correlation coefficient for the new model is denoted by R_{K-1}^2 , and its magnitude will be dependent on which of the *K* independent variables is deleted. The squared semipartial correlation coefficient is $\Delta R^2 = R_K^2 - R_{K-1}^2$ and can be interpreted as the percentage of total variance in the dependent variable that is uniquely associated with the deleted variable.

Hypothesis Test for ΔR^2

Typically, a researcher would be interested in knowing whether the variance uniquely associated with an independent variable is significantly different from

zero. That is, using R_K^2 and R_{K-1}^2 to denote the population squared multiple correlation coefficients for the two models, the researcher wants to test the null hypothesis $H_0 : R_K^2 - R_{K-1}^2 = 0$ against the alternative $H_1 : R_K^2 - R_{K-1}^2 > 0$. The test statistic for this hypothesis is

$$F = (N - K - 1) \frac{R_K^2 - R_{K-1}^2}{1 - R_K^2}, \quad (6)$$

and the critical value is $F_{1-\alpha, 1, N-K-1}$, where α is the Type I error rate for the test. To illustrate, consider testing the significance of the squared semipartial correlation coefficient for *TAS*, that is, the difference between R^2 of the full model given in Equation 1 and the reduced model given in Equation 2. From the results reported earlier,

$$\begin{aligned} F &= (N - K - 1) \frac{R_K^2 - R_{K-1}^2}{1 - R_K^2} \\ &= (200 - 2 - 1) \frac{.169 - .121}{1 - .169} = 11.40, \end{aligned}$$

and the $\alpha = .05$, critical value is $F_{1-.05, 1, 200-2-1} = 3.89$. The null hypothesis is rejected and there is evidence that the variance uniquely associated with *TAS* is different from zero. The *F* statistic would also be 11.40 if the *F* statistic in Equation 6 were used in conjunction with the regression models in Equations 4 and 5 to test whether the *TAS* variance that is uniquely associated with variance in *MA* is significantly different from zero. That is, either Equations 1 and 2 or Equations 4 and 5 yield the same conclusion about whether there is an association between *MA* and *TAS*, taking into account the relationships among *MA*, *TAS*, and *PA*.

Returning to the multiple regression model in Equation 1, the regression coefficient for *TAS* is β_2 . If $\beta_2 = 0$, then it would make sense that $R_2^2 - R_1^2$ would be zero for *TAS* and thus that a hypothesis test of $H_0 : \beta_2 = 0$ against $H_1 : \beta_2 \neq 0$ would yield the same conclusion as would a test of $H_0 : R_2^2 - R_1^2 = 0$ against the alternative $H_1 : R_2^2 - R_1^2 > 0$. In fact this is the case, so that a test on the regression coefficient for a variable can be used as the test on the squared semipartial correlation coefficient for that variable.

Comparison to the Squared Partial Correlation Coefficient

The squared semipartial correlation coefficient measures the strength of association between the dependent variable and one of the independent variables taking into account the relationships among all the variables. The squared partial correlation coefficient, which is denoted by pr^2 for partial *r* squared, can be used to

accomplish the same aim. A comparison between pr^2 and ΔR^2 is presented next in the general context in which there are K independent variables. In the following, the variable that is being correlated with the dependent variable is denoted by X_j and the remaining $K - 1$ variables are referred to as the “other” variables.

The squared semipartial correlation coefficient for X_j is

$$\Delta R^2 = R_K^2 - R_{K-1}^2, \quad (7)$$

and the squared partial correlation coefficient is

$$pr^2 = \frac{R_K^2 - R_{K-1}^2}{1 - R_{K-1}^2}. \quad (8)$$

First, note that numerator of pr^2 is equal to ΔR^2 . Therefore, both pr^2 and ΔR^2 address the question of the amount of variance that is uniquely associated with X_j . In fact, if pr^2 is zero, then ΔR^2 must be zero and vice versa. Similarly, if ΔR^2 is significantly different from zero by using the F statistic in Equation 6, then pr^2 must also be significantly different from zero. Second, note that R_{K-1}^2 is the proportion of the total variance in the dependent variable that is associated with the other variables. Logically, the proportion of total variance in the dependent variable that is associated with the other variables (i.e., R_{K-1}^2) plus the proportion of the total variance in the dependent variable that is not associated with the other variables must add to 1.0. Therefore, $1 - R_{K-1}^2$ is the proportion of the total variance in the dependent variable that is not associated with the other variables. As a result, pr^2 addresses the following question: “Of the dependent variable variance *not associated with the other variables*, what proportion is uniquely associated with X_j ?” By contrast, ΔR^2 addresses the following question: “Of the total dependent variable variance, what proportion is uniquely associated with X_j ?” Thus, it is clear that both are concerned with the amount of variance uniquely associated with X_j , but ΔR^2 expresses the unique variance as a proportion of the total variance for the dependent variable, whereas pr^2 expresses the unique variance as a proportion of a part of the total variance for the dependent variable. By comparing Equations 7 and 8, it can be observed that, because $1 - R_{K-1}^2$ must be between zero and one, pr^2 must be at least as large as ΔR^2 , and therefore pr^2 will provide an impression of a stronger relationship between the dependent variable and X_j than does ΔR^2 .

Because both pr^2 and ΔR^2 address the amount of dependent variable variance that is uniquely associated with X_j , a reasonable basis for choosing between these statistics is the ease of interpretation and comparison across independent variables. The coefficient ΔR^2 expressed as part of a total seems easier to understand.

And if ΔR^2 is available for several variables in the model, they are easy to compare because each is a proportion of the same total.

The partial correlation can be formulated as a correlation between a residualized dependent variable and a residualized independent variable. Consider the example of K independent variables and interest in the partial correlation between the dependent variable Y and X_j taking into account the relationships among Y and all the independent variables. Let $Y - \hat{Y}_{K-1}$ be the residual after relating Y to the set of independent variables that do not include X_j and let $X_j - \hat{X}_{j,K-1}$ be the residual after relating X_j to the set of independent variables that do not include X_j .

The partial correlation is the correlation between the two residual variables and can be interpreted as the correlation between the parts of Y and X_j that are not related to the other independent variables, whereas the semipartial correlation is the correlation between Y and the part of X_j that is not related to the other independent variables.

SEMI-STRUCTURED INTERVIEW

The semistructured interview offers a means for understanding human experience through the engagement of two persons in shared inquiry. It is a qualitative research method involving open-ended questions interspersed with questions of clarification, further meaning-making, and critical reflection within the interview. Semistructured interviews offer much promise across disciplines and research topics.

The investment in preparation of a semistructured interview and attention to the nature of the interactions as they are unfolding in the interview contribute to the

quality of the data gathered. Formulating questions and ordering them requires careful thought and some field-testing of the protocol, the set of questions that guide the interview. Some researchers will engage in a preliminary study of the context or involve individuals who share some connection to the topic or are insiders within the community of study. This level of collaboration can strengthen the formulation of questions and the structure of the interview and assist the researcher in anticipating ethical issues.

The order in which the questions are placed within the interview protocol reflects a deliberate progression toward increasing depth and exploration of the phenomenon under study. However, the instrumentation is not entirely contained in the interview protocol. The researchers themselves act as the primary instrument, as they extend questions and pursue ideas conveyed in the participants' responses, probe particular statements, and reflect back to the participant what the interviewer is understanding. The researcher is acting in the role of a co-inquirer with the participant in working toward answering a broader set of research questions. In this way, the complexity of knowledge produced stems from the intersubjective nature of the social exchange between individuals engaged in inquiry together within an interview.

The semistructured interview offers great versatility in the arrangement and types of questions. It is dependent on the skills of the interviewer, which include but are not limited to the following: (1) the quality of questions structured into the interview protocol; (2) the responsive construction of additional questions as the interview progresses; (3) the degree of care in listening and in understanding what is said; (4) the ability to stay focused on the narrative as it is unfolding while keeping track of unfinished stories, interrupted sequences, and potential insights to which the interviewer might return; (5) the capacity for intersubjective engagement toward grasping another's experience or perspective; (6) the encouragement of description of experience through examples, stories, and details of lived experience; (7) and the creation of generous space for the participant to introduce tangents that may be rich and complex while redirecting the exchange should it move too far out of focus.

As the interview progresses, the interviewer is increasingly engaging in meaning-making with the participant. Questions the interviewer might be conscious of include the following: How is the lived experience as narrated by the participant informing the phenomenon under study? Is there a story, metaphor, or a particular phrase pregnant with meaning within the interview thus far that needs further exploration? Are there contradictions in the participant's narrative that might be

raised with care and perhaps reveal important tensions? As interviewers proceed in the interview, they move in a manner that invites depth but attends to indications on the part of the participant that the topic has been exhausted, is inaccessible, or is off-limits. This can be difficult to ascertain. It relies on one's ability to probe to open up areas the participant may not have directly considered while also reading body language, facial expression, and tone of voice to determine participant desire to move on to the next questions. A useful way to gauge the situation is to close out each major area of questioning by asking, "Anything else?"

With deliberate openness for participants' direction of thought, introduction of stories, and elaboration of meaning, the degree to which standardization and control are attained in the semistructured interview is considerably reduced. This means that the interview tends to be longer and offers more variability in what happens between the first and last question posed by the interviewer. In qualitative research, what the research design gives up in terms of uniformity is of less consequence compared to what the research gains in depth of understanding, closeness to the participants' words, and some ability to view the contextual and relational world of the participants. This priority in qualitative research is reflective of a theory of knowledge in which knowledge is produced through co-constructed processes of meaning-making with others.

Co-construction is not a facile process, since variation exists in the interviewer and participant's relationship to the external environment and to each other. As a result, there is inherent in the interview process, an orientation toward multiplicity rather than assumptions of a single reference point. This philosophical orientation includes as a prerequisite the interviewer's closeness to participants in their exchange of human experience within the inquiry endeavor. It also means attention must be given to the nature of that exchange, the social positionality of the interviewer, and where participant responses need clarification, further generation of meaning, and some degree of critical reflection within the interview.

In sum, the semistructured interview offers versatility and strength in researchers' exploration of specific dimensions of their research question. Because it brings two persons together in a process of understanding a topic of inquiry, the semistructured interview requires that the interviewer play an active role in the interchange with the participant. The method offers depth of meaning and complex renderings of human experience.

SENSITIVITY

Sensitivity is one of four related statistics used to describe the accuracy of an instrument for making a dichotomous classification (i.e., positive or negative test outcome). Of these four statistics, sensitivity is defined as the probability of correctly identifying some condition or disease state. For example, sensitivity might be used in medical research to describe that a particular test has 80% probability of detecting anabolic steroid use by an athlete. This entry describes how sensitivity scores are calculated and the role of sensitivity in research design.

Calculating Sensitivity Scores

Sensitivity is calculated based on the relationship of the following two types of dichotomous outcomes: (1) the outcome of the test, instrument, or battery of procedures and (2) the true state of affairs. The outcome of the test is typically referred to as being positive (indicating the condition is present) or negative (the condition is not present). The true state of affairs is typically defined either by assignment of some experimental condition or classification based on some known gold standard test. Based on these

two types of dichotomous outcomes, there are four possible outcome variables, which are defined as follows:

True positive = the number of cases with a positive test outcome who *do* have the condition

True negative = the number of cases with a negative test outcome who *do not* have the condition

False positive = the number of cases with a positive test outcome who *do not* have the condition (Type I error)

False negative = the number of cases with a negative test outcome who *do* have the condition (Type II error)

Table 1 shows each of these four variables and the statistics generated from them. Sensitivity is based on the variables in the *Does Have the Condition* column and is calculated as the number of True Positives divided by the number of True Positives plus the number of False Negatives.

When a test is measuring some characteristic on a continuous scale, the sensitivity might be changed depending on the cutoff used to define a positive test. To demonstrate this, consider an example in which 5 α -dihydrotestosterone (DHT) levels were measured from 100 athletes, 50 of which were administered a dose of anabolic steroid prior to their test. Table 2 shows, from left to right, simulated data showing DHT levels and the corresponding number of athletes receiving steroids who have that level of DHT. If a positive test is defined as being any athlete with a DHT level of at least 10⁻¹² mol/l, then 49 of the 50 steroid-administered athletes would have a positive test outcome (sample size from the 10⁻¹², 10⁻¹¹, and 10⁻¹⁰ groups). Given this cutoff then, the sensitivity of the procedure would be calculated as: [49 (true positives) ÷ [49 (true positive) + 1 (false negative)]] = 98%. In contrast, if a positive test is defined as a DHT level of at least 10⁻¹⁰, then 30 of the 50 steroid-administered athletes would have a positive test outcome resulting in a sensitivity of 60% (30 ÷ [30 + 20]).

Table 1 Calculation of Sensitivity and Its Relationship to Other Measures of Test Accuracy

		Truth		
		Does Have the Condition	Does Not Have the Condition	
Dichotomous Test Outcome	Positive Test	True Positive	False Positive	Positive Predictive Value
	Negative Test	False Negative	True Negative	Negative Predictive Value
		Sensitivity	Specificity	

The athletes who did not receive the drug are not listed in Table 2 because they would by definition either be “True Negative” or “False Positive” cases, which are not part of the sensitivity calculation. They would instead be pertinent to the calculation of specificity. This example demonstrates how, because sensitivity and specificity are calculated on two different samples of individuals, both of these statistics are free to vary from one another independently.

Sensitivity in Research Design

Sensitivity is typically used to demonstrate or evaluate the accuracy of a test for correctly identifying some condition or disease state. This information is useful both for developers of new instruments and the consumers who use them. Depending on the context though, high sensitivity might or might not be a pertinent variable for evaluating test accuracy. For instance, high sensitivity is typically desired for tests like screening measures that are designed to identify potential disease. Because these measures are typically followed up with more rigorous testing, the cost of false positives at screening is low because these cases can be identified by other tests with greater specificity later. However, the cost of a false negative during screening is high, because it might result in the condition remaining untreated. Therefore, sensitivity is very important during the screening stage of testing.

Sensitivity is not the only relevant measure of test accuracy. One way to achieve perfect sensitivity of a test is to have a positive outcome in every case. However, this might result in a high rate of false positives as well, so specificity (the capacity to correctly identify those as not having the condition) is also important. Also, because of the way that sensitivity is defined, it is a good measure of one aspect of a test’s accuracy for group classification when the true classification of all individuals is known. However, sensitivity is not the most pertinent measure of test accuracy in clinical

settings where decisions are being made about an individual’s test outcome and the true diagnoses or classification is unknown. In this setting, what is of greater interest is the confidence in interpreting an individual test outcome, which is defined by positive and negative predictive values (see Table 1). Unlike sensitivity, predictive values take into account population base rate of the phenomenon of interest.

SENSITIVITY ANALYSIS

Sensitivity analysis is the study of stimulus and response in a system, often characterized as the apportionment of variation in a system’s output among several inputs. The system plays the role of a black box, known only by its inputs and outputs. Sensitivity analysis reveals the effective working of the system by showing which variations of inputs affect the values of the outputs.

Historically, sensitivity analysis emerged as a technique in probabilistic risk analysis, particularly in environmental impact analyses. In this context, deterministic models were executed many times with different parameter sets. The probabilistic nature of the analysis came from selecting parameter values consistent with parameter distributions for the inputs. Consequently, the methods of sensitivity analysis were developed to deal with deterministic computer models where experiments can be reproduced exactly, and both inputs and outputs are known with high precision. These techniques are most effective in this context but also apply to systems with internal sources of variation, such as natural systems or stochastic simulations. A larger design might be required to deal with the resulting noise in the data.

Table 2 Example Showing 5 α -Dihydrotestosterone Among Athletes Receiving Steroids

<i>5α-dihydrotestosterone (DHT) mol/l</i>	<i>Number of Athletes Receiving Steroid</i>
10 ⁻¹³	1
10 ⁻¹²	5
10 ⁻¹¹	14
10 ⁻¹⁰	30

Role of a Sensitivity Analyst

A sensitivity analyst performs several diverse tasks: determining the range or distribution of each input parameter, devising hypotheses for possible system behavior and suitable experimental designs to test the hypotheses, carrying out experiments and analyzing results.

During the life cycle of a sensitivity analysis, goals change. At first, the analyst might stress test the system (typically a computer implementation of a complex mathematical model) to ensure that it behaves as expected. A suitable hypothesis would be that the system can be evaluated and that it will generate appropriate results, everywhere in the sample space. A traditional two-level fractional factorial design, using combinations of extreme parameter values, is particularly effective at rooting out anomalous behavior, exhibited as abnormal program termination or unrealistic outputs. A resolution IV design is ideal as it requires only $2N$ simulations (where N is the number of parameters) to ensure equal frequencies for all eight combinations of high and low values for any selection of three parameters. Where some parameters have infinite distributions (e.g., the normal distribution), a consistent policy is needed for truncation to yield extreme values.

Next, the analyst might screen parameters, hoping to identify a small group that dominate system variation. An appropriate hypothesis is that no individual parameter has any influence on the output(s) of interest. Influential parameters are those for which this hypothesis can be rejected at a high level of significance. If enough runs are performed that the effects of many parameters can be detected, influential parameters are those with the largest effects on system outputs. Initial stress testing runs might have identified parameters with large main effects. These experiments might also have shown the existence of large two-factor interactions, without uniquely identifying them. These effects, based on extreme simulations, might overwhelm less dramatic influences that play a significant role in more probable simulations. The analyst has several design choices to highlight other influential parameters.

Designs where only the value of one parameter changes at a time are particularly effective in identifying even small effects, provided that the experiments are deterministic. It is typically necessary to change the value of a single parameter several times at different locations in the sample space, as the parameter's influence might depend on the values of other parameters. The elementary effects method provides a scheme for varying one parameter at a time on a grid. For each parameter, this method computes an average of the absolute value of the output changes resulting from changing that parameter alone, to provide a statistic to compare against other parameters.

One-at-a-time designs are inefficient if the number of parameters is large and the number of influential parameters is small, as most of the experiments will reveal little of interest about the system. A common alternative is the Latin hypercube design, which was originally developed for sensitivity analysis applications. In this design, each parameter is stratified on M levels, where M divides into the number of experiments. In the simplest approach, the levels are randomly assigned to experiments, independently for each parameter. The stratification gives good coverage for each parameter, but unintended correlations might arise among parameters, particularly where the number of experiments is not much larger than the number of parameters. Several methods have been used to control correlations so that influential parameters can be identified uniquely, including Ronald L. Iman and William J. Conover's original approach and the use of joint Latin hypercube/two-level fractional factorial designs.

After the screening stage, the choice of detailed analysis will depend on the goals of the analysis (e.g., to optimize a particular output) and on the results obtained from screening. It is common to go back and change the system at this point. For instance, an influential part of a model might be chosen for subsequent refinement. Model developers must be careful to avoid a feedback situation where a submodel has an error that makes it appear noninfluential, leading to a low priority for future revisions that would correct the error.

When sensitivity analysis is too expensive in terms of the number of experiments required, analysts sometimes turn to group sampling. In this approach, parameters are collected into groups, and every parameter in the group is treated the same way. Sensitivity analysis then determines the effect of the group as a whole. To determine which parameter is causing a group effect, the analysis can be repeated with a different grouping of the parameters. Logical inference can identify the common parameter in influential groups.

Relationship to Data Mining

Data mining is a related discipline where existing databases are analyzed to determine system behavior. Data mining is analogous to an observational science like astronomy, in which experiments involve only selection and analysis of accessible data. In contrast, sensitivity analysis is more like physical or biological experimentation, where systems can be manipulated to test precise hypotheses.

SEQUENCE EFFECTS

Sequence effects are potential confounding influences in experiments where subjects are exposed to multiple conditions. Sequence effects refer to potential interactions among conditions of an experiment based on the sequences these treatments are presented. Sequence effects are distinct from order effects, where the actual order of conditions influences the outcome, and carry-over effects, where subjects are permanently changed by the manipulation. To illustrate the differences among sequence, order, and carryover effects, imagine an experiment where subjects are asked to pick up and guess the weight of different objects on multiple daily sessions. A sequence effect would be the perceived weight of a given object being influenced by whether a light or heavy object was handled just before. In contrast, an order effect would be the perceived weight of objects increasing as the experimental session progresses and subjects grow fatigued. Finally, a carryover effect would be the perceived weight of objects decreasing across sessions as subjects grow stronger from all the excessive lifting.

Controlling for Sequence Effects

Multiple methods are available for controlling for sequence effects. Ideally, sequence effects can be controlled for within individual subjects. Failing that, experimenters will need to control for sequence effects across subjects.

Controlling for Sequence Effects Within Subjects

Sequence effects can be controlled for by counterbalancing experimental conditions within subjects, where each subject is exposed to every possible combination of experimental conditions. This is only practical when there are relatively few experimental conditions. A more restrictive means of counterbalancing experimental conditions within subjects is to use reverse counterbalancing, where experimental conditions are presented first in one order and then again in reverse order. For example, suppose participants are asked to rate the intensity of a bright, a medium, and a dim light stimulus after placebo or a drug treatment suspected to cause mild light sensitivity. The experimenter suspects that viewing the bright light makes the next light viewed seem less intense, and conversely, viewing the dim light makes the next light viewed seem more intense. To control for these influences, the researcher first presents the stimuli in the order of bright, medium, and then dim, and after a break presents the stimuli in the reverse order of dim, medium, and then bright. Then, the researcher will average intensity ratings obtained for each stimuli during the two orders.

Controlling for Sequence Effects Between Subjects

If counterbalancing within subjects is not possible or not practical for some reason, another strategy is to counterbalance conditions between subjects. Suppose the investigator in the previous example deemed it necessary to test all six possible combinations of the three light stimuli. In this case, it would be possible to present each of the six different orders to individual subjects, match these orders across placebo and drug conditions, and compare the average stimuli intensity ratings after placebo and drug treatment. In experiments examining more conditions, it becomes more practical to control for sequence effects using a balanced Latin square. In a balanced Latin square, each condition is immediately preceded once by all other conditions. A balanced Latin square cannot control for sequence effects as completely as counterbalancing; however, it does offer a reasonable degree of control with far fewer subjects.

SEQUENTIAL ANALYSIS

During the past decade, various sequential design methods in clinical trial designs have been developed to allow for interim decisions and trial modifications based on cumulated information. As part of well-known adaptive designs in group sequential analysis, Yu Shen and Lloyd Fisher proposed a sequential strategy for monitoring clinical trials, namely self-designing trials. The final test statistic is a weighted average of the sufficient statistic from each stage, where the weight for each stage is determined by the observed data prior to that stage. One important feature of this self-designing trial is that the maximum sample size or the maximum number of interim analyses, m , is not specified in advance but at a random stopping time. The flexibility of modifying the sample size allows one to save an underpowered study when unexpected events occur.

Preliminaries of a Self-Designing Trial

Consider an equally randomized clinical trial to compare a treatment, T , and a control, C . Assume that the difference between the two arms is normally distributed with an unknown mean θ and known variance σ^2 . The methodology can be extended to the situation with unknown variance. Positive values of θ imply superiority of the treatment T . Suppose the block size at each stage to be $\{2B_i, i = 1, 2, \dots\}$, where B_i for each arm is pre-fixed. Let $\bar{X}_i = \bar{X}_{T_i} - \bar{X}_{C_i}$ denote the mean difference for the i th block of data. $\bar{X}_i \sim N(\theta, \sigma^2 / B_i)$.

Let S_i define the standardized statistic based on the i th block of data and U_j define the standardized statistic for the cumulated data up to the j th analysis; then

$$S_i = B_i^{1/2} \bar{X}_i / \sigma \sim N(B_i^{1/2} \theta / \sigma, 1), i = 1, 2, \dots, m,$$

$$U_j = \sum_{i=1}^j B_i^{1/2} S_i / n_j^{1/2} \sim N(n_j^{1/2} \theta / \sigma, 1),$$

$$n_j = \sum_{i=1}^j B_i, \text{ for } j = 1, \dots, m.$$

The one-sided null hypothesis, $H_0 : \theta \leq 0$, is tested against the alternative hypothesis $H_1 : \theta > 0$.

The trial is reviewed after observing every $2B_i$ subjects at the i th interim analysis. If the cumulated information shows sufficient evidence that the new treatment is ineffective or inferior to the standard one, the trial should be terminated early. At each interim analysis, the futility boundary is constructed from the confidence limit of θ specified at significance level α_0 and the expected mean difference δ . If U_j is below the futility boundary, the trial is terminated to accept H_0 at the next step. Otherwise, a weight based on the conditional power is calculated using the cumulated data before the current step. The procedure is iterated until the total squared weight reaches one at step m , that is, $\sum_{i=1}^{m-1} w_i^2 < 1$ and $\sum_{i=1}^m w_i^2 \geq 1$. Specifically, after observing the j th block of data,

(i) If $U_j \leq \frac{n_j^{1/2} \delta}{\sigma} - z_{\alpha_0}$, let $m = j + 1$ and accept H_0 .

If $U_j > \frac{n_j^{1/2} \delta}{\sigma} - z_{\alpha_0}$ and $\sum_{i=1}^{j+1} w_i^2 \geq 1$, let $m = j + 1$ and the trial terminates at the $j + 1$ th block.

(ii) If $U_j > \frac{n_j^{1/2} \delta}{\sigma} - z_{\alpha_0}$ and $\sum_{i=1}^{j+1} w_i^2 < 1$, observe the next block of data and repeat (i) and (ii).

The weight functions are constructed using conditional power except at the first step. Specifically, $w_1 = (B_1/N_1)^{1/2}$, where $N_1 = (z_\alpha + z_\beta)^2 \sigma^2 / \delta^2$, and α and β are the specified Type I and II error rates, respectively. Note that α_0 is the significance level used for futility monitoring that can be different from α . For $j \geq 2$,

$$w_j = \left\{ B_j \left(1 - \sum_{i=1}^{j-1} w_i^2 \right) / N_j \right\}^{1/2}, \text{ where}$$

$$N_j = \left\{ \left(z_\alpha - \sum_{i=1}^{j-1} w_i S_i \right) / \left(1 - \sum_{i=1}^{j-1} w_i^2 \right)^{1/2} + z_\beta \right\}^2 \cdot \alpha^2 / \hat{\theta}_{j-1}^2.$$

$\hat{\theta}_j = U_j \sigma / \sqrt{n_j}$ is the naive estimator of θ using the cumulated data up to the j th block, and N_j is solved from an inequality aimed at achieving conditional power of $1 - \beta$. The final test statistic is constructed as

a weighted average of the sufficient statistic of each block:

$$T_m = \sum_{i=1}^m w_i S_i,$$

which follows the standard normal distribution when $\theta = 0$. If $T_m > Z_\alpha$, H_0 is rejected; otherwise H_0 is accepted at the final inference, where w_m^2 is redefined as $1 - \sum_{i=1}^{m-1} w_i^2$.

The Distribution of the Stopping Time

A trial is terminated at the m th analysis if and only if one of the following two events occurs: The cumulated data cross the futility boundary, or the weight is used up at the m th analysis, while the summation of the squared weights is less than 1 and the futility boundary is not crossed for any $j < m$; mathematically, that is

$$\begin{aligned} \{m = k\} = & \left\{ U_j > n_j^{1/2} \delta / \sigma - z_{\alpha_0}, j \leq k-2, \sum_{i=1}^{k-1} w_i^2 < 1 \right\} \cap \\ & \left[\{U_{k-1} \leq n_{k-1}^{1/2} \delta / \sigma - z_{\alpha_0}\} \cup \right. \\ & \left. \{U_{k-1} > n_{k-1}^{1/2} \delta / \sigma - z_{\alpha_0}, \sum_{i=1}^k w_i^2 \geq 1\} \right]. \end{aligned} \quad (1)$$

Decomposing Equation 1 to a sequence of continuation regions at interim analyses facilitates the computation of this probability. When $m = k$, let

$$\begin{aligned} E_{k,1} &= \{U_1 > n_1^{1/2} \delta / \sigma - z_{\alpha_0}, w_1^2 + w_2^2 < 1\}, \\ E_{k,j} &= \{U_j > n_j^{1/2} \delta / \sigma - z_{\alpha_0}, w_1^2 + \dots + w_{j+1}^2 < 1\}, \\ &\text{for } j = 2, \dots, k-2, \\ E_{k,k-1} &= \{U_{k-1} \leq n_{k-1}^{1/2} \delta / \sigma - z_{\alpha_0}\} \cup \\ &\{U_{k-1} > n_{k-1}^{1/2} \delta / \sigma - z_{\alpha_0}, \sum_{i=1}^k w_i^2 \geq 1\}, \end{aligned}$$

where event $E_{k,j}$ only depends on the data from the first j blocks. It is clear that Equation 1 is equivalent to the intersection of $E_{k,j}$ for $j = 1, \dots, k-1$. The probability mass function for the stopping time m can be expressed as

$$\begin{aligned} P_\theta(m = k) &= p_\theta \left(\bigcap_{j=1}^{k-1} E_{k,j} \right) \\ &= P_\theta(E_{k,1}) \prod_{j=2}^{k-1} P_\theta(E_{k,j} | E_{k,1}, \dots, E_{k,j-1}). \end{aligned} \quad (2)$$

The expression on the right-hand side of Equation 2 makes the computation tangible because each conditional probability can be evaluated recursively. To

calculate the probability and each of the conditional probabilities on the right-hand side of Equation 2, define

$$\begin{aligned} b_j &= \frac{n_j(\delta - \theta)}{B_j^{1/2} \sigma} - z_{\alpha_0} \left(\frac{n_j}{B_j} \right)^{1/2}, \quad Z_j = S_j - \frac{B_j^{1/2} \theta}{\sigma}, \text{ and} \\ Y_{j+1} &= \sum_{i=1}^j \left(\frac{B_i}{B_{j+1}} \right)^{1/2} Z_i. \end{aligned} \quad (3)$$

It can be verified that $Z_1, Z_2, \dots$, are independent standard normal variables. The advantage for the transformation is to simplify the derivation of the joint distribution $\{U_1, \dots, U_k\}$ to the derivation of the distribution of $\{Z_1, \dots, Z_k\}$. The region where the weight is not yet used up at the j th analysis is

$$D_j = \left\{ (z_1, \dots, z_j) : \sum_{i=1}^{j+1} w_i^2(s_1, \dots, s_{i-1}) < 1, s_i = z_i + \frac{B_i^{1/2} \theta}{\sigma} \right\} \quad (4)$$

for $j = 1, 2, 3, \dots, m-1$. Continuation region $E_{k,j}$ ($j < k-1$) can be expressed by an intersection of the two events in terms of Z_j and D_j as follows:

$$\begin{aligned} E_{k,1} &= \{Z_1 > b_1\} \cap D_1, \\ E_{k,j} &= \{Z_j > -Y_j + b_j\} \cap D_j, \text{ for } j = 2, \dots, k-2. \end{aligned}$$

The termination region consists of the following two exclusive events: The futility boundary is crossed, or the weight is used up,

$$E_{k,k-1} = \{Z_{k-1} \leq -Y_{k-1} + b_{k-1}\} \cup [\{Z_{k-1} > -Y_{k-1} + b_{k-1}\} \cap \bar{D}_{k-1}],$$

where $\bar{D}_j$ is the complement of D_j . Given $\{Z_1, \dots, Z_{j-1}\}$, the computation of continuation region $E_{k,j}$ depends only on Z_j for $j < k$. The probability mass function of m in Equation 2 can then be formulated by the following integral:

$$\begin{aligned} P_\theta(m = k) &= \int_{E_{k,1}} \phi(z_1) \int_{E_{k,2}} \phi(z_2) \dots \\ &\int_{E_{k,k-1}} \phi(z_{k-1}) dz_{k-1} \dots dz_1, \end{aligned}$$

where $\phi(\cdot)$ is the probability density function of the standard normal distribution.

Evaluation of Operating Characteristics

Fundamental quantities for evaluating a group sequential design include the probability of exiting and rejecting (or accepting) the null hypothesis at a given interim analysis, and the overall probability to reject or accept the null hypothesis with the given design parameters and θ .

To compute the probability of exiting and rejecting H_0 at the k th analysis, express the event to terminate the trial and reject H_0 at $m = k$ as

$$R_k = \left\{ U_j > n_j^{1/2} \delta / \sigma - z_{\alpha_0}, 1 \leq j \leq k-1, T_k > z_\alpha \right\} \\ \bigcap_{i=1}^{k-2} \bar{D}_{k-1} \bigcap_{i=1}^{k-2} D_i,$$

where D_i is defined in Equation 4. Moreover, R_k is equal to the intersection of the following sequential events:

$$C_{k,1} = \{U_1 > n_1^{1/2} \delta / \sigma - z_{\alpha_0}, w_1^2 + w_2^2 < 1\} \\ = \{Z_1 > b_1\} \bigcap D_1, \\ C_{k,j} = \left\{ U_j > n_j^{1/2} \delta / \sigma - z_{\alpha_0}, w_1^2 + \dots + w_{j+1}^2 < 1 \right\} = \{Z_j > b_j - Y_j\} \bigcap D_j, \\ C_{k,k-1} = \{U_{k-1} > n_{k-1}^{1/2} \delta / \sigma - z_{\alpha_0}, w_1^2 + \dots + w_{k-1}^2 \geq 1\} = \{Z_{k-1} > b_{k-1} - Y_{k-1}\} \bigcap \bar{D}_{k-1}, \\ C_{k,k} = \{T_k > z_\alpha\} \\ = \left\{ Z_k > \frac{z_\alpha}{w_k} - \sum_{i=1}^{k-1} \frac{w_i}{w_k} Z_i - \sum_{i=1}^k \frac{w_i B_i^{1/2} \theta}{w_k \sigma} \right\}$$

for $j = 2, \dots, k-2$, where $C_{k,j}$ is the continuation region for $j < k-1$ and $C_{k,k}$ is the rejection region at the k th analysis. $C_{k,k-1}$ shows that the weight is used up to the k th analysis. Event $C_{k,j}$ depends only on data from the first j blocks for $j \leq k$.

The probability of a trial being terminated at the k th analysis and rejecting the null hypothesis can be computed by the product of the following conditional probabilities:

$$P_\theta(R_k) = P_\theta \left(\bigcap_{j=1}^k C_{k,j} \right) = P_\theta(C_{k,1}) \prod_{j=2}^k P_\theta(C_{k,j} | C_{k,1}, \dots, C_{k,j-1}). \quad (5)$$

Because $Z_1, Z_2, \dots, Z_k$ are independent identically distributed standard normal variables and each $C_{k,j}$ is uniquely determined by Z_j conditional on $Z_1, \dots, Z_{j-1}$, Equation 5 can be written as a $(k-1)$ -fold multiple integral:

$$P_\theta(R_k) = \int_{C_{k,1}} \phi(z_1) \dots \int_{C_{k,k-2}} \phi(z_{k-2}) \cdot \\ \int_{C_{k,k-1}} \phi(z_{k-1}) \Phi \left(\sum_{i=1}^{k-1} \frac{w_i}{w_k} Z_i + \sum_{i=1}^k \frac{w_i B_i^{1/2} \theta}{w_k \sigma} - \frac{z_\alpha}{w_k} \right) \\ dz_{k-1} \dots dz_1,$$

where $\Phi(\cdot)$ is a cumulative distribution function of a standard normal variable.

The overall rejection region, R , can be decomposed by the partition $\{m = k\}$, for $k = 2, 3, \dots$. That is, $R = \bigcup_{k=2}^\infty R_k$, where $R_k = R \bigcap \{m = k\}$. Consequently, the overall probability of rejecting the null hypothesis can be calculated by the following summation:

$$P_\theta(R) = \sum_{k=2}^\infty P_\theta(R_k).$$

If a trial is terminated to accept H_0 at a given interim analysis, $m = k$, the trial is terminated either by spending all the weight and $T_k \leq z_\alpha$ at the k th analysis or by crossing the futility boundary at the $k-1$ th analysis.

$$A_k = \{U_j > n_j^{1/2} \delta / \sigma - z_{\alpha_0}, 1 \leq j \leq k-1, \\ T_k \leq z_\alpha, m = k\} \\ \cup \{U_j > n_j^{1/2} \delta / \sigma - z_{\alpha_0}, 1 \leq j \leq k-2, \\ U_{k-1} \leq n_{k-1}^{1/2} \delta / \sigma - z_{\alpha_0}\} \\ = \left\{ \left(\bigcap_{j=1}^{k-1} C_{k,j} \right) \bigcap \bar{C}_{k,k} \right\} \\ \cup \left\{ \left(\bigcap_{j=1}^{k-2} C_{k,j} \right) \bigcap (Z_{k-1} \leq b_{k-1} - Y_{k-1}) \right\}.$$

The probability of accepting H_0 at the k th analysis can be computed by the following multiple integral:

$$p_\theta(A_k) = \int_{C_{k,1}} \phi(z_1) \dots \int_{C_{k,k-2}} \phi(z_{k-2}) \cdot \int_{C_{k,k-1}} \phi(z_{k-1}) \\ \Phi \left(\frac{z_\alpha}{w_k} - \sum_{i=1}^{k-1} \frac{w_i}{w_k} Z_i - \sum_{i=1}^k \frac{w_i B_i^{1/2} \theta}{w_k \sigma} \right) \\ dz_{k-1} \dots dz_1, \\ + \int_{C_{k,1}} \phi(z_1) \dots \int_{C_{k,k-2}} \phi(z_{k-2}) \cdot \\ \Phi(b_{k-1} - Y_{k-1}) dz_{k-2} \dots dz_1.$$

Subsequently, the probability that a trial terminates at the k th analysis is $P_\theta(A_k) + P_\theta(R_k)$. For any given θ , the overall probability of accepting the null hypothesis can be obtained by

$$P_\theta(A) = \sum_{k=2}^\infty P_\theta(A_k).$$

Applications and Numerical Results

The properties derived in the last two sections can be used to design a self-designing sequential trial and to obtain directly the error probabilities for a given set of design parameters. The values of the design parameters $(\alpha, \beta, \alpha_0, \delta)$ determine the distribution of the stopping time and the associated decision rules for any given θ .

For the fixed sample design, the actual Type I error probability would be α if $\theta = 0$, and the actual Type II error probability would be β if $\theta = \delta$, whereas the actual error probabilities might be different if $\theta \neq \delta$. Similarly, in a self-designing trial, the actual overall Type I or II error rate is often different from the specified α or β , given different values of θ . Using the derived formulas, the actual error rates can be estimated for any given value of θ and the probability of rejecting or accepting the null hypothesis at a given interim analysis can be obtained.

Table 1 presents the numerical results given $\alpha = 0.05$, $\beta = 0.1$, $\alpha_0 = 0.05$, and $\delta = 0.4, 0.5$, or 0.6 , with the true mean $\theta = 0, 0.5$, or 0.7 , and prefixed constant block sizes, $B_1 = N_1/2$ and $B_i = 10$ or 12 for $i \geq 2$.

There is a rapid decay of the probability mass $P_\theta(m = k)$ when $k > 3$ in general. As presented in Table 1 for $P_\theta(m \leq 3)$, 85% to 97% of trials were terminated with three or fewer interim analyses either under H_0 or H_1 for the given block sizes. When $P_\theta(m > 3)$ is small, the overall probability of rejecting H_0 , $P_\theta(R)$ can be approximated by the following conditional probability:

$$P_\theta(R | m \leq 3) = \frac{P_\theta(R_2) + P_\theta(R_3)}{P_\theta(m = 2) + P_\theta(m = 3)}, \quad (6)$$

because $P_\theta(R) = P_\theta(R | m \leq 3)P_\theta(m \leq 3) + P_\theta(R | m > 3)P_\theta(m > 3)$.

The performance of this approximation is assessed by comparing the conditional probability (Equation 6) calculated from the numerical integration, denoted by C.P. in Table 1, with the empirical overall probability of rejecting the null hypothesis, denoted by S.P., where S.P. is estimated using the Monte Carlo method with 10,000 repetitions. The quantities under “S.P.” in Table 1 are the empirical estimators of Type I error rates (under $\theta = 0$) or power (under $\theta > 0$). The associated estimator under “C.P.” is the conditional probability directly calculated from the numerical integration. As expected, the conditional probability is a reasonable approximation to $P_\theta(R)$ with a moderate block size ($B \geq 10$) under either H_0 or H_1 .

It is clear that the choice of α_0 determines the futility boundary, which affects the operating characteristics of the design. The largest possible α_0 is searched to achieve a power $(1 - \beta)$ with a specified Type I error rate α by setting $P(R|m \leq 3) \geq 1 - \beta$.

Presented in Table 2 with $\alpha = 0.05$ and $\theta = \delta$, α_0 varies from 0.0015 to 0.045 to attain the specified power, 0.9, depending on the values of δ and α , and the block size. If the true mean θ is smaller than the expected mean δ , a trial with design parameter α_0 , which is determined under the assumption of $\theta = \delta$, might not achieve the desired power. Instead, a much smaller α_0 for the futility boundary is needed to achieve the specified power.

The evaluations of the operation characteristics can help investigators to assess the feasibility of a flexible adaptive design easily under some scenarios of interest. The formulation also allows clinical trialists to select the design parameters so as to construct a sequential design to satisfy regulatory requirements. In particular, the methodology described here can help one to better achieve the targeted Type I and II errors.

SEQUENTIAL DESIGN

Experimental studies in the social and behavioral sciences typically follow a *fixed* experimental design where the sample size and composition (e.g., experimental group allocation) is determined prior to conducting the experiment. In contrast, *sequential* experimental designs treat the sample size as a random variable by allowing sequential interim analyses and decision making based on cumulative data and previous design decisions while maintaining appropriate control over experiment-wise errors in decision making (i.e., Type I [α] and Type II [β] error rates). Also referred to as *adaptive* or *flexible* designs, current design decisions in sequential designs are sequentially selected according to previous design points. Sequential designs rely on the principal of *stochastic curtailment* to stop the experiment if the given data at an interim analysis are likely to predict the eventual outcome with a high probability. In contrast to a fixed design where the size and composition of the sample is determined prior to conducting the experiment, the number of observations or participants is not predetermined in a sequential design. Thus, the size and composition of the sample is considered random because of decision dependence on previous observations. However, a finite upper limit is often set in practice.

Sequential designs allow for the early termination of experiments if cumulative evidence suggests a clear effect or lack thereof. The capacity for sequential designs to terminate early can be beneficial from an ethical perspective by preventing unnecessary exposure to unsafe experimental conditions in terms of both length of exposure and the number of participants exposed, as well as unnecessarily withholding administration when the experimental condition is clearly beneficial. Popular in medical trials and drug studies, the early termination of prevention or intervention experiments might lead to minimized exposure to potentially harmful or ineffective treatments. Sequential designs can also be beneficial from a logistical perspective as they can save both time and resources. More generally, sequential designs have the potential to

lead to financial savings because of reduced sample sizes. Under the null hypothesis of no effect, sequential designs might be stopped for lack of effectiveness at a total sample size smaller than would be the case with a fixed design. Under the alternative hypothesis of efficacious experimental manipulation, a similar savings is observed in the total sample size required, with the sample size savings typically reported as greater under the alternative hypothesis than under the null hypothesis. Actual sample reductions vary by the type of sequential design and certain design decisions but are generally reported to be as large as 10% under the null hypothesis and as large as 50% under the alternative hypothesis. In research contexts where the participant stream might be small or inaccessible, the potential for such substantial sample size savings when implementing a sequential experimental design might be quite beneficial.

This entry discusses the background and design characteristics, along with the benefits and limitations of sequential design.

Background

The origins of sequential designs can be traced back to the development of a double sampling inspection procedure by Harold F. Dodge and Harry G. Romig in 1929 for the purpose of industrial quality control. Prasanta Chandra Mahalanobis's 1938 census of Bengalese jute areas is also considered an important precursor. In 1943, Abraham Wald, with collaboration from members of the Statistical Research Group at Columbia University, including Milton Friedman and W. Allen Wallis, developed the sequential probability ratio test for military armament testing. The development of the sequential probability ratio test also launched the complementary field of sequential analysis. Sequential analyses are statistical hypothesis testing procedures that allow a statistical test to be calculated at any stage of the experiment prior to completion, and then it provides a three-alternative rule for inferential decision making: to fail to reject the null hypothesis, to reject the null hypothesis, or to continue the experiment. In contrast, statistical evaluation of a fixed design experiment only occurs at the completion of the experiment. Peter Armitage's 1960 book on sequential medical trials effectively introduced the sequential design of randomized clinical trials (RCT), and in this research context, sequential designs have observed the greatest growth and development. More recently, psychometricians have developed computerized adaptive testing procedures for educational and psychological testing based on the principles of sequential design of experiments. Psychometric applications of sequential design became

widespread beginning in the early 1980s, but its roots can be attributed to Alfred Binet in 1905 with the start of adaptive individualized intelligence testing.

Design Characteristics

All sequential designs provide the opportunity for at least one interim analysis at a prespecified interim stage prior to formal completion of the experiment, which allows early stopping for either positive or negative results through progress monitoring. Prior to the start of the experiment, the statistical details are determined, including the number of interim stages and, relatedly, the sample size at each stage. Based on the desired nominal α and β levels, critical values, which are also called *boundary values*, are computed for each interim stage. At each interim stage, all available data are analyzed including data from that stage plus all previous stages. The appropriate test statistic and the Fisher information level (the inverse of the squared standard error) are computed at each stage. The test statistic is then compared with critical boundary values chosen a priori to maintain appropriate nominal experiment-wise Type I and Type II error rates given the occurrence of multiple statistical tests at interim stages. If the test statistic falls within a decision region, the experiment stops. Otherwise, the experiment continues to the next stage or until the maximum sample size is reached.

Boundary Values

At any interim stage, the experiment can either be stopped for ethical or efficacy reasons, or continued as a result of insufficient statistical evidence of a significant effect in either direction. Boundary values similar to conventional critical values are set up for each interim stage to determine whether sufficient accumulated evidence is available to conclude experimental efficacy (or futility) or the presence of a harmful effect. Boundary values are derived to maintain experiment-wise Type I and Type II error rates at specified nominal levels. Up to four boundary values are derived a priori depending on the number of tails in the statistical hypothesis test. A one-tailed test has up to two boundary values, while a two-tailed hypothesis has up to four boundary values. Two boundary values define the region of rejection where the experiment stops and the null hypothesis of no difference is rejected. Assuming that the experimental group experiences an increase in outcomes as a result of a particular treatment, if the test statistic exceeds the upper critical value, the null hypothesis is rejected for efficacy. However, if the test statistic exceeds the lower critical value, the null hypothesis is rejected for a harmful effect. Two

additional boundary values can be specified to define the acceptance region where the experiment stops and the null hypothesis is not rejected. If the test statistic falls in between the rejection and acceptance regions, the experiment continues to the next interim stage. At the last stage, the boundaries of the rejection and acceptance regions are identical, the experiment stops, and the decision is made either to reject or fail to reject the null hypothesis. If the experimental protocol only allows early stopping to reject, there are no acceptance boundaries at early stages, and with early stopping only to fail to reject the null hypothesis, there are no interim rejection boundaries.

Boundary Methods

Traditional fixed design methods for determining critical or boundary values cannot be applied in sequential designs because of inflation in the Type I error rate. For instance, a fixed design testing a two-tailed hypothesis where a z test only occurs at the completion of the experiment would use a pair of critical values defining the boundary of the region of rejection of the null hypothesis, ± 1.96 , to control the experiment-wise Type I error rate at the nominal $\alpha = .05$ level. A two-stage sequential design that was required to be carried out to completion rather than stopped early after one interim analysis, resulting in the same sample size as the fixed design, would have a nominal Type I error rate of $\alpha = .083$ using the same critical values because of the experiment consisting of two dependent statistical tests. Consequently, multiple methods have been developed to control the Type I error rate adequately in sequential experiments. These methods are of three general types: fixed boundary shape methods, Whitehead methods, and error spending methods.

The *fixed boundary shape methods* include several popular approaches, including the Pocock and O'Brien-Fleming methods. Use of the O'Brien-Fleming method requires overwhelming evidence to reject the null hypothesis at early stages by implementing initially conservative, but successively decreasing, boundary values. For instance, a five-stage design would use critical values of 4.56, 3.23, 2.63, 2.28, and 2.04, where the final critical value is then close to the fixed design critical z value of 1.96. In contrast, Pocock's method, when used with equally spaced information levels, derives a constant boundary value, but the nominal alpha level is smaller than the desired $\alpha = .05$ level, which makes the overall design more statistically conservative. For instance, a constant boundary value at all five stages would be 2.41 rather than 1.96, but the nominal alpha level at the final stage ($\alpha = .032$) would be smaller than

the overall alpha-level of the design ($\alpha = .050$). Such a discrepancy might result in a failure to reject the null hypothesis despite the final p value falling below the nominal experiment-wise level (i.e., if the final p value is between .032 and .050).

Whitehead methods were generalized from designs requiring continuous monitoring (i.e., after each participant completes the study) to designs with discrete monitoring (i.e., after groups of participants complete the study). They result in triangular or straight-line boundaries, require less computation than the fixed boundary shape methods, and maintain Type I error rates and statistical power that is close to, but does differ slightly from, nominal values.

The third class of boundary methods, the *error spending methods*, requires the most computation (relative to Whitehead and fixed boundary shape methods) when a large number of interim stages are used. Error spending methods use an error spending function to specify an amount of the prespecified nominal alpha and beta rate error to be spent at each stage with boundary values derived from this amount.

Types of Sequential Designs

Sequential experimental designs are generally of three types that differ based on sample recruitment and decision-making criteria.

Fully sequential designs use continuous monitoring and are updated after every observation or after every participant completes the study; thus, the critical boundary values change as the experiment progresses because of the addition of data and a resulting reduction of variance. Fully sequential designs require that the outcome of the experiment is knowable in a relatively short period of time relative to the length of time required for recruitment or follow-up. In such designs, long periods of "no effect" or continuation might be falsely interpreted as equivalence of experimental conditions. Although Abraham Wald's development of the sequential probability ratio test was the origin of this approach, despite its historical longevity, it has not been widely applied. However, one area where fully sequential designs have been widely applied is in the context of computerized adaptive testing (CAT) and computerized classification testing (CCT), where question selection depends on the response to the previous question. In these contexts, each question that a participant responds to is considered an observation. The test (i.e., the experiment) concludes when a prespecified degree of precision or consistency of responses is attained rather than a statistically significant difference between two experimental conditions.

Group sequential designs have been found to be more practical in most settings than fully sequential designs. In some circumstances, an evaluation after each participant completes the study might not be feasible. Also, choosing to stop an experiment early after just a few participants because of strong evidence might not be persuasive either way the evidence falls. Group sequential designs can be considered analogous to fully sequential designs with the distinction that boundary values are computed for a predetermined number of equally spaced stages based on a prespecified number of participants (i.e., a group) rather than after each participant. Likewise, fully sequential designs can be viewed as group sequential designs where the size of the participant group is $n = 1$. Four to five interim stages or data inspections are typically recommended, as a larger number of interim analyses do not lead to extra benefits in terms of reduced overall sample sizes.

Whereas fully sequential and group sequential designs are characterized by prespecified, predetermined, and constant group sizes (with $n = 1$ as a special case), *flexible sequential designs* allow flexible modification during the experiment through an alpha spending function that allocates the amount of the nominal experiment-wise error to be spent at each interim while maintaining the overall nominal Type I error rate at the $\alpha = .05$ level. To protect against potential researcher abuse, the alpha spending function is specified during the study design phase and cannot be changed midexperiment. Flexible sequential designs allow periodic interim evaluation as do other types of sequential designs, but flexible designs also might allow the interim evaluations to become more frequent as the decision point becomes closer. Thus, flexible sequential designs can be viewed as a compromise between fully sequential and group sequential designs where each is considered a special case of a more general flexible design. The flexible design is equivalent to the fully sequential design under continual monitoring and equivalent to the group sequential design when the flexible nature of the interim analyses is not used.

Benefits and Limitations

The primary engine behind the principles of sequentially designed experiments is making use of existing information at interim stages of the experiment to inform future design decisions, especially in regard to participant recruitment. In the case where the researcher has a limited amount of theoretical or empirical knowledge that would otherwise prevent well-informed decision making in terms of the necessary sample size, sequential designs can be quite valuable. The advantage

of a sequential experimental design as compared with a fixed design is primarily tied to the size of the experimental effect in the population. Traditional designs are planned to have sufficient power to detect an effect size specified in advance by the researcher. To the extent that this effect size is incorrect in the population, the researcher has inadvertently overpowered or underpowered the study; both situations are problematic. This brings to light a specific advantage of sequential designs over fixed experimental designs. A sequential design allows early stopping in the event the effect size is larger than previously estimated, as well as subsequent data collection in the event the effect size is smaller than expected. If experimental differences are found to be larger than expected, the probability of early study termination is higher and savings might be obtained in terms of decreased resource allocation (smaller samples, fewer materials, etc.) regardless of the general type of sequential design employed. If the effect of interest is actually smaller in the population than expected, then fully sequential and group sequential designs might result in a decrease in power because of the additional analyses. This result can be ameliorated to an extent by employing a flexible sequential design. For instance, a particular experiment is designed so that a given effect size has a prespecified probability of being detected by the end of the study (power) while controlling the probability of making a Type I error at the nominal $\alpha = .05$ level. However, at an interim stage the effect size might be smaller than expected, which raises the concern that there might be a lack of power for the overall experiment. If the overall design is flexible, the sample size might be increased and the boundary values adjusted to preserve the Type I error rate. This approach would not be as statistically efficient as a group sequential design that does not adapt, but it would protect against insufficient statistical power to reject a null hypothesis that is truly false. Some might argue that adopting a flexible design from the onset of a study is a reasonable approach when the magnitude of the true treatment effect is not clearly known, if there is a discrepancy between a clinically meaningful effect and an observable effect, or if it is not clear that the potential effectiveness warrants using what are otherwise limited resources. In this circumstance, a flexible design would allow accumulation of promising evidence to support better-informed expansion or continuation of the experiment.

Sequential designs are particularly applicable to medical and pharmaceutical trials, which are generally referred to as randomized clinical trials (RCTs). An RCT is a type of randomized experiment in which the effectiveness of a new drug, intervention, or other medical procedure is evaluated by comparing a

treatment group with a control group. RCTs are conducted according to a plan, or *protocol*, which details the RCT's objectives, data collection procedures, and data analysis framework. RCTs typically require a sequentially recruited participant stream and lend themselves well to sequential designs. Sequential designs are particularly appropriate for medical RCTs as well because of the need for trial monitoring to minimize exposure to unacceptable toxicity or potential harm of new interventions or to minimize continuation after the benefit or risk is clearly apparent. Particularly when the clinical outcome is considered irreversible, fixed designs are not acceptable; thus, monitored sequential designs are needed.

Flexible sequential designs are particularly useful in Phase II clinical trials. Whereas a Phase I trial is used to determine whether a new drug or treatment is safe for humans and to estimate an initial effect size, a Phase II trial is conducted on a larger sample of participants to determine how well the drug works while continuing to monitor participant safety. Phase I effect size estimates are sometimes found to be too optimistic, so a Phase II sample size based on an inflated effect size might be smaller than required. A flexible sequential design would allow for interim sample size augmentation to accommodate the smaller-than-expected effect size.

Finally, sequential designs are not without their limitations. In addition to the increased design complexity and computational burdens in determining boundary values and controlling the experiment-wise error rate, the ability to terminate the experiment early (a major benefit of sequential designs) also provides a threat to the validity of the study. If an experiment stops early for efficacy, futility, or participant safety, a smaller sample size can lead to a distrust of the findings because most statistical procedures rely on asymptotic principles that require larger sample sizes. Thus, the decision to exit early is more complex than just a statistical criterion. Therefore, the sequential design plan must be specified so that the resulting analysis is both reliable and persuasive. This includes consistency across both primary and secondary outcomes, risk groups, and so on, to be persuasive after an early termination.

SEQUENTIAL SAMPLING

In experiments, researchers must balance between two competing arguments with respect to the sample size. On the one hand, the sample size must be large enough to have sufficient statistical power for accurate statistical inference. On the other hand, each additional observation comes at a cost and, especially when performing medical experiments or working with test animals, the researcher has the ethical obligation to avoid unnecessary oversampling. The field of optimal stopping, or sequential sampling, studies ways in which to do this. Various techniques for sequential sampling are available. This entry, based on the 2019 work of Casper J. Albers, explains some of these techniques.

Sometimes, researchers simply collect and analyze a sample, look at the resulting p value, and collect more data until either significance is reached or resources are exhausted. This approach is flawed because it leads to multiple testing with an inflated false discovery rate (i.e., too many false positives). This leads to bias in both the p values and the estimated effect size. Several statistical corrections, such as the Bonferroni correction, exist to overcome this. In sequential designs, similar solutions exist. Sequential methods have mostly been designed for classical (frequentist) approaches. For Bayesian analysis, there still is debate among statisticians whether or not it is necessary to correct for multiple testing in a sequential design.

Roughly speaking, there are two classes of such sequential approaches: interim analyses (also known as *group sequential analyses*) and full sequential analyses. In interim analyses, one prespecifies moments when one wants to inspect the data, whereas in full sequential analyses, the data are analyzed after each observation.

As an example of interim analysis, one could decide to analyze the data both after $n_1 = 50$ and, if necessary, after $n_2 = 100$ measurements. The decision rule of testing with $\alpha = 0.029$ after n_1 measurements and stopping when the result is significant or continuing until n_2 and testing again at this α level provides the usual overall false discovery rate of 0.05. The major advantage over nonsequential testing is that in case of sufficient evidence, one can stop data collection halfway through the process. One can specify a priori how many batches of measurements one maximally wants, and how large these should be, and then compute the α level on which to test the interim analyses. Such computations can be based on Pocock bounds, Haybittle–Peto bounds, or O’Brien and Fleming bounds.

In full sequential approaches, one does not check the data at a few prespecified points, but after *every* observation. Statistically, this is the optimal approach of deciding on the sample size, as here one could, for example, stop collection at $n = 62$ when the example of an interim approach would need $n = 100$.

Theories about sequential sampling by statisticians Abraham Wald and Alan Turing date back to the 1940s. These full sequential approaches are quite technical. Wald’s procedure, for instance, involves computing the log-likelihood ratio after each observation and stopping when this sum leaves a prespecified interval. The computation of this log-likelihood ratio is far from straightforward. Under mild statistical assumptions, it can be proven that Wald’s sequential probability ratio test is the optimal mathematical procedure for these types of problems. A similar approach is cumulative sum control charts (CUSUM). CUSUM and related methods are the gold standard in statistical quality control.

Another distinction between both methods is that in interim analysis, one can stop data collection early in case there is sufficient evidence to reject the null hypothesis. This also holds true for the full sequential method, but here one can also stop when it is sufficiently clear that the null hypothesis will *not* be rejected. Thus, in a full sequential analysis, one can actually accept the null hypothesis, something which usually is not possible in frequentist analyses.

Despite its theoretical advantages, full sequential designs are not always possible in practice. For instance, when participants need to undergo group therapy in

groups of size 20, an interim analysis with batches of 20 participants makes more sense than a full sequential approach. Also in situations where it takes a considerable time before one can measure, for instance, when one is interested in a patient’s blood pressure 1 week after the administration of a new drug, it is not feasible to collect the data one by one.

Conventional statistical packages, such as SPSS and Stata, have poor implementations for sequential analysis. In SAS, both full sequential and group sequential methods are possible. There are unfortunately few accessible tutorials for performing sequential methods using these commercial packages. In R, the packages *gsDesign* and *sequential* offer nearly all possibilities for both setting up and performing sequential analyses with accompanying accessible tutorials.

“SEQUENTIAL TESTS OF STATISTICAL HYPOTHESES”

Most statistical work builds on a well-established paradigm. Abraham Wald fully developed and established a new paradigm based on sequential tests of statistical hypotheses. Although formulated in 1943, the new paradigm was first published as “Sequential Tests of

Statistical Hypotheses” in *The Annals of Mathematical Statistics* in 1945. In traditional statistical hypothesis testing, an experiment is performed using a predetermined sample size chosen to ensure sufficient statistical power so the null hypothesis is likely to be rejected when in truth it should be rejected. In sequential hypothesis testing, experiments are designed so that after each observation, a decision could be made to accept or reject the null hypothesis or to gather another observation. Thus, a final decision would be based on a sequence of statistical tests.

Wald’s early work in mathematics focused on geometry, but he became a leading econometrician in Vienna. After the German occupation of Austria, Wald escaped to the United States in 1938. He was appointed a fellow by the Carnegie Corporation, studied statistics at Columbia University with Harold Hotelling, and then joined the faculty.

In 1943, while working as part of the Statistical Research Group at Columbia University, the U.S. Navy Department of Ordinance asked for help with a statistical quality control problem. Parts, including munitions, needed to be machined to a certain tolerance or the resulting equipment might not work or might wear out prematurely. It was too expensive and time-consuming to measure precisely every component, so a random sample of components was usually selected and measured to determine whether the manufacturing process was likely to lead to acceptable quality. If tolerances were not met, the manufacturing equipment or processes needed to be modified. The Columbia Statistical Research Group was asked to think about improving the efficiency of the statistical quality control analyses.

There are simple, straightforward ways to improve the efficiency of sampling. For example, you are testing 1,000 units and you are willing to reject the null hypothesis if 50 units are outside of the acceptable tolerance band: If you test 900 units and 50 units are already outside of tolerance, there is no need to test the remaining 100 units. You know you will reject the null hypothesis. Previous researchers, who were cited in Wald’s article, identified special circumstances where somewhat more sophisticated versions of sequential hypothesis testing showed greater efficiency than classic hypothesis testing approaches.

Wald realized that costs are associated with rejecting the null hypothesis when it is true, not rejecting the null hypothesis when it is false, and collecting and analyzing incremental data. These costs could be translated into weights and applied to the sequential collection of data and testing of hypotheses. Applying this approach to quality control of war material saved

money but perhaps more importantly reduced the time required to get equipment to troops.

Wald realized there were many different sequential test procedures that could be implemented—but how to choose among them was the question. Wald developed a detailed framework and the sequential probability ratio test, which he proved had optimal statistical characteristics including great efficiency. He showed that compared with the most statistically powerful test from a fixed sample size experimental approach, the sequential probability test achieved comparable results with about half the expected sample size. Moreover, he showed the approach could be carried out without knowledge of the probability distribution of the test statistic.

The simplicity and power of Wald’s approach was recognized as so important to the war effort that Wald’s original papers were restricted so the Axis nations would not be able to use this approach. Thus, the work he did in 1943 was not published until after the end of World War II.

Wald’s 1945 paper was divided into an introduction and history and two substantive parts. The first part explored the use of a sequential test comparing a simple hypothesis against a single alternative. The second part expanded his approach to cover a simple or complex hypothesis against a set of alternatives.

Wald died prematurely at age 48 in an airplane crash while he was enroute to a lecture tour as a guest of the Indian government. His work, including this paper, went on to influence many statisticians and psychometricians and is the basis of one form of computerized adaptive testing.

SERIAL CORRELATION

Serial correlation, or autocorrelation, is defined as the correlation of a variable with itself over successive observations. It often exists when the order of observations matters, the typical scenario of which is when the same variable is measured on the same participant repeatedly over time. For example, serial correlation is

an important issue to consider in any longitudinal design.

Serial correlation has mainly been considered in multiple regression and time-series models. Multiple regression models are designed for independent observations, where the existence of serial correlation is undesirable. So the main focus in multiple regression is on testing whether serial correlation exists. Conversely, the purpose of time-series analysis is to model the serial correlation to understand the nature of time dependence in the data. The pattern of serial correlation is essential for identifying the appropriate model. This presentation on serial correlation is around regression and time series.

Multiple Regression Model

Let the multiple regression model be

$$y_i = \mathbf{x}_i \boldsymbol{\beta} + \varepsilon_i, \quad i = 1, 2, \dots, n, \quad (1)$$

where y_i is the response and $\mathbf{x}_i$ is a $1 \times (k + 1)$ vector consisting of a 1 and the values of the k predictors in the i th observation. The assumptions of this model are (a) the expectation of the error ε_i is 0; (b) ε_i has constant variance σ^2 ; and (c) ε_i and ε_j are uncorrelated if $i \neq j$. Let $\hat{\boldsymbol{\beta}}$ be the least squares (LS) estimator of $\boldsymbol{\beta}$ and SSE be the sum of squared errors. When the assumptions are valid, $\hat{\boldsymbol{\beta}}$ is the best linear unbiased estimator and $s^2 = SSE / (n - k - 1)$ is an unbiased estimator of σ^2 . When the errors are correlated (violating assumption c), although $\hat{\boldsymbol{\beta}}$ is still unbiased, s^2 and the estimated standard error of $\hat{\boldsymbol{\beta}}$ are biased. Consequently, the F or t statistic in testing the significance of $\hat{\boldsymbol{\beta}}$ is misleading. Therefore, it is important to test for the presence of serial correlation. The most widely used test is the *Durbin-Watson d test*, which tests for first-order serial correlation $\rho = \text{Corr}(\varepsilon_i, \varepsilon_{i+1})$ using the autoregressive model

$$\varepsilon_i = \eta \varepsilon_{i-1} + e_i, \quad -1 < \eta < 1. \quad (2)$$

Obviously, $\rho = 0$ if $\eta = 0$. To test the null hypothesis $H_0 : \eta = 0$, the test statistic d is formulated as

$$d = \sum_{i=2}^n (\hat{\varepsilon}_i - \hat{\varepsilon}_{i-1})^2 / \sum_{i=1}^n \hat{\varepsilon}_i^2,$$

where $\hat{\varepsilon}_i$ are the LS residuals with fitting Equation 1. Let $\hat{\eta} = \sum_{i=2}^n \hat{\varepsilon}_i \hat{\varepsilon}_{i-1} / \sum_{i=2}^n \hat{\varepsilon}_{i-1}^2$ be the LS estimate of $\cdot$ in Equation 2. It follows from $(\hat{\varepsilon}_i - \hat{\varepsilon}_{i-1})^2 = \hat{\varepsilon}_i^2 - 2\hat{\varepsilon}_i \hat{\varepsilon}_{i-1} + \hat{\varepsilon}_{i-1}^2$ that $d \approx 2(1 - \hat{\eta})$. Thus, if there is no serial correlation, $d \approx 2$; if the serial correlation is close to 1, $d \approx 0$; and if the serial correlation is close to -1, $d \approx 4$. The critical values of d (denote the lower bound as d_L and the upper bound as d_U) depend on n , k , and the significance level of the test. Tables of d_U and d_L can be found in the

Appendix of Arnold Studenmund's book. The appropriate decision rules of testing for positive serial correlation are

$$\begin{array}{ll} \text{reject } H_0 & \text{if } d < d_L; \\ \text{do not reject } H_0 & \text{if } d > d_U; \\ \text{inconclusive} & \text{otherwise.} \end{array}$$

The decision rules of testing for negative serial correlation are

$$\begin{array}{ll} \text{reject } H_0 & \text{if } d > 4 - d_L; \\ \text{do not reject } H_0 & \text{if } d < 4 - d_U; \\ \text{inconclusive} & \text{otherwise.} \end{array}$$

The inconclusive region is one main disadvantage of the Durbin-Watson d test. Moreover, the test ignores serial correlation beyond the first order. It does not allow earlier observed y to predict later y in the regression model either.

The *Lagrange multiplier test* (LM) can overcome the previously mentioned three limitations of the Durbin-Watson d test. To test the null hypothesis that $\rho_j = \text{Corr}(\varepsilon_i, \varepsilon_{i+j}) = 0$ ($1 \leq j \leq q$) in Equation 1, where $\mathbf{x}_i$ might contain observations $(y_{i-1}, y_{i-2}, \dots)$, the first step is to obtain $\hat{\varepsilon}_i$ using LS. Then, based on $\hat{\varepsilon}_i$, a new regression equation,

$$\hat{\varepsilon}_i = \mathbf{x}_i \boldsymbol{\theta} + \eta_1 \hat{\varepsilon}_{i-1} + \dots + \eta_q \hat{\varepsilon}_{i-q} + e_i, \quad (3)$$

$$i = q+1, \dots, n,$$

is formed. Let R^2 be the coefficient of determination (i.e., R -square) of fitting Equation 3 using LS; the LM test statistic is

$$LM = nR^2.$$

The statistic LM is compared with X_q^2 to test for significance. If it is significant, the null hypothesis ($\rho_1 = \rho_2 = \dots = \rho_q = 0$) is rejected. The LS estimates of regression coefficients are biased before the serial correlation among ε_i is explicitly modeled, which is the focus of the time-series analysis described in the next section.

Time-Series Analysis

A univariate discrete time series $\{X_t, t = 0, 1, 2, \dots\}$ is said to be *weakly stationary* if $\mu = E(X_t)$, $\sigma^2 = \text{Var}(X_t)$ and

$$\gamma(h) = \text{Cov}(X_t, X_{t+h})$$

do not depend on t . As a function of h , $\gamma(h)$ is called *autocovariance function* (ACVF). Obviously, $\sigma^2 = \gamma(0)$. For a weakly stationary time series, the serial correlation among X_t ,

$$\rho(h) = \gamma(h) / \gamma(0) \quad (4)$$

is commonly called the *autocorrelation function* (ACF). It satisfies $\rho(h) = \rho(-h)$, where h is referred to as time lag. Another important concept related to serial correlation is the *partial autocorrelation function* (PACF). It measures the correlation between X_t and X_{t+h} given $X_{t+1}, \dots, X_{t+h-1}$. Let $\gamma_h = [\gamma(1), \gamma(2), \dots, \gamma(h)]'$ be the vector of ACVF and

$$\Gamma_h = \begin{bmatrix} \gamma(0) & \gamma(1) & \dots & \gamma(h-1) \\ \gamma(1) & \gamma(0) & \dots & \gamma(h-2) \\ \vdots & \vdots & \ddots & \vdots \\ \gamma(h-1) & \gamma(h-2) & \dots & \gamma(0) \end{bmatrix}$$

be the matrix of ACVF; the PACF is defined as

$$\alpha(h) = \begin{cases} 1, & h = 0; \\ \phi_{hh}, & h \geq 1, \end{cases} \quad (5)$$

where ϕ_{hh} is the last component of the h 1 vector $\phi_h = \Gamma_h^{-1} \gamma_h$.

In time-series analysis, $\gamma(h)$, $\rho(h)$, and $\alpha(h)$ facilitate the identification of the appropriate model, which is discussed later in this entry.

Point Estimators of ACVF, ACF, and PACF

Based on a sample time series $x_1, \dots, x_n$, ACVF, ACF, and PACF can be estimated. The recommended estimator of $\gamma(h)$ is given as

$$\hat{\gamma}(h) = n^{-1} \sum_{t=1}^{n-h} (x_{t+h} - \bar{x})(x_t - \bar{x}), \quad (6)$$

where $\bar{x} = \sum_{t=1}^n x_t / n$. The denominator in Equation 6 is n instead of $n - h$, which makes $\hat{\Gamma}_h$ non-negative definite. However, the estimators with either n or $n - h$ as denominator are biased. The bias is small when n is large.

Consistent estimators of $\rho(h)$ and $\alpha(h)$ can be obtained by replacing $\gamma(h)$ with $\hat{\gamma}(h)$ in Equations 4 and 5, respectively.

Standard Errors of ACF and PACF Estimates

To judge the significance of $\hat{\rho}(h)$ or $\hat{\alpha}(h)$, consistent estimates of their standard errors (SEs) are needed. Under standard regularity conditions and with a large n , $\hat{\mathbf{p}}_m = [\hat{\rho}(1), \dots, \hat{\rho}(m)]'$ approximately follows a multivariate normal distribution with mean vector $\mathbf{p}_m$ and covariance matrix $n^{-1}\mathbf{W}$. The (i, j) 's element of $\mathbf{W}$ is given by the Bartlett's formula

$$w_{ij} = \sum_{k=-\infty}^{\infty} \{ \rho(k+i)\rho(k+j) + \rho(k-i)\rho(k+j) + 2\rho(i)\rho(j)\rho^2(k) - 2\rho(i)\rho(k)\rho(k+j) - 2\rho(j)\rho(k)\rho(k+i) \}. \quad (7)$$

The SE of $\hat{\rho}(h)$ can be calculated from the diagonal elements of $\mathbf{W}$. When $i = j = h$, Equation 7 reduces to

$$w_{hh} = \sum_{k=-\infty}^{\infty} \{ \rho^2(k+h) + \rho(k-h)\rho(k+h) + 2\rho^2(h)\rho^2(k) - 4\rho(h)\rho(k)\rho(k+h) \}. \quad (8)$$

The coefficients $\rho(h)$ and $\alpha(h)$ are used to determine the model for the series $\{X_t, t = 0, \pm 1, \pm 2, \dots\}$. The most widely used model in time-series analysis is the *causal autoregressive and moving average* (ARMA) model

$$X_t - \phi_1 X_{t-1} - \dots - \phi_p X_{t-p} = Z_t + \theta_1 Z_{t-1} + \dots + \theta_q Z_{t-q},$$

denoted as ARMA(p, q), where Z_t are independent and each follows $N(0, \sigma^2)$. The series Z_t is called a *white noise* process. Special cases of ARMA(p, q) are the autoregressive model AR(p) when all the θ s are 0, and the moving average model MA(q) when all the ϕ s are 0. Because of the importance of the ARMA model, the details for obtaining the estimates of w_{hh} in Equation 8 are given below.

For an MA(q) model, there are only a few nonzero terms in Equation 8. For AR(p) and ARMA(p, q) models, although none of $\rho(h)$ is exactly 0, when h is large, $\rho(h)$ is close to 0. Using Equation 8 to estimate w_{hh} , the range of k is usually set at a relatively large number (e.g., $n/2$) and $\rho(h)$ is replaced with $\hat{\rho}(h)$. After the estimate $\hat{w}_{hh}$ is obtained, the estimated SE of $\hat{\rho}(h)$ is

$$\widehat{SE}_{\hat{\rho}(h)} = \sqrt{\hat{w}_{hh} / n}. \quad (9)$$

For large n , $\hat{\alpha}(h)$ ($h \geq p + 1$) is approximately distributed as $N(0, 1/n)$. Then the SE of $\hat{\alpha}(h)$ is given as

$$\widehat{SE}_{\hat{\alpha}(h)} = 1 / \sqrt{n}, \quad h \geq p + 1. \quad (10)$$

In practice, this allows us to identify the order p of the ARMA model using the significance of $\hat{\alpha}(h)$ when compared against $N(0, 1/n)$.

Applications of ACF and PACF

In time-series analysis, sample ACF and PACF are used to identify appropriate models. First, they are used to test for white noise. If the null hypothesis is rejected, they are next used for specifying the appropriate model.

Test for White Noise

Testing for white noise is important because no model is needed if a time series is just white noise. Series being tested for white noise can be the original observations or residuals after adjusting for a systematic effect. If X_t is white noise, by definition, $\rho(h) = 0$, and $\alpha(h) = 0$,

Figure 1 Plots of ACF and PACF of Five ARMA Processes According to Analytical Formulas

for all $h \geq 1$. Then it follows from Equation 8 that $w_{hh} = 1$ and $\hat{\rho}(h)$ is approximately distributed as $N(0, 1/n)$. Equivalently, approximately 95% of $\hat{\rho}(h)$ should fall between the bounds $\pm 1.96 / \sqrt{n}$. A sample ACF plot, which shows $\hat{\rho}(h)$ as vertical bars at each h and the two bounds as horizontal lines, is routinely reported in time-series analysis. Whether the series is white noise is indicated by visual inspection of the number and the magnitude that $\hat{\rho}(h)$ exceeds the bounds.

Test statistics for $\rho(1) = \rho(2) = \dots = \rho(m) = 0$ have also been developed. The so-called *portmanteau statistics*

$$Q = n \sum_{j=1}^m \hat{\rho}^2(j) \quad (11)$$

approximately follows χ_m^2 . A modified version of Q , proposed by Greta Ljung and George Box,

$$Q_{LB} = n(n+2) \sum_{j=1}^m \hat{\rho}^2(j) / (n-j), \quad (12)$$

better approximates χ_m^2 . The applications of Q and Q_{LB} are illustrated using real data in the last section.

Specification of ARMA Models

The ACF and PACF for $AR(p)$, $MA(q)$, and $ARMA(p, q)$ processes have certain characteristics. To illustrate these characteristics, plots of analytically derived ACF and PACF of two $AR(1)$, one $MA(1)$, one $AR(2)$, and one $ARMA(1, 1)$ processes are provided in Figure 1.

For process 1, an $AR(1)$ process with $\phi_1 = 0.8$, its ACF decays exponentially to 0 when h increases and its PACF only has one nonzero spike at $h = 1$; that is, $\alpha(1) = 0.8$. For process 2, an $AR(1)$ process with $\phi_1 = -0.8$, its ACF is a damped sine wave and its PACF also has only one nonzero value at lag 1, which equals -0.8 . For process 3, an $MA(1)$ process with $\theta_1 = -0.8$, its ACF has only one nonzero value at lag 1, while its PACF decays exponentially to 0. Process 4 is an $AR(2)$ process with $\phi_1 = 0.8$ and $\theta_1 = -0.64$. Its ACF is a damped sine wave, while its PACF has two nonzero spikes. For process 5, an $ARMA(1, 1)$ process with $\phi_1 = 0.8$ and $\theta_1 = 0.8$, its ACF shows exponential decay, while its PACF is a damped sine wave. ACF and PACF for more general $AR(p)$,

Table 1 Characteristics of ACF and PACF of $AR(p)$, $MA(q)$, and $ARMA(p, q)$ Processes

Model	ACF	PACF
$AR(p)$	decays exponentially or as a damped sine wave	equals 0 after lag p
$MA(q)$	equals 0 after lag q	decays exponentially or as a damped sine wave
$ARMA(p, q)$	decays exponentially or as a damped sine wave starting at lag q	decays exponentially or as a damped sine wave starting at lag p

$MA(q)$, and $ARMA(p, q)$ processes have also been studied. Their characteristics are summarized in Table 1.

In applications, $\hat{\rho}(h)$ and $\hat{\alpha}(h)$ are calculated and plotted against h . Comparison of the sample plots with the characteristics in Table 1 often suggests appropriate models. However, the sample ACF and PACF with real data are rarely as well shaped as those in Figure 1, especially for a series of small number of time points in social sciences. Thus, in addition to ACF and PACF, other criterion such as Akaike information criterion (AIC), or AICC, a bias-corrected version of the AIC, are also used to determine the order of a model.

An Illustrative Example

In this section, the usefulness of ACF and PACF is illustrated by analyzing a real data set. It consists of a 120-day daily score y_t of a schizophrenic patient on a perceptual speed test. This data set was discussed in the book by Gene Glass, Victor Willson, and John Gottman. The raw data were first-order differenced by $x_t = y_t - y_{t-1}$ to achieve stationarity. All the analyses were conducted on x_t using R 2.5.0, a language and environment for statistical computing and graphics.

The sample ACF and PACF plots in Figure 2, with the bounds $\pm 1.96 / \sqrt{n}$ for white noise, suggest that the data are not white noise, because $\hat{\rho}(1)$, $\hat{\alpha}(1)$, $\hat{\alpha}(2)$ and $\hat{\alpha}(4)$ exceeded the bounds. The sample PACF decays to 0,

Figure 2 The Sample ACF (left) and PACF (right) for the Schizophrenia Data and the Bounds $\pm 1.96 / \sqrt{n}$ (dashed lines)

whereas the sample ACF has only one big spike, which is at lag 1. These further suggested that an MA(1) model might be appropriate.

Next, a sequence of models from MA(1) to MA(10) was fit to the data, using the function *arima*. In R, *arima* is a function to fit an autoregressive integrated moving average (ARIMA) model to a univariate time series. Both AIC and AICC confirmed MA(1) as the best model. The maximum likelihood estimates of θ_1 and its *SE* were $\hat{\theta}_1 = -0.688$ and $\widehat{SE} = 0.061$. For an MA(1) process, Equation 8 is simplified to

$$w_{hh} = \begin{cases} 1 - 3\rho^2(1) + 4\rho^4(1), & h = 1; \\ 1 + 2\rho^2(1), & h > 1. \end{cases} \quad (13)$$

Assuming the true process is $X_t = Z_t - 0.688Z_{t-1}$, $\widehat{SE}_{\hat{\rho}(h)} = \sqrt{\hat{w}_{hh}/n}$ and 95% confidence intervals (CIs) $\hat{\rho}(h) \pm 1.96\sqrt{\hat{w}_{hh}/n}$ are obtained when replacing $\rho(1)$ with $\hat{\rho}(1)$ in Equation 13. In Figure 3, the model implied ACF is plotted as black dots, the sample estimates as vertical bars, 95% CI as dashed lines, and the bounds $1.96\sqrt{\hat{w}_{hh}/n}$ ($h \geq 2$) as dot-dashed lines. The estimated value $\hat{\rho}(1) = -0.478$ was close to the model implied value 0.467; the 95% CI always contained the model implied ACF; and no $\hat{\rho}(h)$ ($h \geq 2$) was outside the bounds. These all suggested the adequacy of the MA(1) model. In practice, because the sample estimates are subject to sampling errors, especially when the time-series length is short, $\hat{\rho}(h)$ is often compared with

Figure 3 The Sample ACF (vertical bar), Model Implied ACF (black dot), 95% CI (dashed lines), and the Bounds $1.96\sqrt{\hat{w}_{hh}/n}$ ($h \geq 2$) (dot-dashed lines) for the Schizophrenia Data

Figure 4 The Sample ACF (vertical bar) of Residuals from Fitting the MA(1) Model to the Schizophrenia Data and the Bounds $\pm 1.96\sqrt{n}$ (dashed lines)

$\pm 1.96/\sqrt{n}$ for significance, which are bounds for a white noise process.

Finally, for diagnostic purposes, the residuals from fitting the MA(1) model were tested for white noise. In the sample ACF plot of residuals in Figure 4, no $\hat{\rho}(h)$ exceeded the bounds. With $m = 10$, the portmanteau test $Q = 5.086$, $p = 0.885$, and $Q_{LB} = 5.522$, $p = 0.854$, both failed to reject the null hypothesis that the residual series is white noise. Thus, no further analysis was needed.

SHRINKAGE

Shrinkage reflects the bias found between sample statistics and inferred population parameters. Multiple regression generally overestimates population values from sample multiple correlation coefficients (R) and coefficients of multiple determination (R^2). A common adjustment method for overinflation is to use the shrunken or adjusted R^2 . The adjusted R^2 accounts for the amount of shrinkage between the sample R^2 and the population squared multiple correlation (ρ^2). Similarly, results from a model fitted in one sample are often an overestimate of how it would fit using a separate sample from the same population (i.e., a cross-validation sample), and such results also often need to be adjusted for shrinkage.

This entry begins by explaining why regression overestimates the population parameters. Next, the entry provides an example of shrinkage and discusses its use in cross-validity. This entry ends with a brief discussion of subsequent knowledge in this area.

Why Regression Overestimates Population Parameters

When working with a random sample of data from a larger population, it is expected that the mean will not exactly match the true population value. Sometimes the mean might be a little higher, and sometimes it might be a little lower. This fluctuation is generally considered to be caused by sampling error. Sampling errors also are present when estimating other numbers, including regression parameters. Regression analyses (in fact all analyses that use the least squares solution) do not account for these positive and negative fluctuations from the true population value when computing the multiple correlation coefficient (R). Multiple R is the product-moment correlation between the dependent variable and a linear combination of the set of independent variables. Because least squares maximizes the correlation between the set of independent variables and the dependent variable, and because multiple R cannot be negative (thus all chance fluctuations are in the positive direction), R is overfitted to the sample from which it was estimated. Each sample has its own idiosyncratic characteristics, and ordinary least squares capitalize on these, thus inflating the estimate of R .

Increasing the number of predictors also results in an artificially higher multiple R value. If all the chance fluctuations are positive, then adding a variable into the model might increase the multiple R by sampling error variance alone—a situation typically referred to as capitalization on chance. An overestimate of multiple R leads to an overestimate of the coefficient of multiple determination (R^2)—an estimate of the proportion of the variance of the dependent variable accounted for by the predictor variables. This positive inflation can easily be found in any statistical program: Add more predictor variables—even ones not significantly related to the dependent variable—and watch both R and R^2 increase. Positive inflation becomes even greater for small samples. Because of this bias, statisticians recommend estimating the amount of shrinkage that would occur and adjust the R^2 appropriately. In many computer programs, this more appropriate measure of the population value is labeled “adjusted R^2 .”

Example

Following is a common R^2 shrinkage adjustment formula that is often used in statistical packages:

$$R^2_{\text{adjusted}} = 1 - (1 - R^2) \frac{n - 1}{n - k - 1},$$

where n = sample size and k = number of independent variables.

Consider a model with an R^2 of .30 that has three independent variables and a sample size of 100. Using the formula

$$\begin{aligned} R^2_{\text{adjusted}} &= 1 - (1 - .30) \frac{100 - 1}{100 - 3 - 1} \\ &= 1 - .721875 = .278125. \end{aligned}$$

The difference between the R^2 and the adjusted R^2 is the amount of shrinkage ($.30 - .278125 = .021875$).

The adjusted R^2 can vary depending on the size of the R^2 , the sample size, and the number of independent variables; generally, the smaller the R^2 the larger the shrinkage. If the $R^2 = .10$, then the adjusted R^2 would be .071875 and the shrinkage is .028. Or, conversely, if the $R^2 = .8$, then the adjusted R^2 would be .79375 and the shrinkage is .006.

Additionally, the larger the ratio of the number of independent variables to sample size, the larger the shrinkage. If the number of independent variables in the original example increases from three to ten, the adjusted R^2 drops from .278 to .221. Instead, if the sample size drops from 100 to 30, then the adjusted R^2 drops from .278 to .219. And if both the number of independent variables increased to ten and the sample size decreased to 30, then the adjusted R^2 dramatically declines from .278 to $-.068$ (generally reported as an R^2 of zero). As can be observed, when sample size is small, it is wise to choose carefully which variables to include in the model.

Cross-Validation

The previous section refers to the amount of shrinkage that occurs between the sample value (R or R^2) and the population value (ρ or ρ^2). However, shrinkage can also occur between one sample drawn from a population and a second sample drawn from the same population. In other words, shrinkage can occur between the sample multiple R and the population cross-validity multiple correlation (ρ_c), or the sample R^2 and the squared population cross-validity coefficient (ρ_c^2). Simulation studies have shown, however, that it is not appropriate to use the adjusted R^2 formula given previously to estimate the squared population cross-validity.

It is common for applied researchers to develop a model and then use it for future prediction. One major problem in prediction is that the weights used in one sample might not generalize to another sample—they are affected by sampling variability. The regression equation might work well in one sample, explaining a significant amount of variance. When applied to a new sample, however, the R^2 will often be smaller. Therefore, when using prediction equations, one should cross-validate the equation. Cross-validation applies

the weights to a new sample and estimates the R^2 . If the variance explained is sufficiently large (as defined by the researcher), then the weights are sufficiently generalizable. In a general population, cross-validity (ρ_c or ρ_c^2) has been estimated either through empirical means or through formula-based methods.

Splitting a total sample into two subsamples is one example of an empirical method. A regression equation formed in one sample is then used to predict the criterion in the other sample. The biggest problem with this approach is that by splitting the sample, one loses power and generally the standard errors increase, thereby leading to less stable estimates.

The formula-based approach is often preferred because it uses the full sample that provides the most stable regression weights. This approach uses a formula to estimate what the R^2 would be in a different sample. Several different formulas have been proposed (see Further Readings presented at the end of this article for literature that presents these formulas), and similar to the formula for adjusted R^2 , one would plug in the sample size, number of predictors, R^2 , and other information obtained through the original regression into the formula. The most appropriate formula to obtain the population squared cross-validity (ρ_c^2) often depends on the sample size, number of predictors, and relationships between the predictors in the hypothesized model.

Further Knowledge

Every sample has unique characteristics, which are often purely a result of chance fluctuations. Models fit to these samples overestimate the amount of variance explained by the independent variables. As such, downward adjustments are often needed. To estimate the true population correlation more accurately and adjust for this capitalization on chance, it is wise to estimate the amount of shrinkage that would occur between the sample and the population parameter. The formula given previously to estimate the adjusted R^2 for the population squared multiple correlation (ρ^2) is commonly used, and this adjusted R^2 is printed in many statistical programs. There seems to be less agreement, however, on the correct formula for estimating the population squared cross-validity (ρ_c^2). As the technology continues to improve, it is increasingly likely that new information will be available to guide one's decision. Techniques such as bootstrapping, jackknifing, and simulation studies will add to the knowledge of how and when these different methods and techniques work best. What is fairly consistent, however, is the fact that the larger the original sample,

the more robust the estimates and the less shrinkage one would expect.

SIGN TEST

The sign test, first introduced by John Arbuthnot in 1710, is a nonparametric test that can be applied in a variety of situations such as the following:

When the data have two possible outcomes, it can be used to test whether these two outcomes have equal probabilities. In this situation, the sign test can be regarded as a special case of the binomial test.

It can be used when the variable of interest is ordinal, interval, or ratio, and one wants to test whether the median of this variable is some given value.

It can be used in paired data analysis where there are two categorical variables and one continuous or ordi-

nal variable. One of the categorical variables has only two values, such as “before treatment” and “after treatment” or “left” and “right,” and the other categorical variable identifies the pairs of observations. The directions of change in the continuous or ordinal variable can be increase (denoted as “+”), decrease (denoted as “-”), or no change (denoted as “0”). The sign test is used to test whether the numbers of change in each direction are equal or not; that is, it tests whether there are equal probabilities for values “+” and “-.”

McNemar’s test, which is a nonparametric test used on categorical data to determine whether the row and column marginal probabilities are equal, can be viewed as a variation of the sign test.

The Cox-Stuart test, which is used to test for the presence of a trend in one sample ordinal, interval or ratio data, can also be regarded as a variation of the sign test.

These situations are discussed in subsequent sections in the same order as they are listed here. In the last section, the sign test is compared with other similar tests.

Sign Test for One Sample Categorical Data

Suppose that $X_1, X_2, \dots, X_N$ are the observations on N subjects, and assume the following:

1. The random variables $X_1, X_2, \dots, X_N$ are mutually independent.
2. Each X_i takes one of three possible values, denoted as “+” (plus), “-” (minus), or “0” (zero).
3. The X_i ’s have consistent probability distributions, in that if $P_+ > P_-$ for one i , then it also holds for the rest indices, where P_+ denotes the probability that $S_i = +$, P_- denotes the probability that $S_i = -$. The same is true for $P_+ < P_-$ and $P_+ = P_-$.

To test whether X_i has equal probabilities of taking “+” and “-,” the test statistics to use is $S_+ =$ the total number of “+”s. The null distribution of S_+ is binomial ($n; 1/2$), where n is the number of nonzero X_i s. The following tests can be performed.

The Two-Sided Test

$$H_0: P_+ = P_- \text{ versus } H_1: P_+ \neq P_-.$$

Denote s as the observed S_+ , then the p value is $2 \min (P(S_+ \leq s), P(S_+ \geq s))$ where

$$P(S_+ \leq s) = \sum_{i=0}^s \binom{n}{i} \left(\frac{1}{2}\right)^n$$

and

$$P(S_+ \geq s) = \sum_{i=s}^n \binom{n}{i} \left(\frac{1}{2}\right)^n.$$

If $n > 20$, then $Z = \frac{2S_+ - n}{\sqrt{n}}$ is approximately standard normal, and the normal approximation to binomial can be used to calculate the p value as

$$p \text{ value} = 2 \left[\min \left(P \left(Y \leq \frac{2s - n - \text{sign}(2s - n)}{\sqrt{n}} \right), P \left(Y \geq \frac{2s - n - \text{sign}(2s - n)}{\sqrt{n}} \right) \right) \right],$$

where Y is a standard normal random variable, and

$$\text{sign}(2s - n) = \begin{cases} 1 & \text{if } 2s > n \\ 0 & \text{if } 2s = n \\ -1 & \text{if } 2s < n \end{cases}$$

The One-Sided Lower-Tail Test

$$H_0: P_+ = P_- \text{ versus } H_1: P_+ < P_-$$

Denote s as the observed S_+ , then the p value is

$$P(S_+ \leq s) = \sum_{i=0}^s \binom{n}{i} \left(\frac{1}{2}\right)^n.$$

If $n > 20$, using normal approximation

$$p \text{ value} = P \left(Y \leq \frac{2s - n - \text{sign}(2s - n)}{\sqrt{n}} \right),$$

where Y is a standard normal random variable.

The One-Sided Upper-Tail Test

$$H_0: P_+ = P_- \text{ versus } H_1: P_+ > P_-.$$

Denote s as the observed S_+ , then the p value is

$$P(S_+ \geq s) = \sum_{i=s}^n \binom{n}{i} \left(\frac{1}{2}\right)^n.$$

If $n > 20$, using normal approximation

$$p \text{ value} = P \left(Y \geq \frac{2s - n - \text{sign}(2s - n)}{\sqrt{n}} \right),$$

where Y is a standard normal random variable.

Example

Suppose that the cholesterol level of 30 patients was measured right before and 10 days after they received some treatment. It was observed that 30 days after they received the treatment, 20 of the 30 patients had a lower cholesterol level and 10 had a higher cholesterol level. To determine whether the treatment significantly lowered the cholesterol level, let “+” denote a higher cholesterol level after the treatment, and “-” denote a lower one; thus, there are 10 “+”s and 20 “-”s in the sample. The test is $H_0: P_+ = P_-$ vs $H_1: P_+ \neq P_-$ based on $S_+ = 10$. Because the sample size $n = 30 > 20$, a normal approximation is used, and the p value is calculated as

$$\begin{aligned} p &= 2 \min \left(P \left(Y < \frac{2 \times 10 - 30 + 1}{\sqrt{30}} \right), \right. \\ &\quad \left. P \left(Y < \frac{2 \times 10 - 30 + 1}{\sqrt{30}} \right) \right) \\ &= 2 \min (0.051, 0.049) \\ &= 0.10. \end{aligned}$$

This nonsignificant p value indicates that the cholesterol level was not significantly lowered by the treatment.

Sign Test for the Median

Suppose there is a sample of continuous or ordinal random variables $Z_1, Z_2, \dots, Z_n$ from some distribution with unknown median m , and one wants to test the null hypothesis $H_0: m = m_0$ against a one-sided or two-sided alternative hypothesis. One way to test this is to define new random variables $S_1, S_2, \dots, S_n$, such that S_i is assigned the value “+” if Z_i is greater than m_0 , “-” if Z_i is less than m_0 , and “0” if Z_i equals m_0 . If H_0 is true (i.e., the sample comes from a distribution with the median m_0), then on average, there are equal numbers of observations to be greater and smaller than m_0 . Denote the number of plus signs as n_+ and the number of minus signs as n_- . Thus, $H_0: m = m_0$ is equivalent to $H_0: p_+ = p_-$, where $p_+ = P(S_i = “+”)$, and $p_- = P(S_i = “-”)$. The alternative hypothesis $H_1: m > m_0$ is equivalent to $H_1: p_+ > p_-$. The two-sided hypothesis $H_1: m \neq m_0$ is equivalent to $H_1: p_+ \neq p_-$. The sign test for one sample categorical data, as discussed in the last section, can be used on $S_1, S_2, \dots, S_n$ to test the previous hypotheses about p_+ and p_- and, equivalently, the corresponding hypotheses about m .

Sign Test for Two Paired Samples

Suppose that there are the following paired observations on each of n subjects:

$$(Y_{11}, Y_{21}), \dots, (Y_{1n}, Y_{2n}).$$

The two numbers within each pair (Y_{1i}, Y_{2i}) are compared and a binary variable Z_i is defined based on the comparison as: If $Y_{1i} < Y_{2i}$, then $Z_i = “+”$ and $Z_i = “-”$ if $Y_{1i} > Y_{2i}$. If $Y_{1i} = Y_{2i}$, then $Z_i = “0.”$ Assume the following:

- The random vectors $(Y_{1i}, Y_{2i}), i = 1, 2, \dots, n$ are mutually independent.
- Each $Y_{ij}, i = 1, 2, j = 1, 2, \dots, n$ should be ordinal [i.e., each pair (Y_{1i}, Y_{2i}) can be determined to be “+,” “-,” or “0”].
- Each pair difference $Y_{2i} - Y_{1i}, i = 1, 2, \dots, n$ comes from a continuous population (not necessarily the same) that has a common median.

The null hypothesis to test is median $(Y_{2i} - Y_{1i}) = 0, i = 1, 2, \dots, n$, that is $P(Z_i = “+”) = P(Z_i = “-”)$, meaning that there is not a significant difference between the two pairs. This test is equivalent to the simple sign test on the data $Z_1, Z_2, \dots, Z_n$.

Example

Table 1 shows the days of pain relief provided by two analgesic drugs in 10 patients. Is there any evidence that drug A provides longer relief than drug B?

Here the null hypothesis is that the median of the difference is zero. The alternative hypothesis is that median of the difference is not 0. The last column gives

Table 1 Days of Pain Relief

Patient ID	dA : Days of Pain Relief by Drug A	dB : Days of Pain Relief by Drug B	Sign (dA - dB)
1	14	15	-
2	25	24	+
3	33	25	+
4	12	7	+
5	9	12	-
6	14	7	+
7	8	5	+
8	4	2	+
9	13	17	-
10	12	11	+

the sign of $d_A - d_B$. Notice that there are 7 “+” signs out of 10 patients. The two-sided test has a p value

$$2 \min \left(\sum_{i=7}^{10} \binom{10}{i} \left(\frac{1}{2} \right)^{10}, \sum_{i=0}^7 \binom{10}{i} \left(\frac{1}{2} \right)^{10} \right) \\ = 2 \min(0.95, 0.17) = 0.34,$$

which is greater than .05, indicating that there is no evidence that drug A provides longer relief than drug B. Note that the Wilcoxon signed rank test is also appropriate in this case, and it is more powerful because it uses the information about the magnitude of the differences as well as the signs.

McNemar's Test

Suppose that each Y_{ij} in the paired data $(Y_{11}, Y_{21}), (Y_{12}, Y_{22}), \dots, (Y_{1n}, Y_{2n})$ is nominal with two categories denoted by “0” and “1.” The pairs (Y_{1i}, Y_{2i}) are mutually independent, and the difference $P(Y_{1i} = 1, Y_{2i} = 0) - P(Y_{1i} = 0, Y_{2i} = 1)$ is negative for all i , or zero for all i , or positive for all i .

The question of interest is, “Is there a difference between the probability of (0, 1) and the probability of (1, 0)?” This question is often asked when Y_{1i} in the pair (Y_{1i}, Y_{2i}) represents the status of the subject before the experiment and Y_{2i} represents the status of the same subject after the experiment. Such a question also arises when Y_{1i} in the pair (Y_{1i}, Y_{2i}) represents the measurement with an instrument and Y_{2i} represents the measurement with another.

The data are usually summarized in a 2×2 contingency table as shown in Table 2, where a , b , c , and d are the numbers of (0,0), (0,1), (1,0) and (1,1), respectively.

The hypotheses are usually expressed as

$$H_0 : P(Y_{1i} = 1, Y_{2i} = 0) = P(Y_{1i} = 0, Y_{2i} = 1) \text{ for all } i$$

versus

$$H_1 : P(Y_{1i} = 1, Y_{2i} = 0) \neq P(Y_{1i} = 0, Y_{2i} = 1) \text{ for all } i.$$

The previous hypothesis is equivalent to

$$H_0 : P(Y_{1i} = 0) = P(Y_{2i} = 0) \text{ for all } i$$

Table 2 Data Table for McNemar's Test

	$Y_2 = 0$	$Y_2 = 1$
$Y_1 = 0$	a	b
$Y_1 = 1$	c	d

Table 3 Summary of Test Result

	Results Were Positive Before Treatment	Results Were Negative Before Treatment
Results Were Positive After Treatment	12	5
Results Were Negative After Treatment	20	13

versus

$$H_1 : P(Y_{1i} = 0) \neq P(Y_{2i} = 0) \text{ for all } i,$$

and

$$H_0 : P(Y_{1i} = 1) = P(Y_{2i} = 1) \text{ for all } i,$$

versus

$$H_1 : P(Y_{1i} = 1) \neq P(Y_{2i} = 1) \text{ for all } i,$$

so this is the test of whether Y_{1i} and Y_{2i} have the same marginal distributions.

The test statistic for McNemar's test is usually written as

$$T_1 = \frac{(b - c)^2}{(b + c)}.$$

Under the null hypothesis, T_1 follows χ^2 distribution with one degree of freedom, that is $T_1 \sim \chi_1^2$.

Example

In a study, a test is performed in 50 patients before treatment and after treatment. Before treatment, 32 patients had positive results and 18 had negative results (Table 3). After treatment, 20 of the 32 patients with positive pretreatment test results now had negative results, and 5 of the 18 patients with negative pretreatment results now had positive results. Is there a significant change in the test result before and after treatment?

The test statistic is

$$T = \frac{(5 - 20)^2}{(5 + 20)} = 9.$$

The p value is $.003 < .05$, indicating that the treatment can significantly improve the test result.

Cox and Stuart Test for Trend

The Cox and Stuart test was introduced in 1955 and it is used to test for the presence of a trend. A sequence of numbers is said to have a trend if in the sequence the

later numbers tend to be larger than the earlier numbers (upward trend) or smaller than the earlier numbers (downward trend).

Suppose that the data consist of continuous or ordinal observations $X_1, X_2, \dots, X_n$, and the random variables $X_1, X_2, \dots, X_n$ are mutually independent. To test whether there is a trend in the data; that is, whether the later random variables are greater than the earlier random variables or vice versa, the null hypothesis is: no trend is present. one-sided test is used to detect an upward (or a downward) trend. The two-sided test is used if the alternative hypothesis is that any type of trend exists.

The random variables are grouped into pairs. If $n = 2m$ is even, then form m groups as $(X_1, X_1 + m), (X_2, X_2 + m), \dots, (X_m, X_m + m)$. If n is odd, then discard the middle observation and use the remaining numbers to form groups in the same way. Next replace each pair (X_i, X_{i+m}) with a "+" if $X_i < X_{i+m}$ or a "-" if $X_i > X_{i+m}$, eliminating ties. Once these are done for all the pairs, one can follow the same procedure of the simple sign test given previously using the test statistic $T = \text{total number of "+"s}$. Under the null hypothesis, $T \sim \text{binomial}(n; 1/2)$. A preponderance of plus signs supports the hypothesis of an upward trend of $X_1, X_2, \dots, X_n$, and a preponderance of minus signs suggests the presence of a downward trend.

Example

The length of growth season is recorded for 21 years. The length in days is 224, 253, 216, 204, 231, 225, 236, 200, 243, 260, 215, 262, 233, 215, 242, 249, 227, 254, 225, 208, and 246. To determine whether these data provide sufficient evidence to indicate the presence of a trend in the length of growth season, hypothesize that there is no reason to suspect one type of trend (either upward or downward). As $n = 21$ is odd, the middle number 215 is omitted. Pairing the i th observation of the first half with the i th observation of the second half yields the following: (224, 262), (253, 233), (216, 215), (204, 242), (231, 249), (225, 227), (236, 254), (200, 225), (243, 208), and (260, 246). There are no ties, so $n = 10$ and $T = 6$. The p value for the one-sided upper tail test is

$$\sum_{i=6}^{10} \binom{10}{i} \left(\frac{1}{2}\right)^{10} = 0.38,$$

which is nonsignificant. There is no evidence for the presence of a trend.

Similar Tests

As a nonparametric test for paired observations, the sign test is used when the null hypothesis is that there are equal numbers of differences in each direction. There are other tests for paired observations of an ordinal or continuous variable. If the pair difference is a continuous variable and normally distributed, and the null hypothesis is that the mean of the difference between pairs of observations is zero, then the paired sample t test can be used. If the null hypothesis is that the median of the difference between pairs of observations is zero, then the Wilcoxon signed rank test can be used.

SIGNIFICANCE LEVEL, CONCEPT OF

The concept of significance level originates from the discipline of statistical inference, which might be summarized as the application of the scientific method to either observed or collected data. In this setting, it is assumed that the data might be described by some stochastic model, which means that random variation is associated with the variables being measured.

First, an appropriate model for the data must be determined. Then, two hypotheses, known as the null hypothesis (typically denoted H_0) and the alternative hypothesis (typically denoted H_a), are formulated. These hypotheses are precisely stated in terms of a parameter for the chosen model, such as a mean, proportion, or standard deviation. The null hypothesis specifies a particular value for the parameter of interest, and the alternative hypothesis considers a range of possibilities different from the specified value. Based on the data, the strength of the evidence against the null

hypothesis is assessed, considering the probability of observing the data if, in fact, the null hypothesis is correct. Because it was assumed that the data are the product of a random process, it can never be concluded with perfect certainty that the null hypothesis is right or wrong, because even the most unlikely outcomes might occur at one time or another. The probability that the null hypothesis is incorrectly rejected based on the observed data is called the p value of a statistical test, and such a false rejection is called a *Type I error*. Common practice is to decide to reject null hypotheses if p values fall below a certain threshold, such as .05 or .01, so that the probability of a Type I error is small. These thresholds are known as *significance levels*, and it is common to make statements such as “the test was significant at the .05 level” as an alternative to reporting a precise p value.

As an example, suppose a referee for an upcoming professional football game is responsible for the official coin toss. Before the game, the referee decides to determine whether the coin is “fair” by performing the simple experiment of tossing it ten times and counting the number of heads that are observed. If the coin is fair, then the number of heads should follow a binomial distribution with parameters $n = 10$ (number of tosses) and $p = .5$ (probability of a head on each toss). The referee formulates the null and alternative hypothesis, $H_0 : p = .5$ and $H_a : p \neq .5$. This is known as a *two-sided* alternative, which considers the possibility that the true value of p might be either larger or smaller than the value specified in the null hypothesis. After tossing the coin ten times, the referee observes eight heads and two tails. The mathematical probability of observing an outcome at least as extreme as this one, assuming that the coin is actually fair, turns out to be .11. This means that, if the referee rejects the null hypothesis on the basis of this evidence, then he or she would be incorrect in doing so 11% of the time. Because the p value is not smaller than .05, he or she cannot reject the null hypothesis at this significance level and also cannot reject the null hypothesis at the less conservative .10 significance level. This does not mean, however, that the coin is fair and that the referee can accept the null hypothesis. It simply means that there is insufficient evidence to reject this hypothesis with a high degree of statistical confidence on the basis of the available data.

The previous example considered a discrete probability distribution, one for which there are a countable number of possible outcomes. In ten coin tosses, the total number of heads that can be observed can be no fewer than 0 and no more than 10, and the exact probability of any of these outcomes can be computed using the mathematical functions associated with the binomial distribution.

Often, however, cases are considered for which an infinite number of outcomes are possible, known as continuous distributions. The most commonly applied continuous distribution is the normal, or Gaussian distribution, which has a bell-shaped curve and is an appropriate model for many naturally occurring phenomena. This distribution is defined by its mean μ , which indicates the center of the curve, and its standard deviation σ , which is a measure of the spread of the curve about its center. A variation of this distribution, which is known as the Student's t distribution, is employed when the normal distribution is considered to be an appropriate model, but both the mean and the standard deviation are estimated from observed data.

To illustrate, suppose there is a study in which a new compound is being tested as a weight-reducing drug. Fifty individuals are enrolled in a study and their weights are taken prior to beginning the drug and then again after 8 weeks of following the specified regimen. The data of interest for this study are the *differences* for each participant from his or her starting weight, so that positive values indicate losses and negative values indicate gains. Because the pharmaceutical company is interested in demonstrating the effectiveness of their drug, the study leader wishes to show that the mean weight loss in the group of participants is significantly greater than 0. She formulates the hypotheses $H_0 : \mu = 0$ and $H_a : \mu > 0$. She specifies a priori that she will reject the null hypothesis of no effect if the test results are significant at the .05 level, which is the level typically specified for consideration by the scientific community. She observes that, in her participant group, the average weight loss is 1.2 lbs with standard deviation 4.6 lbs. She constructs her test statistic, and using the appropriate methods, she finds that the p value for this paired t test was .036. Because this value is smaller than her previously specified significance level of .05, she can reject the null hypothesis, publish her findings, and seek U.S. Food and Drug Administration approval for her company's drug.

SIGNIFICANCE LEVEL, INTERPRETATION AND CONSTRUCTION

Hypothesis testing is not set up so that a researcher can absolutely prove a null hypothesis. Rather, it is set up so that when a researcher does not find evidence against the null hypothesis, he or she fails to reject the null hypothesis. When the researcher does find strong enough evidence against the null hypothesis, he or she rejects the null hypothesis. This, although often confusing, is a subject with vast field of statistical application. In hypothesis testing, the significance level at some preassigned small value α is used to control the probability of Type I error (rejecting the null hypothesis when it is true), which is vital in building up theory and methods. Among many significance-level-related notions for interpretation and elements for construction of hypothesis testing, some important ones are addressed in this entry.

The Need of Level of Significance in Hypothesis Testing

In hypothesis testing, it is often impossible, too costly, or too time-consuming to obtain the entire population data on any variable to determine whether a null hypothesis is true. Decisions of hypothesis testing, thus, should be made using sample data. Whenever an experiment in collecting evidence is undertaken, despite how seriously care and controls are introduced by the researcher, the outcome is always subject to some variability of chance. Hence, falsely rejecting the null hypothesis or falsely not rejecting the null hypothesis always exists. The classic way to solve this dilemma is to confine the class of tests for consideration. A conventional setting for confining the tests is assigning the level of significance. Once a test is chosen to deal with a given null hypothesis, the calculated value of the test statistic is compared with tables of critical values at specific level of significance. If the calculated value exceeds the critical value, then the null hypothesis is rejected.

Setting the Level of Significance

A significance level $\alpha = .05$ means that there is a 5% chance a researcher will accept the alternative hypothesis (reject the null hypothesis) when the null hypothesis is true. Then, in the long run, the proportion of times the researcher will make a Type I error will be .05. However, the selection of the level of significance should not be affected by the results of the data; the researcher should choose it before the data have been collected. If the level α is affected by the data, a bias on stated error probabilities should be entered to the study. In fact, for avoiding a bias of the study, a complete decision process involving the selection of test statistic, the choice of significance level α , for determining one-sided or two-sided test, and the cutoff points must be set up in advance of making any observation of the data.

Size, p Value, and Significance Level

People often do not make a clear distinction between the size and significance level of a test, and sometimes these two terms are used interchangeably. By letting null hypothesis $H_0 : \theta \in \Theta_0$, a clear distinction might be made by saying that a test with power function $\pi(\theta)$ is a size α test if $\sup_{\theta \in \Theta_0} \pi(\theta) = \alpha$ and is a level α test if $\sup_{\theta \in \Theta_0} \pi(\theta) \leq \alpha$. Constructing a size α test sometimes is so difficult for computation that the researcher might turn to setting the compromise of constructing a level α test. Once the level of significance has been set as α , the rule of hypothesis testing is to reject the null hypothesis when its size is smaller than α .

One useful procedure in hypothesis testing is to look at the total probability of the set of observations, under the model of null hypothesis, which are at least as extreme as observed. This cumulated probability is called the p value of the test. It is also very important to distinguish between p value and significance level. The level of significance is a notion in the context of the approach developed by Jerzy Neyman and Egon Pearson, dealing with the null and alternative hypotheses; and the p value is a notion, introduced by J. D. Gibbons and J. W. Pratt, in the context of significance test, dealing with a null hypothesis without specifying an alternative one. In connection of these two terms, the p value represents the minimum significance level for which the null hypothesis would have been rejected. In this circumstance, if the p value is lower than the significance level α , then the null hypothesis is rejected.

Optimal Significance Level α Test

Suppose that we have a random sample $\mathbf{X} = (X_1, \dots, X_n)$ drawn from a distribution with pdf $f(\mathbf{x}, \theta)$. One of the needs in setting significance level is restricting a class of tests for developing optimal test. Given a significance level α and considering the simple null hypothesis $H_0 : \theta = \theta_0$, the general interest in hypothesis testing is searching a best one from the following class of level α tests,

$$K_\alpha = \{C : P_{\theta_0} \{ \mathbf{X} \in C \} \leq \alpha \},$$

where each C in K_α represents a level α critical region. For this hypothesis testing problem, Neyman and Pearson proposed to specify a simple alternative hypothesis, saying $H_1 : \theta = \theta_1$ and defined the best one with the largest power, that is, the largest probability of rejecting H_0 when H_1 is true. Denote the likelihood function as $L(\theta, \mathbf{x}) = \prod_{i=1}^n f(x_i, \theta)$ with $\mathbf{x}$ being the observation of random sample $\mathbf{X}$, the most powerful test has a critical region determined by

$$\frac{L(\theta_0, \mathbf{x})}{L(\theta_1, \mathbf{x})} \leq k,$$

where k satisfies $\alpha = P \left(\frac{L(\theta_0, \mathbf{X})}{L(\theta_1, \mathbf{X})} \leq k \right)$. To maximize

the power of the test, the sample points that are more likely under H_1 than under H_0 should be put into the critical region. Hence, if a sample point $\mathbf{x}$ makes the denominator of the likelihood ratio $\frac{L(\theta_0, \mathbf{x})}{L(\theta_1, \mathbf{x})}$ larger, this $\mathbf{x}$ is the point more likely under H_1 . This is why the requirement uses likelihood ratio to set up level α critical region.

A test considering only one hypothesis such as $H_0 : \theta = \theta_0$ is called a significance test or pure significance test. In fact, significance tests were given their modern justification and then popularized by Ronald Fisher, who derived most of the test statistics that researchers now use, in a series of papers and books during 1920s and 1930s. Unlike the formulation of Neyman and Pearson, there is no optimality theory to support the classic techniques of significance test. It is, therefore, argued that a significance test cannot use likelihood ratio for test derivation. Recently, H. C. Chen defined the best level α significance test as the one in K_α with smallest volume of its acceptance region. To accomplish this, Chen constructed critical region only through an observation's probability $L(\mathbf{x}, \theta_0) = \prod_{i=1}^n f(x_i, \theta_0)$, the joint pdf of the random sample when H_0 is true. By letting $\mathbf{x}_a$ and $\mathbf{x}_b$ be two

observation points, observation $\mathbf{x}_a$ is more probable than $\mathbf{x}_b$ if the following holds:

$$\frac{L(\mathbf{x}_a, \theta_0)}{L(\mathbf{x}_b, \theta_0)} \geq 1.$$

To minimize the volume of the test, the sample points of the highest densities have to be set as the acceptance region. Chen shows that the level α significance test with acceptance region of highest densities as

$$A_{bdt} = \{ \mathbf{x} : L(\mathbf{x}, \theta_0) \geq a \}, \text{ subjected to}$$

$$1 - \alpha = P_{\theta_0} \{ \mathbf{X} \in A_{bdt} \}$$

is the best one.

Let us see an example for interpretation. Consider a random variable X that has a pdf $f(x, \theta)$ under null hypothesis $H_0 : \theta = \theta_0$ as follows:

x	1	2	3	4	5
$f(x, \theta_0)$	0.7	0.025	0.025	0.20	0.05

Suppose that the significance level is $\alpha = .05$. The highest density significance test has acceptance region $A_{bdt} = \{ \mathbf{x} : f(x, \theta_0) \geq a \}$ subjected to $0.95 = P_{\theta_0} \{ X \in A_{bdt} \}$, which leads to $A_{bdt} = \{1, 4, 5\}$. The classic significance test chooses test statistic X and sets rejection region $\{x : x \geq b\}$ subjected to $.05 = P_{\theta_0} \{ X \geq b \}$. The resulting rejection region is $C_{cla} = \{5\}$ and acceptance region is $A_{cla} = \{1, 2, 3, 4\}$. Let us also consider an alternative hypothesis $H_1 : \theta = \theta_1$, with its corresponding pdf and likelihood ratio being shown as follows:

x	1	2	3	4	5
$f(x, \theta_1)$	0.07	0.025	0.025	0.08	0.80
$f(x, \theta_1) / f(x, \theta_0)$	0.1	1	1	0.4	16

The most powerful test of Neyman–Pearson chooses rejection region based on

$$0.05 = P_{\theta_0} \left\{ x : \frac{f(x, \theta_1)}{f(x, \theta_0)} \geq c \right\}$$

that leads to the rejection region $C_{np} = C_{cla}$ and the acceptance region $A_{np} = A_{cla}$.

Null Hypothesis Setting

Often, major decisions for research of many sciences are based on the results of a hypothesis test. However, in most circumstances, researchers' attitudes to the null

hypothesis and the alternative hypothesis are different, and they know that when the probability of Type I error is minimized, the probability of the Type II error must be increased. With this concern, the significance level specifies the criterion for rejecting the null hypothesis. Thus, the decision ultimately rides on the question, “Which hypothesis erroneously rejected is more serious in consequence?” No rule handles the setting of null hypothesis for all the statistical hypothesis testing problems.

There are generally two philosophies in setting the null hypothesis H_0 . The most commonly accepted rule for setting null hypothesis is through the following philosophy:

If one wishes to prove that A is true, one first assumes that it is not true.

Suppose that we are studying a new drug treatment for reducing the patient’s pain. We might state the null hypothesis H_0 as “There will be no significant difference in reducing pain” and the alternative hypothesis H_1 as “There will be a significant difference in reducing pain.” This philosophy defined the hypotheses based on the concept of proof by contradiction that gives the null hypothesis a statement of “no effect” or “no difference.” It, in fact, tries to prevent the consumer’s risk with that if we are going to make an error, we would rather error on the side of consumer’s benefit. As the example given previously, when it is claiming that a new drug is better than the current drug for treatment of the same symptoms, the null hypothesis indicates that no difference exist between these two drugs.

There is an approach of philosophy that considers a situation employed in some engineering problems. The quality of product is distributed from background noise and abnormal noise. If the process operator adjusts the process based on the tests performed periodically for hypothesis defined from the commonly accepted rule, it will often overreact to the background noise and deteriorate the performance of the process. Hence, to prevent this unnecessary adjustment, a rule guiding the null hypothesis is as follows:

Unless it is broken, we will not fix it.

This philosophy tries to prevent the manufacturer’s risk with that if we are going to make an error, we would rather error on the side of manufacturer’s benefit.

One useful technique following this philosophy is the control chart. In the online quality control, without evidence of existing assignable cause, the manufacturing process is considered to be in control. For example, one constructs the $\bar{X}$ chart as

$$\begin{aligned} \text{UCL} &= \mu_0 + 3 \frac{\sigma_0}{\sqrt{n}}, \\ \text{LCL} &= \mu_0 - 3 \frac{\sigma_0}{\sqrt{n}}, \end{aligned}$$

where μ_0 and σ_0 , respectively, are the mean and standard deviation for in-control process, and the process is considered to be in control when sample mean $\bar{x}$ falls within the control limits, lower control limit (LCL) and upper control limit (UCL). In a situation where μ_0 and σ_0 are unknown, they might be replaced by estimates computed from the training samples. This chart aims in detecting whether there is a mean shift. So, the hypothesis represented behind this chart is $H_0 : \mu = \mu_0$, whereas a probability 0.9973 of the acceptable region does favor no mean shift. Following this philosophy for preventing the manufacturer’s risk, the wish of proving that the process is in control is to set it up as the null hypothesis.

Two Cautions in Applying Significance Tests

Test results sometimes lead researchers to inappropriate conclusions. Can a researcher say that the data show practical significance, when it reaches statistical significance with significance level α as small as .01? The sample size of the data set directly impacts its corresponding p value. On the one hand, large sample sizes do produce small p values even when there is no effect or differences between groups. In this case, statistical significance is practically not meaningful. On the other hand, a sample size that is too small can result in a failure to identify an effect or a difference when one truly exists. Researchers should always verify the practical relevance of the computed results. Let us use one example for interpretation. Suppose that we have a random sample $X_1, \dots, X_n$ from a normal distribution $N(\mu, 1)$ and we consider hypothesis $H_0 : \mu = 0$ versus $H_1 : \mu > 0$. We also assume that we have observation $\bar{x} = 0.01$ and consider the test rejecting H_0 if $\sqrt{n}\bar{X} > z_{0.01} = 2.33$ occurs. If $n = 30$, this observation provides evidence statistically insignificant. However, when $n > 233$, it provides evidence statistically significant but $\mu = 0.01$ is not practically significant, with a difference being from $\mu = 0$ in many applications.

One other caution in the significance test is the tendency for multiple comparisons to yield artificial significant differences even when the null hypothesis of no differences is true. If we apply test of significance level .05 for a study of 20 multiple comparisons, one comparison will be likely to yield a significant result despite the null hypothesis being true. This problem can be more serious when researchers deal with some modern multiple comparison problems such as the gene

expression analysis where more than 10,000 genes need to be simultaneously studied to classify influential genes. As a result of classic t test for differences of means, hundreds of noninfluential genes could be identified as influential ones just by chance.

SIGNIFICANCE, STATISTICAL

Statistical significance refers to the difference between two measurements that results from more than randomness. Every research project, experiment, or study that counts, measures, quantifies, or otherwise collects or handles data will ultimately have the need to make comparisons between their data and some other standard. If a difference between two measurements or a measurement and some standard is detected, then that difference is a statistically significant difference if it is caused by an actual difference between the two, rather than simply a result of random variation.

For example, a psychologist might be interested in determining which of two treatments is more effective in treating depression. Having determined some means of determining each treatments' effectiveness, the researcher might, then, administer the different treatments to selected individuals as a part of a designed experiment. Of course, any measure of the treatments' effectiveness, no matter how objective, will only be an estimate of the actual effect. This estimate will vary from the true amount because of many factors, including idiosyncrasies in the testing process, errors in subjective judgment, flaws in measurement, or any number of other sources. Because of the inherent variability in

the estimation of any unknown population parameter (in this case, the true effectiveness of each test), in comparing these two measures, the researcher must determine whether the difference between the two results is only caused by variability in the estimation process or if it is caused by an actual difference between the measurements. If the latter is true, then the difference in the measurements is said to be statistically significant. Although there are other methods, this determination is made most frequently by means of hypothesis testing. After briefly discussing the history, this entry discusses hypothesis testing and multiple comparisons and then the objections to statistical significance testing.

History

Although the formal development of hypothesis testing would not begin until 1925, less formal, ad hoc testing for statistical significance was being done around the turn of the 20th century. In 1908, William Gosset, who is commonly known as "Student," developed his t test for the mean of a normally distributed population with unknown population standard deviation, and before that, in 1892, Karl Pearson published work on chi-square tests for significance with frequency distributions. Perhaps the earliest example of testing for statistical significance is a paper entitled "An Argument for Divine Providence Taken From the Constant Regularity of the Births of Both Sexes" by John Arbuthnot written in 1710, in which he examines birth records in London and concludes that there is good reason to think that the birth rate of males was higher than that of females (i.e., significantly higher). It was not until 1925, however, that R.A. Fisher began the formal development of testing for statistical significance. His work, along with that of Jerzy Neyman and Egon Pearson a few years later, is the foundation for what is known today as hypothesis testing.

Hypothesis Testing

Fisher and others writing on this topic at that time were influenced by the view, which was largely advanced by Karl Popper, that scientific theories must be falsifiable. To that end, the chief purpose of hypothesis testing is not to determine the actual size of the difference between two measurements, but rather to demonstrate that the difference exists (i.e., is not zero) given some observed data. Specifically, hypothesis testing requires two hypotheses: the null hypothesis (often written H_0) and the alternative hypothesis (often written H_a or H_1). The null hypothesis is a straw man. It is the theory that the researcher is attempting to falsify by experimentation. The alternative hypothesis is a statement of what

the researcher believes to be the true state of affairs. For instance, if a sociologist performs research to determine whether after-school programs reduce the likelihood that participants will be involved in violent crime, the appropriate null hypothesis is that such programs do not reduce the likelihood that participants will be involved in violent crime, whereas one alternative hypothesis might be that these programs do, in fact, reduce such crimes. An educational researcher might want to determine whether preschool attendance increases test scores in at-risk children. That researcher's null hypothesis would be that preschool does not increase test scores, whereas the alternative hypothesis might suggest that it does. In practice, the null hypothesis generally involves the "equals" sign, whereas the alternative hypothesis employs some sort of inequality.

Typically, two types of alternative hypotheses are used: one-sided and two-sided. Although the null hypothesis states the simple and specific equality that the researcher seeks to disprove, the one-sided alternative hypothesis gives the direction in which the true value differs from the hypothesized value. A one-sided alternative hypothesis can be right-tailed, indicating that the true value of the population parameter under consideration is greater than the value hypothesized in H_0 , or left-tailed, indicating that the true value is less than the hypothesized value. For example, if a particular null hypothesis states that the true mean of a given population is, say, 5, then the corresponding right-tailed alternative hypothesis would be that the true mean is greater than 5, whereas the corresponding left-tailed hypothesis is that the true mean is less than 5. A two-tailed alternative hypothesis is different only in that it does not indicate direction (e.g., the true mean is not equal to 5). These hypotheses must be chosen before the data are collected. If the researcher allows the data to influence the choice of hypotheses, then the test for statistical significance will lose accuracy.

Hypothesis tests rely on the calculation of a statistic from the observed data and the determination of the distribution of that statistic under the terms of the null hypothesis. Whereas in modern times, a multitude of software packages have been created to perform the calculations required for most hypothesis testing, they have not always been available and they are not necessary to the process. They are merely programmed with the probability distributions of various test statistics under the user-inputted null hypothesis. Regardless of the details of how a test is formed and the means by which it is executed, tests for significance allow a researcher to make a determination regarding statistical significance by means of a p value.

After setting the null and alternative hypotheses, collecting data, choosing the appropriate test, and calculating the appropriate test statistic(s), performing the hypothesis test returns a p value. The p value is a measure of statistical significance. Specifically, the p value is the probability of observing data as extreme or more extreme than what was observed given that the null hypothesis is true. In other words, the p value is a measure of how likely (or unlikely) it is for the collected data to have occurred given that the null hypothesis is true. Consequently, a smaller p value means that if the null hypothesis describes the true state of things that a rare event has occurred. Depending on how small the p value is, the researcher might conclude that it is more likely that the null hypothesis is in error. Conversely, a large p value means that the data collected are more in line with what is stated in the null hypothesis.

Typically, the results of a hypothesis are interpreted in two ways. First, a hypothesis test is an indicator of whether to reject the null hypothesis. Having collected data, the researcher compares that value with a previously calculated critical value. If the observed test statistic exceeds the critical value in the appropriate direction (depending on the direction of the alternative hypothesis), then the decision is to reject the null hypothesis. Otherwise, the researcher fails to reject the null hypothesis. The critical value is the value such that, had the observed test statistic exactly equaled the critical value, its p value would be exactly α . Consider Figures 1–3. Let the horizontal axis represent values for the test statistic and the shaded area under the curve represent the probability of the test statistic exceeding that value. Figures 1–3 represent, respectively, left-tailed, right-tailed, and two-tailed alternative hypotheses. Observed test statistic values that fall within this shaded critical region indicate that the null hypothesis should be rejected. Values that fall outside the shaded

Figure 1 Critical Region for a Left-Tailed Test

Figure 2 Critical Region for a Right-Tailed Test

Figure 3 Critical Region for a Two-Tailed Test

region indicate that there is not enough evidence to reject the null hypothesis.

Many contexts do not fit this decision-making understanding of statistical significance. In the life sciences, for instance, researchers often are not trying to make a decision but rather are aiming to advance a particular understanding. In this case, researchers typically understand the p value as the weight of evidence against a particular theory. Although a value for α

might not be required for making a decision, one is often chosen (commonly .05) and used as provided previously. According to this understanding of statistical significance, a low p value represents strong evidence against the null hypothesis, whereas a higher p value indicates weaker or no evidence. Oftentimes, research of this sort is ongoing and includes repeated experimentation and repetition to understand a particular state of affairs, disprove a scientific theory, or collect evidence in support of a new theory. In many such cases, researchers rely on so-called Bayesian methods to incorporate prior knowledge resulting from previous experience and experimentation into their understanding of statistical significance. As with traditional significance testing, these Bayesian approaches have their weaknesses.

The reader will note that hypothesis testing is not without the chance for error. In fact, there are two types of errors, which are known as Type I and Type II error, that the researcher must consider when attempting to determine statistical significance. Consider Table 1. A Type I error (i.e., the error made when the researcher rejects the null hypothesis when the null hypothesis is, in fact, true) occurs when the p value resulting from the hypothesis test is less than α . Recalling the definition of the p value, a p value of .04 indicates that only 4% of the time will results as extreme or more extreme occur given that the null hypothesis is true. Although 4% of the time might be considered a rare event, it is certainly not an impossible one. For that reason, when the researcher chooses α , he or she is choosing the probability that a Type I error will occur. Alpha (α) is not set at an exceedingly low value because, all other things held constant, a low probability of making a Type I error results in an increased probability of making a Type II error.

A Type II error occurs when the researcher does not reject the null hypothesis when, in fact, the null hypothesis is false. The probability of making an error of Type II is referred to as β and relates to the sensitivity, or power, of a significance test. Power (calculated as $1 - \beta$) is the probability of correctly rejecting the null hypothesis under a specific set of circumstances.

Table 1 Type I and Type II Errors

		True State of Nature	
		H_0 is true	H_0 is false
Decision resulting from hypothesis test	Reject H_0	→ Type I error	Correct decision
	Do not reject H_0	→ Correct decision	Type II error

As was mentioned, all other variables held constant, a higher α leads to a lower β and vice versa. This makes intuitive sense. Consider a test in which the researcher chooses α very close to zero. In other words, there is almost no chance of rejecting the null hypothesis in error. That is, it will take overwhelming evidence to convince the researcher that the null hypothesis is incorrect. The consequence is that the test is very blunt or insensitive to all but the largest discrepancies between the data and the null hypothesized value. Conversely, suppose a researcher chooses β to be exceedingly low (i.e., chooses a test that is very sensitive to even the smallest error). The researcher will be much more likely to call significant differences that might have resulted only from randomness.

Two other variables must be considered when performing a hypothesis test: effect size and sample size. Effect size, which was popularized by Jacob Cohen, refers to the size of difference that the researcher would consider meaningful. For instance, an increase of 3 points on a standardized test might not be of interest to an education researcher, but an increase of 15 points might be practically and theoretically important. This effect size should be fixed at the same time as the hypotheses as well as α and β .

Finally, the sample size is a function of all these things. Intuitively, one would expect an increased sample size to increase the sensitivity of a test, and rightly so. The researcher should consider the sample size to be a function of the effect size the researcher seeks to observe, α , β , and the hypotheses. Consequently, some studies might be infeasible because a lack of resources or time prevent the gathering of an adequate sample to achieve the desired power, Type I error rate, and effect size. Also of interest is the cost of making either a Type I error versus the cost of making a Type II error. These considerations and others must be factored into the choosing of these experimental settings.

In short, the algorithm for performing a hypothesis test for statistical significance is as follows:

1. Select an appropriate null and alternative hypothesis
2. Set α , β , and effect size
3. Choose appropriate test and test statistic
4. Compute sample size n required for detecting desired effect size, given α and β
5. Collect data
6. Compute the value of the test statistic from collected data
7. Compare observed test statistic value to critical value
8. Make a decision either to reject the null hypothesis or to fail to reject the null hypothesis
9. Calculate exact p value to determine weight of evidence against the null hypothesis

Multiple Comparisons

It is frequently the case that multiple determinations of statistical significance must be made. That is, if a researcher wants to compare three test statistics, instead of two, then one option might be to make multiple pairwise comparisons. An increase in the number of groups being compared, however, quickly inflates the number of pairwise comparisons that must be made. Although 3 groups require only 3 pairwise comparisons, 4 groups require 6 comparisons, 5 groups require 10 comparisons, and so on. In the case of multiple groups, care must be given to the overall, or experiment-wide, error rate. Whereas the error rate for any one of these pairwise tests might be small, the probability that all the tests result in the right decision decreases with the number of tests preformed. To remedy this difficulty, tests have been developed to compare multiple groups in one statistical test (e.g., analysis of variance, for one). In these tests, a low p value indicates that there is a statistically significant difference among at least two groups. This result is less informative than multiple pairwise comparisons would be. It has the advantage, however, of preserving the experiment-wide error rate. In the case of a statistically significant result, typically, the next step is to perform these multiple tests using some sort of correction to the significance level α to correct for experiment-wide error rate inflation.

One such adjustment, the so-called Bonferroni adjustment, is made by dividing the α level of a test by the number of statistical tests being performed to determine the α level to be used for each statistical test. Using that result for each test guarantees that the experiment-wide error rate will be at most α .

Some Objections to Statistical Significance Testing

Although significance testing is common in most areas of quantifiable academic and applied research, it is not without cautions and criticism. Some have even called for abandoning the use of p values altogether. There are two main objections to the traditional, frequentist use of the p value: The first objection has to do with the effect of sample size. The sensitivity of a statistical test increases with the size of the sample being analyzed. As a result, if a very large sample is analyzed, then a hypothesis test will be able to detect even minute differences between the value in the null hypothesis and the observed data. Because of this increased sensitivity,

large sample sizes tend to produce statistically significant results, even if the actual difference between the measured data and null hypothesis is very small. Furthermore, a hypothesis test performed on a small sample that demonstrates a large difference between the hypothesized value and the observed data might result in the same p value that would result from a hypothesis test performed on a very large sample that demonstrates only a tiny difference between the two. Consequently, researchers with large amounts of data have to distinguish between statistically significant and practically significant differences. Although there is ample mathematics for determining statistical significance, there is no clear, unambiguous, or agreed on way to determine what is practically significant.

The second main objection to the use of the p value is in its definition: A p value is the probability of observing a test statistic as extreme or more extreme than what was observed given that the null hypothesis is true. Some argue that the phrase “or more extreme” points to values of the test statistic that have not been observed. In other words, if the null hypothesis is rejected, it is because of how unlikely it would be to observe data that were not, in fact, observed.

These objections have led others to consider alternate methods of evaluating data, including Bayesian approaches that incorporate prior information about the parameter being studied into the analysis. In Bayesian methods, the results of the current experiment will be used to update the prior knowledge. That prior knowledge can then be used in future experimentation. This updating procedure is sometimes used in place of or in addition to traditional hypothesis testing. By this means, rather than specifying a specific value for an unknown parameter in the population of interest, a Bayesian researcher treats that parameter as a random quantity and attaches a probability distribution to it. In this way, rather than comparing the data with a specific postulated value, researchers can make probability statements about the value of a population parameter over a range of values. This approach, of course, has its own difficulties, including the nontransferability of subjective probabilities, the computational challenges, and the use and selection of noninformative and informative prior probability distributions.

SIMPLE MAIN EFFECTS

A great deal of psychological research examines the effect a single independent variable has on a single dependent variable. However, it is perfectly reasonable to examine the effects multiple independent variables simultaneously have on a single dependent variable. Experimental designs that include multiple independent variables are known as factorial designs. They come in a wide variety including between-group and within-subject variables and a mixture of both kinds. When two or more variables in a factorial design show a statistically significant interaction, it is common to analyze the simple main effects. Simple main effects analysis typically involves the examination of the effects of one independent variable at different levels of a second independent variable.

Figure 1 The Means and Standard Errors for Different Hint Conditions for Solving the Tower of Hanoi Problem

Interactions

Suppose an experiment was conducted that examined the consequences of providing different hints for solving the tower of Hanoi problem. The first condition simply provides the rules and the goal for the problem (*No hint*). The second condition involves telling the participants not to think about moving disks but moving pyramids of disks (*Pyramid*). The third condition involves telling participants about moving pyramids of disks and states what the first move is (*Pyramid + First*). The dependent variable is the number of moves to solution of the problem. The results are shown in Figure 1.

These results are explained in terms of reducing the amount of planning that is required. The greater the amount of planning that is necessary, the more mistakes that are made because it is easier to forget long plans.

A different experiment using the tower of Hanoi was also conducted. Three groups were selected according to age: 5–7 years, 9–11 years, and 13–15 years old. Figure 2 shows the results.

The results are also explained with respect to planning such that younger children cannot remember the plans they have made, whereas older children can. In the first experiment, the reduction in planning demands is obtained by changing the representation of the problem. In the second experiment, the ability to deal with planning demands vary according to age. To determine whether reducing the planning demands for younger children by changing the representation of the problem helps them to overcome their problems in planning, the two variables (age and problem representation) are considered at the same time.

Suppose the results shown in Figure 3 were obtained. In this case, the effects of changing the representation of the problem differ with respect to age. In other words, the effects of one variable are different for the

different levels of the second variable. This is known as an interaction.

A more formal definition of an interaction is as follows:

An interaction is present when the simple effects of one independent variable are not the same at different levels of the second independent variable.

The simple effects of an independent variable are the effects of one independent variable at the specific levels of the other independent variable.

Analyzing Simple Main Effects

When an analysis of variance (ANOVA) is used to examine interactions, both independent variables are entered into the analysis simultaneously. The output from most statistical packages resembles that shown in Table 1.

Figure 3 The Mean and Standard Errors for the Interaction Between Different Ages and Hint Conditions for Solving the Tower of Hanoi Problem

Figure 2 The Mean and Standard Errors for Different Ages for Solving the Tower of Hanoi Problem

Table 1 An Example ANOVA Output

Source	Sum of Squares	df	Mean Square	F ratio	p value
Learning	3.20	1	3.20	2.56	.13
Task	105.80	1	105.80	84.64	8.65×10 ⁻⁸
Learning * Task	7.20	1	7.20	5.76	.03
Error	20.00	16	1.25		
Total	136.20	19			

The following is an example of a between groups analysis. In this case, the first independent variable is expressed as two groups of participants. The first is presented with instructions that lead to learning an artificial grammar implicitly (*implicit condition*), whereas the second is given instruction to learn an artificial grammar explicitly (*explicit condition*). The second independent variable involves one group of participants working on their task with no further task (*single task condition*) with a second group given a secondary task to complete at the same time (*dual task condition*). The dependent variable is the number of correctly identified, novel grammatical items at post-test. Altogether, there are four separate conditions. The results are shown in Figure 4.

In this analysis, there is no evidence that the learning manipulation has led to a difference in the implicit and explicit condition means for the number of correctly identified grammatical items. At the same time, there is a significant main effect of task. That is, the mean number of correctly identified grammatical items is less in the single task condition than in dual task condition. Finally, there is a significant interaction between the task and learning variables. By simply looking at the graphs, it is not immediately obvious how this interaction works. Instead, we need to examine statistically the interaction even more to understand how the means differ.

The most commonly used technique for the subsequent analysis of interaction is known as simple effects analysis. It is sometimes also known as simple main-effects analysis. The simplest way to understand simple effects analysis is to consider the overall experiment being broken down into several smaller constituent experiments. For example, the example given previously can be broken down into four constituent experiments (see Figure 5). First, the simple effect of learning

Figure 4 The Means and Standard Errors for the Interaction Between Learning and Task Instructions

at single task can be considered. This involves comparing the implicit and explicit condition means for the single task condition alone. Then, there is the simple effect of learning at dual task. The means for the implicit and explicit conditions are contrasted for just the dual task data. In contrast, there is the simple effect task at implicit learning which examines the difference in the means for the single task and dual task means for the implicit data by itself. Finally, the simple effect of task at explicit learning compares the means for the explicit condition between the single and dual task conditions. Typically, simple effects are referred to as the effect of variable A at levels 1 to k of variable B and vice versa.

For each of the simple effects that represent the interaction, a separate F ratio is calculated. A typical completed analysis looks like Table 2.

Figure 5 A Breakdown of a Two-Way Interaction Into Its Constituent Simple Effects

Table 2 An Example Simple Effects Analysis

Source	Sum of Squares	df	Mean Square	F ratio	p value
Learning at					
Single	0.40	1	0.40	0.32	.58
Dual	10.00	1	10.00	8.00	.01
Task at					
Implicit	28.90	1	28.90	23.12	1.93×10^{-4}
Explicit	84.10	1	84.10	67.28	4.00×10^{-7}
Error	20.00	16	1.25		

The simple effect of learning at a single task is not significant. There is, therefore, no evidence to support the hypothesis that implicit and explicit learning conditions means are different when a single task is presented. However, the remaining three simple effects are statistically significant. This implies that the effect of a dual task is to increase the means when compared with a single task and that this increase is sufficiently large for it to lead to a difference between the means for the dual task condition between the implicit and explicit learning conditions.

Simple Effects Analysis for More Complex Designs

The previous example is relatively straightforward in the sense that there were only two independent variables, and each of those independent variables only had two levels (or conditions). The situation is more complicated when at least one of the independent variables has more than two conditions. When this happens, the *F* ratio associated with the simple effect with more than two conditions tests whether overall those three or more means are significantly different from each other. It does not test directly how those means actually differ. In this case, two basic approaches are often taken. First, if the pattern of mean differences had been predicted prior to the experiment, it is possible to use planned (a priori) contrasts to test the differences between the means. If, however, the mean differences had not been predicted prior to analysis, it is common to use unplanned (post hoc) comparisons. In both cases, it is important not to conduct unnecessary statistical tests because this rapidly increases the chance of making a Type I error. Planned comparisons are usually conducted using the method of weighted means and are sometimes referred to as *contrasts*. Post hoc comparisons are somewhat more problematic. There is no overall agreement in the literature about which post hoc test is best used for which experimental design. However, the Tukey's Honestly Significant Difference test has been adapted to work fully between groups designs, fully within subjects designs, and designs in which there is both a between-group and within-subject component.

A second way in which designs can be more complicated is when there are more than two independent variables. In this case, not only might two factor interactions be found but also higher level interactions between three or more factors. Fortunately, the analytic strategy that is adopted is simply an extension of what has already been outlined.

For example, Figure 6 shows a two-way interaction between instruction type (diagram vs. procedures) and

Figure 6 The Means and Standard Errors for the Three-Way Interaction Among Instruction, Task, and Time

Figure 7 The Means and Standard Errors for the Interaction Between Two Trends

task type (fault vs. switch) at time 1. However, that interaction is no longer obvious at time 2. These data show a three-way interaction. One way to understand such an interaction is that the subsumed two-way interactions are not the same. An analytic strategy that examines the two-way interactions, therefore, can help test this hypothesis. The simple effects of task at (diagram, time 1), task at (procedure, time 1), instruction at (fault, time 1) and instruction at (switch, time 1) can be examined as well as the equivalent simple effects at time 2. In this way both, the two-way interactions are examined and can provide a helpful insight into the three-way interaction.

Choosing the Appropriate Error Term for Simple-Effects Analysis

One important concern when conducting a simple-effects analysis is choosing the appropriate error term. For the standard between-groups analysis, the error used when calculating the F ratio for the simple effects is usually the same error used in the overall ANOVA. This is the pooled error term calculated by combining all the data in the experiment. However, when there are heterogeneous variances across the levels of an independent variable, comparisons are made such that the actual variability when comparing conditions is either significantly greater or less than the average variability. When this happens, the observed F ratio can be biased and lead to either Type I or Type II errors. It is usually safer in this case to use an error term that is based solely on the variability around the means that are actually being compared. In a two-way between-groups design this is equivalent to extracting the appropriate data from the design and conducting the equivalent of an independent samples t test for two levels or a one-way between groups ANOVA when there are more than two levels.

In a completely within-subjects design, the overall error term is used as is normally the case in the completely between-groups design. However, for a mixed design with both between-groups and within-subjects variables, the error that is adopted depends on whether a between-groups simple effect or a within-subject simple effect is being examined. When examining the between-groups simple effect, a more accurate estimate of the error variability is obtained using a pooled within-cell error term, which has more degrees of freedom. This assumes that there is homogeneity of within condition variances. This error term is often larger than the usual simple effect error term, but the critical value of the F ratio will be smaller given the greater degrees of freedom, thus giving more statistical power to the test. If there is heterogeneity of within-condition variances, then this is not appropriate and separate error terms are calculated for each level of the within-subject variable.

Alternatives to Simple Effects Analysis

One problem with using simple effects analysis, particularly with complicated designs, is the proliferation of statistical tests and the ensuing increase in familywise Type I error rates. As more tests are conducted, the chance of falsely finding a significant result also increases. An alternative to this strategy is to conduct what are known as interaction contrasts. Figure 7 shows an example where such a method is particularly useful.

In this case, there is a descending linear trend for level A1 and an increasing linear trend for level A2 across the three B treatment levels. In this case, an interaction contrast can be constructed that directly tests the hypothesis that the two trends are statistically different.

SIMPSON'S PARADOX

The marginal association between two categorical variables might be qualitatively different than the partial association between the same two variables after controlling for one or more other variables. This is known as Simpson's paradox. Simpson's paradox is important for three critical reasons. First, people often expect statistical relationships to be immutable. They often are not. The relationship between two variables might increase, decrease, or even change direction depending on the set of variables being controlled. Second, Simpson's paradox is not simply an obscure phenomenon of interest only to a small group of statisticians. Simpson's paradox is actually one of a large class of association paradoxes. Third, Simpson's paradox reminds researchers that causal inferences, particularly in nonexperimental studies, can be hazardous. Uncontrolled and even unobserved variables that would eliminate or reverse the association observed between two variables might exist.

Illustration

Understanding Simpson's paradox is easiest in the context of a simple example. The inspiration for the one presented here is the classic article published by Peter Bickel and his colleagues.

Table 1 Graduate Admissions by Gender

	<i>Admit</i>	<i>Deny</i>	<i>Total</i>
Women	31	95	126
Men	66	100	166
Total	97	195	292

Suppose that a university is concerned about gender bias during the admission process to graduate school. To study this, applicants to the university's graduate programs are classified based on gender and admissions outcome. These data, which are summarized in the cross-classification table depicted in Table 1, would seem to be consistent with the existence of a gender bias because men (40%) were more likely to be admitted to graduate school than women (25%).

To identify the source of the difference in admission rates for men and women, the university subdivides applicants based on whether they applied to a department in the natural sciences or to one in the social sciences and then conducts the analysis again (see Table 2). Surprisingly, the university finds that the direction of the relationship between gender and outcome has reversed! In natural science departments, women (80%) were more likely to be admitted to graduate school than men (46%); similarly, in social science departments, women (20%) were more likely to be admitted to graduate school than men (4%).

Although the reversal in association that is observed in Simpson's paradox might seem bewildering, it is actually straightforward. In this example, it occurred because both gender and admissions were related to a third variable, namely, the department. First, women were more likely to apply to social science departments, whereas men were more likely to apply to natural science departments. Second, the acceptance rate in social science departments was much less than that in natural science departments. Because women were more likely than men to apply to programs with low acceptance rates, when department was ignored (i.e., when the data were collapsed over department), it seemed that women were less likely than men to be admitted to graduate school, whereas the reverse was actually true. Although hypothetical examples such as this one are simple to construct, numerous real-life examples can be found easily in the social science and statistics literatures.

Table 2 Graduate Admissions by Gender by Department

<i>Social Science</i>				<i>Natural Science</i>			
	<i>Admit</i>	<i>Deny</i>	<i>Total</i>		<i>Admit</i>	<i>Deny</i>	<i>Total</i>
Women	23	93	116	Women	8	2	10
Men	1	25	26	Men	65	75	140
Total	24	118	142	Total	73	77	150

Definition

Consider three random variables X , Y , and Z . Define a $2 \times 2 \times K$ cross-classification table by assuming that X and Y can be coded either 0 or 1, and Z can be assigned values from 1 to k .

The *marginal association* between X and Y is assessed by collapsing across or aggregating over the levels of Z . Three possible patterns of association might be distinguished.

$$P(Y = 1 | X = 1) > P(Y = 1 | X = 0),$$

$$P(Y = 1 | X = 1) = P(Y = 1 | X = 0),$$

$$P(Y = 1 | X = 1) < P(Y = 1 | X = 0).$$

The *partial association* between X and Y controlling for Z is the association between X and Y at each level of Z or after adjusting for the levels of Z . Simpson's paradox is said to have occurred when the pattern of marginal association and the pattern of partial association differ. In the example discussed earlier, if women are coded 1 and men are coded 0, and admits are coded 1 and denies are coded 0, then the marginal association between gender and admissions will correspond to the third of the three possible patterns of association, whereas the partial association between gender and admissions for the two departments separately will correspond to the first pattern.

Various indices exist for assessing the association between two variables. For categorical variables, the odds ratio and the relative risk ratio are the two most common measures of association. Simpson's paradox is the name applied to differences in the association between two categorical variables, regardless of how that association is measured, whether descriptively in terms of conditional probabilities, as provided previously, or through one of the measures of association.

Association Paradoxes

Association paradoxes, of which Simpson's paradox is a special case, can occur between continuous as well as categorical variables. For example, the best-known

measure of association between two continuous variables is the correlation coefficient. It is well known that the marginal correlation between two variables can have one sign, whereas the partial correlation between the same two variables after controlling for one or more additional variables has the opposite sign.

Reversal paradoxes, in which the marginal and partial associations between two variables have different signs, such as Simpson's paradox, are the most dramatic of the association paradoxes. A weaker form of association paradox occurs when the marginal and partial associations have the same sign, but the magnitude of the marginal association falls outside of the range of values of the partial associations computed at individual levels of the variable(s) being controlled. These have been termed *amalgamation* or *aggregation paradoxes*.

Problem of Causality

When confronted with a reversal paradox, it is natural to ask whether the marginal or the partial association is the correct description of the relationship between two variables. Assuming that the relationships among the variables in one's sample mirror those of the population from which the sample was drawn, then the usual statistical answer is that both the marginal and partial associations are correct. Mathematically, there is nothing surprising about a reversal in the direction of the marginal and partial associations. Furthermore, in an analysis, such as the one presented previously, the reversal of the marginal and partial associations is easily understood once the role of the control variable is understood.

If social scientists were merely interested in cataloging the relationships that exist among the variables that they study, then the answer given previously might be sufficient. It is not. Often, social scientists are interested in understanding causal relationships. In the example given previously, one might be interested in knowing whether the admissions process is biased toward males, as the marginal association might suggest, or biased toward females, as the partial association might suggest. This is the real dilemma posed by Simpson's paradox for the researcher. It is problematic in two ways.

First, the statistical analysis provides no guidance as to whether the marginal association or the partial association is the spurious relationship. Based on our knowledge of graduate admissions, it is reasonable to conclude that the marginal relationship in this example is spurious because admissions decisions are made by departments, not by universities. Substantive information guides this judgment, not the statistical analysis. It might be tempting to conclude, as some authors do,

that the marginal association is always spurious. Certainly, that is the impression that is given by much of the published work on Simpson's paradox. Indeed, some authors characterize Simpson's paradox as a failure to include a relevant covariate in the design of a study or in the relevant statistical analysis. Unfortunately, this simple answer is inadequate, because it is possible to construct examples in which the partial association is the spurious one.

Second, the field of statistics provides limited assistance in determining when Simpson's paradox will occur. Particularly in nonrandomized studies, there might exist uncontrolled and, even more dangerously, unobserved variables that would eliminate or reverse the association observed between two variables. It can be unsettling to imagine that what is believed to be a causal relationship between two variables is found not to exist or, even worse, is found to be opposite in direction once one discovers the proper variable to control.

Avoiding Simpson's Paradox

Although it might be easy to explain why Simpson's paradox occurs when presented with an example, it is more challenging to determine when Simpson's paradox will occur. In experimental research, in which individuals are randomly assigned to treatment conditions, Simpson's paradox should not occur, no matter what additional variables are included in the analysis. This assumes, of course, that the randomization is effective and that assignment to treatment condition is independent of possible covariates. If so, regardless of whether these covariates are related to the outcome, Simpson's paradox cannot occur. In nonexperimental, or nonrandomized, research, such as a cross-sectional study in which a sample is selected and then the members of the sample are simultaneously classified with respect to all of the study variables, Simpson's paradox can be avoided if certain conditions are satisfied. The problem with nonexperimental research is that these conditions will rarely be known to be satisfied *a priori*.

Brief History of Simpson's Paradox

Given the nature of the phenomenon, perhaps it is only fitting to discover that Edward Simpson neither discovered nor claimed to have discovered the phenomenon that now bears his name. In his classic 1951 paper, Simpson pointed out that association paradoxes were well known prior to the publication of his paper. Indeed, the existence of association paradoxes with categorical variables was reported by George Udny Yule as early as 1903. It is for this reason that

Simpson's paradox is sometimes known by other names, such as the Yule paradox or the Yule-Simpson paradox. It is possible to trace the existence of association paradoxes back even further in time to Karl Pearson, who in 1899 demonstrated that marginal and partial associations between continuous variables might differ giving rise to spurious correlations. Pearson reported that the length and breadth of male skulls from the Paris catacombs correlated .09. The same correlation among female skulls was $-.04$. After combining the two samples, the correlation was .20! In other words, skull length and breadth were uncorrelated for males and females separately and positively correlated for males and females jointly. Put slightly differently, the marginal association between skull length and breadth was positive, while the partial association between skull length and breadth after controlling for gender was zero.

Not only is Simpson not the discoverer of Simpson's paradox, but the phenomenon that he described in his 1951 paper is not quite the same as the phenomenon that is now known as Simpson's paradox. The difference is not critical, but it does reflect the confusion that persists today about what Simpson's paradox actually is. Some authors reserve the label Simpson's paradox for a reversal in the *direction* of the marginal and partial association between two categorical variables. Some authors apply Simpson's paradox to reversals that occur with continuous as well as categorical variables. Still other authors have abandoned the term *Simpson's paradox* altogether, preferring terms such as *aggregation*, *amalgamation*, or *reversal paradoxes*, which are often defined more broadly than Simpson's paradox.

SINGLE-BLIND STUDY

A single-blind study occurs when the participants are deliberately kept ignorant of either the group to which they have been assigned or key information about the materials they are assessing, but the experimenter is in possession of this knowledge. Single-blind studies are typically conducted when the participants' knowledge of their group membership or the identity of the materials they are assessing might *bias* the results. However, there are situations where creating such ignorance might be impossible or unethical, and in others, it might be advisable for more than the participants to be kept unaware of the test conditions. This entry discusses the single-blind study in relation to the unblinded (neither experimenter nor participants are kept ignorant) and double-blind study (both experimenter and participants are kept ignorant). It also presents some illustrative examples and examines the advantages and disadvantages of the single-blind study.

The Unblinded Study

To understand the blind study, it is advisable first to consider the unblinded study. In this, both participant and observer are fully aware of the groupings and/or materials. For example, a group of patients might be fully aware of which of two types of treatment they are receiving, such as in judging a group of singers in a competition, the participants are fully aware of the identity of each singer. Sometimes, an unblinded study is unavoidable. For example, many routine clinical treatments are done in an unblinded manner, with the patient and therapist actively discussing all the methods available before choosing one. Accordingly, any naturalistic, purely observational study of such a situation will of necessity have to accept that the participant is aware of what is taking place. Likewise, in some circumstances, asking participants to make judgments will also require them to know the identity of what is being judged (e.g., judging the relative merits of famous singers). The unblinded study is, thus, in some instances unavoidable. In practical terms, it is also generally far

easier to run than a blind study, which requires greater organization.

However, the unblinded study also carries disadvantages that sometimes outweigh its merits, and experimenters will usually avoid it when a blind study is a viable alternative. At its most basic, the unblinded study provides the participant with information about how they are grouped or what they are assessing, and this knowledge might lead to self-expectations of how they should respond. This can potentially distort results, as is discussed next.

Illustrative Examples

In contrast to unblinded studies, single-blind studies deliberately withhold key information from the participants (though not the experimenters). A commonplace example of withholding key information about test materials is a measure of consumer preference where the participant is asked to judge which of two or more brands of the same basic product is preferred, but the brand identities of the products are hidden from the participant. For example, in comparing the quality of different hi-fi components, products could be hidden behind visually opaque but acoustically transparent material, and the participants could be asked to listen to music played over these systems without being aware of the brands of product. All the participant can do is judge the quality of what they hear. However, the experimenters are aware of the true identity of each piece of equipment being assessed. An example of participants lacking knowledge of which group they belong to is the common clinical procedure where patients are given one of two or more drug treatments, but they do not know which one. However, the experimenters providing the treatments and assessing the treatment are aware of this information.

Advantages

The key advantage of the single-blind study is that, all things being equal, the participant is deprived of the biasing effect that knowledge of the test materials or group membership might bring. For example, in the case of the hi-fi experiment, because the participant does not know the brand of the products being tested, it is assumed that the participant cannot be swayed in his or her judgment by brand loyalty or brand status. Thus, if expensive and inexpensive pieces of hi-fi equipment are being compared, the former cannot be automatically preferred because it is more expensive and hence “must” be better, because the participant cannot see which product is which and hence is compelled to judge on sound alone, rather than sound distorted by

biased expectations. In the drug trial experiment, the knowledge of which treatment a person is receiving could have a biasing effect. For example, suppose that the patient knows that he or she is being given an established (and not very effective) drug instead of the new drug that the other group is receiving. The patient might feel depressed that he or she is getting a less effective treatment, and this depression might lessen the patient’s recovery rate. Conversely, if a patient feels suspicious of new methods and prefers the tried and tested, then receiving the old drug might make him or her feel more optimistic and might artificially elevate his or her mood and, hence, aid recovery. These are examples of what in loose terminology are called *nocebo* and *placebo* responses (lowering or raising of beneficial effects through expectation alone). The placebo and related effects are central to the single-blind study, and the dangers (or perceived dangers) of bias through participant expectation lie at the heart of many blind study designs. By removing knowledge of group assignment, expectation is also removed and, hence, it is argued, possible biasing effects.

Disadvantages

However, nocebo and placebo responses cannot be quite so easily disposed of. It is possible that *any* treatment a person receives might have an effect, even if it is supposed to be totally inert. For example, a drug might have part of its effect, not because of its pharmacological function, but because the patient expects the drug to have an effect and thus will change the patient’s mood accordingly. Typically, patients expect to get better after treatment, and so the simple effect of taking their medicine regularly might cause an improvement in reported mood and health because they expect to be feeling better. To counteract this, single-blind studies might contain a placebo group — in other words, a group whose treatment is inert (literally, in the case of a drug trial, the placebo “drugs” taken have no pharmacological effect). This enables experimenters to judge how much of the effect of treatment is a result of the simple act of administering a treatment. For one of the real treatments to be effective, it has to offer advantages above and beyond that conferred by the placebo dose. However, there are ethical limitations to placebo treatments. If patients have a life-threatening condition, for example, it is morally very difficult to deny a patient an active treatment and offer them a sham therapy instead. A related issue is whether patients are treated equally in all other respects. The argument has been raised that if a clinician believes that a patient is receiving an inferior treatment to that being given to patients in another group, he or she might be tempted

(for entirely understandable reasons) to give the patient other therapies and drugs to compensate. This of course will distort the results, because it will artificially diminish the real size of the difference between the two drugs. This might bring benefits to the patients in the study, but if the better drug is not then adopted because it (spuriously) seems to be not sufficiently better than other available treatments, then the entire population of patients suffers.

Related to this point, another key problem with the single-blind study is that although the participants might be naïve about what they are assessing or the groups into which they have been placed, the experimenters are not. The key problem is *experimenter bias* (a type of *experimenter effect*). In other words, the experimenters might unwittingly bias the results either through influencing the participants or in recording their own assessments. To return to the drug trial example: suppose that the drugs being tested are antidepressants, and the experimenters have the task of assessing the patients' level of depression during the trial. If the experimenters have a vested interest in the outcome of the experiment, they might unwittingly be drawn toward observing bigger improvements in those patients who receive the drug therapy they most support. In the hi-fi equipment example, if the experimenters have a vested interest in one of the products, then they might, through body language or suggestion, imply that "their" product is better than the others. In addition, factors such as the sequencing of presentation might also have a biasing effect. Furthermore, there are potentially cases of outright fraud or of less-than-honest practices (e.g., comparing two brands of soda pop, and serving the one intended to win at a cooler temperature). Activities akin to this have been rumored to take place in *some* less-than-scrupulous consumer trials intended to produce spurious statistics to support a marketing campaign. However, arguably this is a problem of the probity of experimenters and not the single-blind study per se.

The Double-Blind Procedure

The single-blind study is potentially impervious to these criticisms if, issues of experimenter honesty aside, the measures being taken are entirely objective (e.g., subjective opinions of a particular drug's efficacy are unlikely to matter if the drug is a growth hormone and all measurements are objective ones of length). However, such situations rarely arise and critics can nearly always find real or potential sources of experimenter bias. Therefore, it is generally desirable to remove experimenter bias as far as possible by using a double-blind procedure. In essence, the double-blind method

ensures that not only the participants but also the experimenters do not know to which group the participants belong. Thus, any observations by the experimenters must by definition be objective. As they do not know to which group a participant belongs, there is no impetus to distort the findings.

However, although the double-blind procedure is generally presented by authors as being automatically superior to the single-blind study, there are some caveats to consider. The first is that just as the single-blind study is more complex to run than an unblinded study, so in turn is the double-blind study more difficult to run than a single-blind study. If the potential for experimenter bias justifies this, then it should be done, but if the measures are arguably objective enough to withstand any biasing effects, then running a double-blind measure seems a little excessive and unnecessarily wasteful of time and resources. It should also be noted that, in double-blind studies of clinical trials, a lack of knowledge about the treatment group to which a patient belongs could in certain circumstances be dangerous. Although unlikely, it is possible that a certain set of symptoms might give early warning of a serious side effect that the experimenter might notice if he or she knew the drug being administered, but which are merely noted as a set of minor symptoms in a blind observation. Again, in some cases, experimenter knowledge might be unavoidable. For example, if the observations to be made can only be made during the therapeutic process itself (and not, for example, simply in tests conducted after a drug has been administered), then the experimenter of necessity must be aware of the treatment he or she is administering. It should also be noted that in some instances, even if the identity of the treatment is hidden from the experimenter, the experimenter might quickly identify it by other characteristics (e.g., side effects reported by patients might enable a clinical observer to make an accurate guess about the nature of the drug treatment).

SINGLE-CASE RESEARCH DESIGN

Single-case research designs are a family of scientifically rigorous strategies for documenting experimental effects. Single-case designs have been used to establish basic principles of behavior, document the impact of specific interventions, and more recently validate evidence-based practices. The defining feature of single-case research is that each participant (subject) serves as their own experimental *control*. This approach to research design arose from early work in the 1940s and 1950s focusing on behavior analysis and was codified in a seminal book, *Tactics of Scientific Research* by Murray Sidman, in 1960. Sidman defined in detail how repeated measurement of an individual's behavior over time could be used to test important experimental concepts and expand our fundamental understanding of human behavior.

During the past 70 years, single-case methods have become a standard approach for conducting educational, behavioral, and psychological scholarship. Over 45 professional journals now publish single-case studies. Although single-case research is accurately associated with behavioral psychology, single-case methods are now used to document advances across an array of fields including social-learning theory, medicine, education, social work, and communication disorders.

The basic goal of single-case research designs is to evaluate the extent to which a causal (or functional) relation exists between the introduction of an *intervention* (e.g., pace of instruction) and change in a specific dependent variable (e.g., reading performance). In most cases, a researcher conducting a single-case study wishes to establish that

- (1) prior to the intervention, a subject behaved in a consistent, clear manner that does *not* meet social expectations (e.g., the student read slowly or inaccurately, the student engaged in high rates of problem behavior);
- (2) after the intervention, the participant behaved in a manner that is both different and improved when compared to preintervention (e.g., the student read faster and/or more accurately, the student behaved

with less problem behavior and more positive behavior); and

- (3) this clearly measured change is unlikely to be the result of anything other than the intervention (e.g., not related to normal development, not some other unmeasured intervention, not illness or change in the personal life of the participant).

It is the final assertion, that the change in behavior was *causally* associated with introduction of the intervention, that establishes the scientific credibility of single-case designs. This entry reviews the defining features of single-case experimental research designs, noting their contribution to a science of human behavior.

Defining Features of Single-Case Research Designs

An array of single-case research designs have been proposed and published. Across these options, a small set of defining features characterize single-case designs.

The Individual Is the Unit of Analysis

Single-case research involves fine-grained analysis of change across time. The individual subject serves as the unit of analysis, and each subject is observed multiple times before and after an intervention. An experimental effect is demonstrated through the consistency and replicability of documented change by individual participants. Single-case designs are constructed around varying options for building and replicating this comparison of preintervention and postintervention performance of individuals.

Although the individual always serves as the core unit of analysis in a single-case design, there are two caveats worth noting:

- (1) An *individual* may be a person, or even a group (e.g., whole classroom of students, whole school), and
- (2) to demonstrate a convincing effect, it is expected that change will be replicated across multiple individuals.

Replication of effect can occur in many ways, but in most single-case designs, replication involves demonstrating that an effect observed with one individual is also observed with other individuals.

Replicable Description of Participants and Setting

A core feature of any experimental research is a precise and replicable description of the research

procedures. In addition to including a replicable description of experimental methodology, single-case research aides replicability through detailed description of (a) the individuals involved in the research (age, race/ethnicity, gender, disability, how selected [e.g., based on level of problem behavior]), (b) the interventionists (age, race/ethnicity, gender, education, experience, how selected), and (c) the context or setting of the study.

Measurement of Dependent and Independent Variables

An underemphasized feature of single-case research is the rigorous measurement of both the dependent variable (outcome measure) and the independent variable (intervention). Because single-case research focuses on change of individual behavior across time, the designs require collecting data about the dependent variables at multiple points in time. This requires careful and repeated measurement of the dependent variables (e.g., percentage of addition problems solved correctly, frequency of problem behavior). Single-case research studies utilize graphed data of the dependent variables, and often of the independent variable, to visually represent individual performance. However, these measurements must occur with a level of precision and validity that allows the reader to trust the accuracy of measurement. Single-case research results typically include not only replicable descriptions of how data were collected (and by whom) but also the documentation that the data meet minimal standards for reliability (e.g., interobserver agreement) and validity.

Interest in measurement fidelity within the broader research community has led to an expectation that research must also document the procedural fidelity with which the independent variable (the intervention) was implemented across all conditions of the experiment, including baseline and treatment phases. Not only is it essential to define the procedures within an intervention using replicable precision, but it is also important to document that the intervention was implemented as intended (treatment integrity). Only by measuring treatment integrity, can results (whether positive or negative outcomes) be used to assess the effects of the independent variable.

Baseline Documentation

Single-case research studies typically begin with a formal *baseline* period in which data are collected under *typical* or control conditions. The purpose of the baseline is to document a pattern of performance that

is different than is desired (e.g., too much problem behavior, too little learning) and allows prediction of future performance if no intervention was to occur.

The baseline condition establishes the standard for comparison of the dependent variable across time. Documenting an adequate baseline pattern typically involves at least five data points, although more data points may be needed if high variability or trend in the data prevents identification of a stable baseline pattern. Once baseline performance is established, the experimenter manipulates (changes) only the independent variable (the intervention). This allows the researcher to ask, “If all other variables are held constant and the intervention is introduced, is there change in the dependent variable?”

Experimental Designs That Document Casual Relations

Experimental research is expected to describe a phenomenon (e.g., behavior) with precision and clarity, demonstrate that important and valued change has occurred with respect to that phenomenon, and provide experimental controls allowing inference that the change was causally linked to the intervention. With single-case research, these goals are achieved through a variety of experimental designs, each of which allows at least three demonstrations of effect across at least three different points in time. This emphasis on replication of effects is a key difference between single-case *experimental* research and traditional case studies. Figures 1–4 provide examples of four commonly used single-case designs and an index of how each allows at least three demonstrations of effect across at least three different points in time.

Reversal or Withdrawal Designs

A frequently used single-case design is the reversal/withdrawal design (ABAB where A is baseline condition and B is intervention condition), shown in Figure 1. As with most single-case designs, the dependent variable (outcome variable) is indexed on the ordinate (vertical *y*-axis), and time is indexed on the abscissa (horizontal *x*-axis). The design begins with documentation of baseline performance (Baseline 1). The first demonstration that manipulation of the independent variable is associated with an effect on the dependent variable occurs when the intervention is introduced (Intervention 1). The second demonstration of effect occurs with a return to the baseline condition (Baseline 2). If the dependent variable returns to baseline levels, there is increased confidence that the change in the dependent variable was causally related to introduction

of the intervention and not some other factors (e.g., child maturation). The third demonstration of effect is provided when the intervention is reintroduced (Intervention 2) and the dependent variable again improves. By convention, three demonstrations of the effect across three different points in time are considered sufficient to infer that change in the dependent variable is functionally (or causally) related to the intervention. To identify the pattern of responding within each phase of a study (e.g., A1, B1), the convention is to obtain at least five data points per phase. There are instances, however, where three data points in a phase may be acceptable (with reservation). Note that in Figure 1, the brackets indicate each of the three demonstrations of effect at three different points in time.

It is important to note that a traditional case study in which data were collected in baseline (A1) and compared with performance during intervention (B1) would **not** qualify as an experimental single-case design. An A1-B1, or even an A1-B1-A2, design would provide description of a problem, documentation of change, but would not offer three demonstrations of the effect at three different points in time. As such, these case studies would not have the level of experimental control needed to demonstrate a causal or functional relation.

Multiple Baseline Designs

The multiple-baseline design addresses a major weakness of the reversal/withdrawal design, particularly in applied settings: There are some dependent variables that cannot be reversed once the intervention has been successful (e.g., reading skills, steps completed correctly in a task analysis) or are clinically undesirable to reverse (e.g., severe self-injurious behavior). As the name implies, the multiple-baseline design is organized around concurrent multiple baselines (at least three and often more), with the intervention introduced sequentially after each baseline has been established. Figure 2 provides an example of a four-series, multiple-baseline design. Note that each baseline documents a pattern of behavior that is undesirable and sufficient consistency of responding (minimum of five data points) to allow prediction of future responding. The same intervention is introduced across each baseline in sequence, with sufficient delay to allow demonstration of a clear *effect* in the prior series. Taken together, the four baselines in Figure 2 meet the criterion of documenting at least three demonstrations of effect across at least three different points in time.

Although multiple-baseline designs commonly evaluate a staggered intervention across participants for a

Note: Design provides four demonstrations of clinical effects at four different points in time (indicated by numbers in circles).

single behavior, they can be used to evaluate the effects of an intervention on a single participant across multiple behaviors or across more than one condition or setting.

Alternating Treatment/Multielement Designs

A variation of the ABAB reversal/withdrawal design is the alternating treatment (or multielement) design depicted in Figure 3. This design compares the effects of two or more *treatments* or intervention *conditions* on a dependent variable. The design requires rapid alternating among the two or more treatments (or intervention condition and control condition) in a non-predictable, counterbalanced ordering of presentation. Importantly, the participant must be able to discriminate between the conditions and the dependent variable must be reversible without carryover into the subsequent condition. In the most basic form of alternating treatment design, one treatment condition (e.g., 30-min teaching session where instructional trials are delivered every 30 s during play) is alternated with a treatment as usual condition (e.g., 30-min teaching session where instructional trials are delivered every 30 s, but play is not available during intertrial periods) and measurement of the dependent variables (e.g., problem behavior and academic engagement) occurs during both conditions.

Multielement designs are commonly used in the assessment of problem behavior and involve rapid alternation of three or more treatment conditions and

may also include a control, or treatment-as-usual, condition. Although experimental effects may be demonstrated from consistent altering of conditions (e.g., ABABAB), interactions may occur that artificially inflate or suppress effects of one condition through carryover or sequencing. To control for these potential threats to internal validity, constrained randomization is often used—random assignment of condition order with no more than three of the same conditions in a row.

Other common adaptations to the alternating treatment/multielement design include incorporation of a baseline phase before the alteration of treatment conditions and/or a follow-up phase in which the treatment condition with the optimal effect is implemented. Although an initial baseline phase adds rigor by demonstrating pretreatment performance, many alternating treatment designs forgo an initial baseline phase due to logistical constraints. Including a baseline as one of the alternating conditions, either continuously or as probe sessions, provides comparison of treatments to control and can help rule out potential interaction effects between conditions.

Changing-Criterion Design

Changing-criterion designs are used less frequently and are more idiosyncratic than other single-case designs. These designs include only a single participant and one dependent variable, and they are ideal for interventions where large, immediate shifts in behavior

Figure 3 Simulated Alternating Treatment Design Assessing the Effects of Different Consequences on Darin's Problem Behavior

Note: Ovals index each of the five demonstrations of effect.

are difficult. The research question addressed by a changing-criterion design is whether specification of a performance criterion, or limit (e.g., a specific number of cigarettes smoked, number of math problems completed, distance run), affects the targeted dependent variable. The focus of the analysis is on the specification of “a criterion level of performance” and change in behavior when the level of the criterion is altered. Intervention is implemented over a series of phases, or steps, with each phase serving as a baseline for the next phase. For example, if, as in Figure 4, a special reward was provided for reading two books in a month, and a child moved from zero books per month to two books per month, it could be argued that specification of the criterion (and reward) was related to the increase in books read. However, to rule out the influence of

extraneous variables on reading, the effect must be replicated at least three times across at least three time points. This could be done by stepped increases in the criterion for reward from two to three books per month and then from three to four books per month. If reading performance matched the criterion at *each* intervention criterion, it is inferred that increased reading was functionally related to establishing a criterion for reward. Although setting the criterion levels is somewhat subjective, the designs are strengthened by including a mini reversal of treatment effects, varying phase lengths, including a range-bound performance criterion, or varying the performance criteria across phases. Importantly, changing-criterion designs target behaviors already in person’s repertoire rather than shaping new behaviors.

Figure 4 Simulated Changing Criterion Design Providing Five Demonstrations of Effect at Five Different Points in Time

Figure 5 Simulated Combination of Multiple Baselines Across Students Design and Reverse Design

Combined Designs

As research questions have become more complex, it is not uncommon for single-case researchers to ask multiple questions within one study and to incorporate more than one design within a study. Figure 5 provides simulated intervention data in which multiple-baseline and reversal design elements are employed to evaluate first whether the intervention is effective and second whether the intervention effects will maintain once the intervention features are removed. Ultimately, the appropriate design is driven by the research questions of interest and grounded in the *baseline logic* of documenting three basic effects at three different points in time.

Analysis of Single-Case Research

Historically, single-case research designs have used visual analysis for interpretation of effects. The process of visual analysis involves review of raw data from each study, typically in the form of a line graph. Typically, there are no transformations or aggregations of data prior to reporting single-case data. The reader sees the same data as the researchers. Visual analysis involves determining first whether the basic design controls for major threats to internal validity and has the experimental integrity to allow documentation of a functional relation. After examining the design elements of a study, the reader focuses on the patterns of data first within each phase and then across phases to determine whether the intervention is associated with a predicted effect and whether that effect is replicated to allow three demonstrations across three different points in time.

The process of visual analysis has been challenged on two fronts. The first is concern that simply looking at the data is too subjective a process to allow reliable analysis, and the second is that although visual analysis allows documentation of the level of a functional relation, it does not produce a standardized index of effect size. The first concern has been addressed by improved guidelines for conducting visual analysis and research demonstrating strong reliability among single-case researchers trained in visual analysis protocols. The second concern, defining an effect size metric, is more substantive and has been a key obstacle to productive meta-analysis of single-case research. Recent innovations, however, are encouraging, and single-case researchers are now more likely to report both non-parametric approaches to effect size measurement (e.g., Tau-U) and design-comparable effect size measures to report the size of effects.

An array of recommendations exists for conducting analysis of single-case research. The following is a

four-step process that can be used as a conservative integration of current recommendations.

Step 1: Analysis of Design

The first step in evaluating a single-case research study is to determine whether the design allows documentation of experimental control. The design must include replicable description of measurement and procedures and allow for three demonstrations of a basic effect (i.e., change in the dependent variable across two adjacent phases) over at least three different points in time.

Step 2: Visual Analysis of Data

The second step in analysis of single-case research is to examine the patterns of data within and across the experimental phases. A researcher examines each phase of a single-case design by assessing the *level*, *trend*, and *variability* of the data within the phase. *Level* refers to the mean score of data along the ordinate scale value in a phase, *trend* refers to the slope of the best-fit straight line for the data within a phase, and *variability* refers to the range or standard deviation of data about the best-fit straight line (in some cases, variability may be assessed as the range of scores within a phase rather than about the best fit straight line). Examination of the data within a phase is used to describe the observed pattern of performance and to project expected performance if no changes were to occur. This assessment is then used to compare the observed and projected patterns with the actual pattern observed after manipulation of the independent variable.

In addition to comparing the level, trend, and variability within each phase, the researcher also examines how these three variables change across phases. Visual analysis across phases of a study focuses on the *immediacy of effect*, *overlap*, and *consistency of data in similar phases*. *Immediacy of effect* refers to the level of change between the last three data points in one phase and the first three data points of the next. The more rapid, or immediate, the effect, the more likely the effect is due to manipulations of the independent variable. *Overlap* refers to the proportion of data from the second phase that overlaps with data from the previous phase along the ordinate, or vertical, axis. The smaller the proportion of overlapping data points (or conversely, the larger the separation), the more likely the data document a change due to the intervention. "Consistency of data in similar phases" involves looking first at data only from all *baseline* phases and then only from all *intervention* phases to assess the extent to which there are consistent patterns in similar phases.

The greater the consistency, the more likely the data represent a functional effect due to the intervention.

Regardless of the single-case research design, visual analysis of level, trend, variability, overlap, immediacy of effect, and consistency of data patterns across similar phases is used to assess whether the data demonstrate at least three basic effects across at least three points in time. If this criterion is met, the data document a functional relation, and an inference may be made that change in the dependent variable is causally related to manipulation of the independent variable.

An underappreciated feature of visual analysis is that documenting experimental control (three demonstrations of effect) is also key to confirmation of the integrity of the research design. If the data document an immediate and dramatic shift from baseline to intervention phases, replicated across three points in time, alternative explanations for the change are unlikely. Visual analysis is used to determine whether an experimental effect is observed and to rule out threats to internal validity. If statistical tests are included in an analysis, they should occur only after visual analysis. Conducting statistical analysis of single-case data without first confirming demonstration of a functional relation via visual analysis is analogous to conducting statistical tests for group design studies without first documenting that random selection or assignments of participants has occurred. In both cases, the validity of the resulting statistics is compromised.

Step 3: Effect Size

The third step in a complete analysis of a single-case study is assessment of the size of the observed treatment effect. These calculations are based in three strands of methodological research:

- (1) approaches that summarize the effect of each case and then synthesize these case-specific effect sizes,
- (2) methods that use multilevel models for analyzing the raw (or standardized) data from one or multiple single-case design studies, and
- (3) methods that use design-comparable effect size metrics.

Effect size calculations such as between-case *d*-statistics for single-case designs and multilevel modeling allow for comparison of the magnitude of the intervention effect when comparing findings of single-case designs and group comparison designs (i.e., randomized control trials). A major topic for the next decade will be monitoring the emergence and use of effect size measures in single-case research.

Step 4: Social Validity

The fourth step in analysis of single-case research is the most subjective, although often the most meaningful. If a study documents a functional relation and has adequate effect size, the final determination is whether the intervention goals, and procedures, are *acceptable* to stakeholders and whether the observed outcomes are socially important. Single-case research designs were developed as a rigorous approach for building practical interventions to social challenges. The designs are used to assess basic theory of behavior and more often to assess whether interventions based on these theories can produce desired improvement in learning, social behavior, and emotional development. Thus, any complete interpretation of single-case research must include measures that determine whether those implementing and experiencing the intervention found the process acceptable and feasible and whether the magnitude and durability of the effect were sufficient to make a real change in the living, learning, and working life of those involved.

Final Thoughts

Single-case research is a rigorous approach to conducting behavioral science. A growing array of design options exist for documenting experimental control. In addition, a four-step process has emerged for assessing the rigor of the research designs, the validity of the data, the size of the effect, and the extent to which the procedures and outcomes are socially valid. Together, advances in single-case research methods are solidifying the value and feasibility of this research approach for making major contributions across multiple disciplines.

SOCIAL CAPITAL THEORY

Social capital theory contends that social relationships are essential to one's well-being and are associated with happiness and belongingness of an individual. Social capital has been used to explain high school dropout, educational inequality, economic growth, and social innovation. This entry presents major social capital theories proposed by Pierre Bourdieu, James Coleman, Lin Nan, and Robert Putnam. For each theory, examples of social capital and supporting evidence are provided. Understanding different types of social capital theories may help researchers to identify appropriate theoretical framework to guide their research design.

What Is Social Capital?

Social capital represents a form of capital that produces individual gains and public goods. Unlike human capital (i.e., the knowledge and skills possessed by an individual), social capital generates value through interpersonal relationships, a shared norm, honesty, trust, and reciprocity. One example is when someone

hears about a job opportunity from a friend. Another example is a group of volunteers who help out in their neighborhood park. In the first example, social capital is seen as a property of the individual, but in the second example, it is seen as the property of the collective. It is important to note that theorists differ whether social capital is a property of the individual, collective, or both.

Major Social Capital Theories

Various social capital theories have been proposed. This section explores four major theories.

Bourdieu's Social Capital Theory

Bourdieu is a French sociologist, anthropologist, and philosopher, who is primarily concerned about social structural inequality. He uses social capital as a way to explain social hierarchy whereby people vary greatly in power, influence, and wealth. For Bourdieu, social capital is key to understanding the formation and development of such a hierarchy. He argues that social capital depends on types of social networks. Consider someone who has higher social status, is economically well-off, and graduates from an ivy league *versus* someone who is more associated with a network consisting of people who have no higher education and struggle financially. Although both individuals have a social network, the quality of the network and accessibility to resources offered by the network are quite different. Such differences lead to inequality in power and socioeconomic status. In sum, people with more social capital are in a better position to obtain other forms of capital, such as economic and cultural capital. Bourdieu views social capital as a property of the individual and believes that social capital, along with cultural and symbolic capital, can explain social and economic inequality.

Coleman's Social Capital Theory

Coleman's work is perhaps one of the most frequently discussed social capital theory in education. Central to Coleman's theory is the trustworthiness within the network. He argues that a group of people who trust each other are able to accomplish more compared to a comparable group without that trust. He also argues that social capital, just like other forms of capital, represents a type of resource that is available to its group members and allows the members to achieve their personal goals as well as public goods. Furthermore, different from Bourdieu, Coleman views social capital as a property of the collective.

Coleman views family capital as part of social capital for students. His research has shown that family capital is closely linked to positive student outcomes. His research suggests that students with more siblings who come from single-parent households are more likely to drop out of high school. Another indicator of social capital is the mother's expectation of their child going to college. Coleman found that students of parents who expect their child to go to college were less likely to drop out of high school.

The most compelling evidence supporting Coleman's theory comes from his study of high school students. He argues that when adults around a child are more connected to each other, the child is less likely to drop out of high school. Supporting evidences include the following:

- Children in families with two parents are less likely to drop out than are those from single-parent households because two parents provide more supervision than a single parent;
- children who live in the same neighborhood are less likely to drop out compared to their highly mobilized peers—being in the same community provides the advantage of a social network of parents, teachers, friends, and neighbors who know each other and can collaborate in supervising the child; and
- children in catholic schools are less likely to drop out—the advantage of being in a catholic school is the embedded resources provided by church communities.

Putnam's Social Capital Theory

Putnam proposed the concepts of bonding and bridging capital. Bonding capital is characterized by strong ties and close relationships. One example is a group of friends from the same church who meet weekly. Another example of bonding capital includes ties between family members. A defining characteristic of bonding capital is a strong trust. In contrast, bridging capital represents a more diverse network. In academia, this may refer to a group of people who attend the same conference. Bonding capital provides emotional support, whereas bridging capital enables information diffusion. Bridging ties are important as they lead to employment opportunities and potentially other resources. For example, people may find out about different restaurants to go to through weak ties. In sum, bonding ties are essential as these relationships provide opportunities for an individual to branch out and to increase the diversity of one's social network, which leads to benefits such as employment opportunities.

In his book *Bowling Alone: The Collapse and Revival of American Community*, Putnam argues that America's social capital is declining, and several negative consequences are associated with declining social capital. Expanding on Coleman's idea, Putnam defines social capital as civic engagement, such as participating in campaign activities, attending a public meeting on school affairs, or serving as an officer of some clubs or organizations. Putnam argues that social capital in the form of civic engagement improves health and well-being and suggests bringing civics education and extra extracurricular activities back to school.

Lin's Social Capital Theory

Lin argues that social networks and social relations are the root of all social capital theories and thus defines social capital as resources embedded in the social structure that can be accessed and mobilized by individuals as a purposive action. This theory emphasizes individual agency. Based on this definition, social capital has several elements including

- resources embedded in a social structure,
- accessibility (network location and resources), and
- mobilization (use of contacts).

Specifically, Lin states that within a social network structure, people hold different economic and political positions, and such a variation affects the embedded resources that can be accessed by an individual. Three hypotheses can be formed based on this theory:

- (1) individuals who can access the resources embedded in a social network and who are able to use these contacts have better well-being,
- (2) individuals who can use and mobilize are more likely to gain values from the network, and
- (3) accessibility and mobilization are positively associated with each other.

Individuals who have better access to resources can also mobilize network resources better.

Evidence is provided for each of the three hypotheses. Regarding accessibility to embedded resources, Ronald Burt has done extensive research on locations of social structure and shown theoretically and empirically individuals have differential accessibility to embedded resources depending on the location of the social network. For example, a manager belongs to several social networks. As such, this person has accessibility to different flows of information from both networks. This strategic location may lead to a promotion or other career advancement opportunities.

In terms of mobilizing resources, a classic example provided by Coleman is a mom who moved from Detroit to Jerusalem to provide a more safe environment for her children. The choice made by the mom mobilizes richer social capital by moving the family to a different city.

Final Thoughts

Despite various theories being proposed to explain social capital, there is a tendency to integrate these theories. At the root of all these theories is the concept of social network and social relationships. With its wide application in multiple fields, social capital theory, whether at an individual or a collective level, will likely continue to guide research and practice to result in individual and societal gains. Researchers have suggested the value of social capital as the property of both an individual and a community.

social desirability is often associated with self-report questionnaires; however, it can also affect any research based on behavioral observation. Researchers from many sciences, including psychology, business, public opinion, medicine, political science, sociology, and exercise science, must consider the potential effects of social desirability. Researchers have long studied the nature of social desirability, the factors affecting social desirability, its potential impact on research, and various methods for coping with the problem.

The Nature of Social Desirability

Seeming simple at first glance, social desirability has a rather complex nature. There are at least two important issues concerning the nature of social desirability. The first issue is its psychological content—the number and nature of the psychological dimensions likely to be affected by social desirability. Early research focused on a single psychological dimension—the need for approval from others—as the basis of social desirability. That is, early work focused on the general tendency to claim or demonstrate desirable characteristics and deny or conceal undesirable characteristics (i.e., to claim an uncommon degree of virtue and deny a common degree of vice). More recent work, most notably research conducted by Del Paulhus and his colleagues, has highlighted two dimensions of social desirability—an *egoistic* dimension reflecting the exaggeration of traits such as competence, dominance, and intelligence, and a *moralistic* dimension reflecting the exaggeration of traits such as friendliness, impulse control, and responsibility.

A second issue concerning the nature of social desirability is intentionality. Although socially desirable behavior is sometimes conscious and intentional, it also can be unconscious or unintentional. *Impression management* occurs when people intentionally exaggerate socially desirable qualities (or intentionally deny socially undesirable qualities). *Self-deception* occurs when people unintentionally exaggerate such qualities. That is, self-deception occurs when people truly but inaccurately believe that they have more desirable qualities than they actually have. This issue is closely related to a common terminological distinction between response sets and response styles. Although researchers are inconsistent in using these terms, a *response set* is a temporary tendency toward social desirability (e.g., impression management that occurs while completing a job application), and a *response style* is an enduring tendency for some people to respond in a socially desirable manner (e.g., a stable disposition for some people to view themselves in an overly positive light).

SOCIAL DESIRABILITY

Social desirability is the tendency for research participants to attempt to act in ways that make them seem desirable to other people. Such attempts to “look good to others” can compromise the validity of research, particularly research with participants who know they are being studied. Frequently viewed as a response bias,

What Produces Social Desirability

Several factors affect socially desirable behavior. First, some people might be predisposed toward socially desirable behavior. Such people are said to have a socially desirable response style, behaving in a socially desirable way in many kinds of research settings.

A second factor affecting social desirability is the behavioral characteristic being examined in a given study. That is, some behavioral characteristics are more likely to elicit socially desirable behavior than are others. For example, some traits, behaviors, or attitudes are particularly valued, stigmatized, or otherwise sensitive (e.g., mental health, racial attitudes, sexual practices, drug use, morality, and general psychological adjustment). When such characteristics are measured and/or observed, participants' responses are relatively likely to be affected by social desirability. For example, whether they are intentionally attempting to present an image consistent with common social norms or they are unintentionally failing to recognize their true nature, some people might claim racial tolerance when they are, in fact, racially intolerant.

A third factor affecting socially desirable responding is the observational context; socially desirable responding is more likely to occur in some measurement contexts than in others. Most simply, desirable responding is more likely to occur when people expect consequences from their responses than when they expect no consequences. For example, a person completing an integrity survey as part of a job application might be more likely to exaggerate his or her virtues than a person completing the same survey as an anonymous participant in a large research project. Interestingly, some observational contexts elicit socially *undesirable* responding rather than socially desirable responding—a phenomenon called *malinger*ing. Specifically, when people can benefit from being viewed as suffering from psychological, social, or physical deficiencies (e.g., when suing for cognitive impairment suffered during an accident), they might respond in a way that exaggerates these deficiencies or problems.

Impact of Social Desirability

Social desirability is often recognized as a bias that creates problems for research and for applied measurement. Most directly, social desirability can compromise the validity of scores on a measure. That is, if peoples' measured behaviors or responses are affected by social desirability, then those measurements are biased as indicators of their intended construct. For example, a researcher wishes to measure participants' self-esteem by using a self-report questionnaire. Ideally, people

who obtain high scores on the questionnaire would have high levels of self-esteem. However, if some participants have a socially desirable response style (e.g., an egoistic bias), then those people might respond to the questionnaire in a way that exaggerates their true level of self-esteem. Consequently, at least some high scores on the questionnaire reflect social desirability motivation rather than self-esteem; thus, the validity of the responses as indicators of self-esteem has been compromised. When a measure is associated significantly with social desirability, researchers sometimes say that the instrument is "contaminated" by social desirability.

Compromised measurement validity can have harmful effects on research. For example, social desirability bias might produce spuriously strong correlations, incorrectly indicating that two variables are more strongly associated with each other than they truly are. Again, imagine a researcher interested in self-esteem and its association with creativity. Furthermore, imagine that, in reality, the association between the two constructs is weak. Unfortunately, socially desirable response styles might produce a spuriously strong correlation between measures of the constructs. This arises from the combined effect of two factors. First, participants might differ in the tendency to respond in a socially desirable manner (i.e., some people have a socially desirable response style and some do not). Second, the two constructs might be affected by social desirability. That is, both self-esteem and creativity might be desirable qualities, eliciting overly positive responses from some participants but not others. The fact that people with a socially desirable response style would obtain inflated scores on *both* measures will produce a relatively strong correlation between the measures, not reflecting the truly weak association between self-esteem and creativity. Although the real correlation between the traits of self-esteem and creativity might be weak, social desirability bias can affect scores on measures of both constructs and inflate the correlation between the measures. Consequently, the researcher is likely to conclude mistakenly that self-esteem is strongly related to creativity.

Measurement validity that is compromised by social desirability can also have harmful effects in applied measurement. When decisions are even partially based on observations of behavior (including verbal behavior and self-report behavior), the quality of those decisions hinges on the validity of the observations. As a factor that might diminish measurement validity, social desirability can reduce the quality or accuracy of decisions. For example, hiring is a real-life decision that might be based partly on some form of behavioral observation (e.g., interview and personality tests). Consequently, if

applicants engage in substantially biased impression management, then hiring decisions might result in the employment of relatively less-qualified applicants.

Coping With Social Desirability

In attempting to cope with potential problems introduced by social desirability, researchers have developed strategies targeting two main goals. First are strategies designed to prevent or minimize the occurrence of socially desirable responding. Among these are strategies for managing the content of psychological surveys and questionnaires. For example, researchers can use relatively neutral or “unloaded” phrasings for questionnaire items—an item like “I am very irresponsible” might be rephrased to “Sometimes, I am not as responsible as other people,” which is a less undesirable (i.e., less evaluatively loaded) phrasing that people might be more willing to endorse. In managing test content, researchers can also use a forced-choice format, in which participants are presented with two equally desirable (or undesirable) characteristics (e.g., “responsible” and “creative”) and must choose the one that is more descriptive of themselves. Although some research suggests that this is not a fully effective method for controlling impression management, a forced-choice format is often believed to minimize social desirability. Also among the strategies for preventing or minimizing the existence of bias are methods of managing the testing context. As mentioned earlier, facets of the testing context can affect the occurrence of socially desirable behavior; thus, researchers can emphasize participants’ anonymity when possible, or they can warn participants that inaccurate or deceptive behavior can be detected in some way (whether such detections can be made or not).

A second set of strategies has been developed to detect the existence of biased responding and intervene in some way. Several such approaches have been developed, but the most common is the use of self-report scales intended to detect socially desirable responding. For example, some wide-ranging, multidimensional inventories such as the well-known Minnesota Multiphasic Personality Inventory include “validity” scales intended to detect various forms of response bias. Similarly, specialized questionnaires, such as the Marlowe-Crowne Social Desirability Scale and the Brief Inventory of Desirable Responding (BIDR), have been developed as stand-alone inventories that can be used as part of larger projects in which researchers are concerned about social desirability. Such scales often include items reflecting qualities so rare (e.g., “I have never told a lie”) that few people could legitimately endorse them. Participants who endorse many such items are assumed

to be presenting an inaccurately positive image of themselves.

After socially desirable behavior has been detected, researchers can intervene in some way. For example, researchers might omit data from participants who have provided questionable responses, as indicated by their scores on a measure of socially desirable responding. That is, analyses can proceed without data that are potentially biased. Alternatively, researchers might statistically control for scores on a social desirability scale. Statistical procedures such as partial correlation or multiple regression could be used in this way. For example, a researcher might compute the partial correlation between self-esteem scores and creativity scores, controlling for scores on the BIDR. Such procedures statistically account for the fact that some people might have responded with a socially desirable response style.

Bias Versus Substance

A final important issue is whether social desirability reflects inaccuracy/bias or valid responding. The typical perspective is that social desirability is a source of error, bias, or contamination compromising the quality of social and behavioral research. However, some researchers maintain a different perspective, offering various arguments that social desirability has some legitimately substantive psychological meaning. For example, some researchers have found that statistically correcting for the potential bias caused by social desirability does *not* affect the association between personality trait scores and criteria such as trait ratings from well-acquainted informants. Similarly, some research suggests that people who obtain high scores on measures of social desirability are actually viewed by others in desirable ways (e.g., they are recognized as relatively well-adjusted). Such findings suggest that high scores on measures of social desirability reflect, to some degree, validly desirable personality characteristics.

Despite such emerging evidence, most researchers still view social desirability as a source of error, bias, and invalidity in research. After decades of concern over social desirability and after decades of empirical research regarding the existence and potential effects of social desirability, our understanding of the nature, impact, and control of social desirability continues to evolve.

SOCIAL NETWORK ANALYSIS

Social network analysis studies social relations, structures, and networks between various social entities such as individuals, groups or teams, parties, and organizations. It relates to the core issues in research design as social network analysis has a collection of innovative methods in questionnaire designs, sampling techniques, and analytical methods.

Social network analysis is premised on three main pillars: theory, methods, and applications. In theory, social network analysis is central to Mark Granovetter's (1985) classical piece on social embeddedness and economic actions. Social network analysis also contains three main theoretical assumptions that critically challenge the traditional egoistic view of individual behavioral analysis, inspiring many studies that adopted the relational and structural paradigm in their analyses. In methods, social network analysis has been benefiting greatly from its multidisciplinary roots, achieving interdisciplinary synergy that involves social sciences and science, technology, engineering, and mathematics (STEM) fields. In applications, social network analysis stimulates many studies in disciplines that traditionally build on individualistic and egoistic approaches.

This entry discusses details of social network analysis in the domains of theory, methods, and applications. In particular, the theory section describes three key theoretical assumptions in social network analysis. The

methods section starts with a typology of the four types of social networks, describing each type in detail and providing a real-life example to each. The section then moves to describe four analytical methods—centrality, density, centralization, and structural equivalence in social network analysis—focusing on their substantive interpretations. The methods section uses graphs and tables to illustrate basic structures of various social networks. The section on applications of social network analysis describes the history and development of social network analysis in sociology. It then moves to discuss the applications of social network analysis methods and perspectives in the fields of work, organization studies, criminology public health, and political sciences.

Theories

Many scholars perceive social network analysis as a collection of mathematic methods that are applied to analyzing various social topics. However, such perception is far from the truth. Since its inception, social network analysts consider networks themselves as important social structures and institutions that demand serious investigations. For example, a simple summation of parts does not predict the system outcome at the network level and the network outcome cannot be due to a simple aggregation of individual contributions. A group of talented physicians does not produce fruitful outcomes if they are isolated from each other and do not work well together. Conversely, a research team that produces many innovations and patents may not comprise individuals who are all geniuses.

Granovetter's (1985) classical piece on social embeddedness and economic actions laid the foundation for neoclassic socioeconomics. To start, he criticized the undersocialized view of human behavior by economists, and surprisingly, he also disapproved of the oversocialized view of sociologists. To overcome the over- and undersocialized views, he advocated for social network analysis, which accounts for one's social networks in explaining his or her economic actions. Knoke and Yang (2020) further elaborated the three theoretical assumptions propagated in social network analysis.

First, structural relations are often more important for understanding observed behaviors than are individual attributes such as gender, race, age, education, income, and occupations. For example, political analysts have long observed that gender, race, age, and one's socioeconomic status affects whom they vote for president. However, one's social networks may also have an impact on one's voting behaviors (people vote

for whomever their friends and families voted for); such peer influence effects are particularly pronounced among undecided voters, as the number of undecided voters has been increasing in recent years. By shifting the analytical focus from thing-concept to structural relations and social networks, social network scholars offer distinctive theoretical and empirical explanations of the origins of social action.

Second, social networks affect an individual's perceptions, beliefs, and actions through diverse structural mechanisms. The famous social network analysis of the strength of network ties and job search (later dubbed as the strength of weak ties) reveals that contrary to popular beliefs, job seekers benefit from diverse information passed along from their weak-tie contacts more than from their strong-tie buddies. Along the same line, the more the structural holes in one's social networks, the more the information and control benefits being afforded to the network actors in terms of getting early promotion and big pay raise. Structural holes are the gaps or disconnections between two individuals or between multiple clusters of individuals or collective entities. However, those benefits to one's job search and career advancement of weak-tie contacts and structural hole networks only materialize to certain gender, occupational groups, and within a certain national context. For example, weak-tie benefits only accrue to job seekers of managerial, professional, and technical jobs and within the U.S. job market. In other societies, such as China, strong ties matter for job seekers. Likewise, structural holes afford information and control benefits that facilitate early promotion and big raise, but it only occurs to men. For women, having social cohesive groups, the opposite of structure holes helps with their career advancement. A chief reason for this is that women need to bond collectively against gender discrimination to break the glass ceiling.

Third, the structural mechanism that sustains a network is dynamic, changing, and evolving out of its components or constituents' purposive or unpurposive actions. Marriage between two lovers is the result of the natural progression of their love relationship. However, marriage can also dissolve into divorce due to irreconcilable disagreements between spouses. A pair of organizations entering strategic alliance commonly adopts a contractual form of governance at first. Those contractual forms overlaid with legal terms only give way to more relaxing mutual understanding as successful partnership progresses. Such dynamics in network forms and developments afford both challenges and rewards for network scholars trying to understand those network processes that are independent of the actions of the individual entities.

Methods

Before discussing various methods, this section first describes basic concepts in social network analysis and a typology of different social networks. First, a network contains nodes (also called *social actors* or *social entities*), lines (also called *ties*, *connections*, or *relations*) connecting those nodes, and values attached to the lines. Outside of social science disciplines, particularly in STEM fields, a network is called a *graph*, which contains vertices (nodes), edges (lines), and weights (values attached to the lines). A social network is a network structure comprising a set of nodes linked together with one or more social relations. Real-life examples of social networks abound, from children's friendship network where boys befriend boys and girls befriend girls to a group of coworkers where colleagues befriend, consult, conspire, or even backstab each other.

Social networks have two very important distinctions: the values that are attached to the relations and the directions of the relations. Many social relations do not have direction specifying the sender and receiver of those relations. For example, in a marriage network, a marriage pair does not need to specify the direction of the marriage (Jack is married to Mary, so Mary is married to Jack). But for some other networks, directions of the relations between social actors are important, such as a communication network.

Another important distinction to social networks is the values attached to the lines, often indicating the intensity of the relations or ties. To some networks, the binary indication (present/absence) of the relations is fairly sufficient, such as marriage networks between families or diplomatic ties between nations. However, for other types of networks, values are important dimensions to specify the intensity of the ties, such as communication network between classmates or trade volumes between nations. With cross-tabulation of the two distinctions—values to the ties and direction to the ties—social networks can be categorized into four different types, which are shown in Table 1. Those networks are (1) binary and undirected networks (Type I), (2) binary and directed networks (Type II), (3) valued and undirected networks (Type III), and (4) valued and directed networks (Type IV).

Figure 1 shows an artificial network of friendship between six coworkers in an organization. The presence of a line between a pair of workers indicates the friendship between the pair. Conversely, the absence of a tie indicates an absence of a friendship. Note that the lines do not have values attached to them or carry a direction to them: James is a friend of Mary, so Mary is also a friend of James. Such a network with a simple dichotomous value (0/1) and without direction in its lines is called *binary undirected network*.

Table 1 Typology of Social Networks

Values to the ties	Directions to the ties	
	Undirected	Directed
Binary	Binary and undirected networks (I)	Binary and directed networks (II)
Valued	Valued and undirected networks (III)	Valued and directed networks (IV)

**Figure 1** An Artificial Social Network of Friendship Among Six Coworkers

If we conceive these relationships between the same set of six coworkers as reporting networks, this network will become binary and directed network (Type II in Table 1). For example, for the reporting schema, James reports to Mary, while receiving reports from Linda, Susan, and Mike. In addition to James, Mary receives reports from Susan and Mike. While Linda reports to James and Susan, she receives report from John. Susan reports to Mary and James, while receiving report from Linda. Mike reports to John, James, and Mary. John reports to Linda, receiving report from Mike. Figure 2 illustrates such a network.

Valued undirected networks (Type III in Table 1) have real-life counterparts in friendship networks, but with relationship intensity specified. For example, using the same set of six coworkers and their friendship network, we can add the values attached to their ties to indicate the closeness or intensity of the friendships, such as 1 = acquaintances, 2 = friends, and 3 = confidants. Figure 3 shows such a relationship network. Two pairs (between James and Mary, and between Susan and Linda) have confidant relationship. Other

**Figure 2** An Artificial Social Network of Reporting Among Six Coworkers**Figure 3** An Artificial Social Network of Friendship Intensity Among Six Coworkers

dyadic relationships have lower intensity or closeness than those two pairs.

Figure 4 depicts the most complicated social networks, the directed and valued networks (Type IV in Table 1). It shows a message exchange network between six coworkers. While James sends five messages to Mary, Mary does not send any message back to James. In fact, Mary does not send any message to anybody in this network. Linda sends one message to James and two messages to Susan. Susan sends two messages to James and three messages to Mary. Mike sends one message to John, two messages to James, and one message to Mary. John sends two messages to Linda. Two outstanding features appear in this network:

- (1) *The relational direction matters.* A tie from Node A to Node B may not be reciprocated from Node B

Figure 4 An Artificial Social Network of Message Exchanges Among Six Coworkers

back to Node A: James sends lots of messages to Mary, but Mary does not send any to James.

- (2) *Intensity matters.* Rather than the mere presence or absence of the directed relations, the network emphasizes the intensity of those relationships. James sends Mary five messages, while receiving one message from Linda, two messages from Susan, and two messages from Mike.

Although visual illustrations such as Figures 1–4 greatly facilitate the communications with audiences, they do not allow for computing processes, which would normally require a matrix input. Commercial software for social network analysis such as UCINET, R, or STATA may have different formats for data input; however, the most common form is the matrix representation. For example, Table 2 shows a matrix representing Figure 1: the binary undirected graph among six coworkers. Several features of this matrix are worth noting:

- (1) It is called *binary adjacency matrix* because it contains only binary value (1/0) to indicate the presence or absence of a tie; it is called *adjacency matrix* because it indicates only the direct connection, it does not reveal indirect connections.
- (2) It is a squared matrix because the number of rows equals the number of columns, and the entering sequence of row and column are identical: James, Mary, Linda . . . in the column from left to right, and James, Mary, Linda . . . in the rows from top to bottom.
- (3) The entry of the row (i) and column (j) indicates the direct connection between the row and the column (e.g., $X_{ij} = 1$; whereby $i = \text{James}$ and $j = \text{Mary}$).
- (4) The diagonal values are all 0 because a person will not have a relationship with themselves ($X_{ii} = 0$ when $i = j$).
- (5) Because this is an undirected network, the connection between i and j equals the connection between j and i ($X_{ij} = X_{ji}$; $i \neq j$). For example, the connection between James (Row) and John (Column) equals the connection between John (Row) and James (Column), which is 0 ($X_{\text{James}, \text{John}} = X_{\text{John}, \text{James}} = 0$).

Table 3 shows the binary adjacency matrix for Figure 2. Tables 2 and 3 are the same except for the relationships in Table 3 being directed. In particular, the rows in Table 3 are the senders of the relationship, whereas the columns are the receivers. For example, James reports to Mary ($X_{\text{James}, \text{Mary}} = 1$), whereas Mary does not report to James ($X_{\text{Mary}, \text{James}} = 0$). Such distinction between senders and receivers in a relationship does not exist in Table 2. It is for this reason that Table 2 (also Figure 1) is often called *symmetric network*, and Table 3 (also Figure 2) is called *asymmetric network*.

Table 4 is the valued adjacency matrix that represents Figure 3. Table 4 resembles Table 2, with one

Table 2 The Binary Adjacency Matrix Representing Figure 1

	James	Mary	Linda	Susan	Mike	John	Row Margins
James	0	1	1	1	1	0	4
Mary	1	0	0	1	1	0	3
Linda	1	0	0	1	0	1	3
Susan	1	1	1	0	0	0	3
Mike	1	1	0	0	0	1	3
John	0	0	1	0	1	0	2
Column Margins	4	3	3	3	3	2	

noticeable exception: the values in the matrix of Table 4 are not binary. For example, while James and Mary have friendship with intensity at 3, the friendship between James and Linda has an intensity of 1. Such variation in values in network ties reflects the fact that relationships vary depending on their intensity or closeness, which is more than a mere presence or absence of a tie. Note that Table 4 as well as Figure 3 relationships are undirected network ($X_{ij} = X_{ji}; i \neq j$). For example, $X_{\text{James}, \text{Mary}} = X_{\text{Mary}, \text{James}} = 3$.

Table 5 is the valued adjacency matrix that represents Figure 4. Table 5 resembles Table 3, except that the values in the matrix of Table 5 are not binary but rather valued. For example, Susan sends two messages

to James but three messages to Mary. In addition, Table 5 or Figure 4 is also a directed network, meaning that $X_{ij} \neq X_{ji}; i \neq j$. Such directed and valued graphs are the most difficult to analyze, but many real-life situations are demanding methodological advancement to address the analytic needs of those graphs.

The next sections discuss a few basic methods in social network analysis. Table 6 presents a list of some well-known methods, the level of their measurements, the type of network they can be used for, and the genre of those methods. Note that this is not an exhaustive list because it does not contain those methods measuring distances between dyads (e.g., shortest path, random walk, community detection) or newly emerged

Table 3 The Binary Adjacency Matrix Representing Figure 2

	<i>James</i>	<i>Mary</i>	<i>Linda</i>	<i>Susan</i>	<i>Mike</i>	<i>John</i>
James	0	1	0	0	0	0
Mary	0	0	0	0	0	0
Linda	1	0	0	1	0	0
Susan	1	1	0	0	0	0
Mike	1	1	0	0	0	1
John	0	0	1	0	0	0

Table 4 The Valued Adjacency Matrix Representing Figure 3

	<i>James</i>	<i>Mary</i>	<i>Linda</i>	<i>Susan</i>	<i>Mike</i>	<i>John</i>
James	0	3	1	1	1	0
Mary	3	0	0	2	1	0
Linda	1	0	0	3	0	2
Susan	1	2	3	0	0	0
Mike	1	1	0	0	0	2
John	0	0	2	0	2	0

Table 5 The Valued Adjacency Matrix Representing Figure 4

	<i>James</i>	<i>Mary</i>	<i>Linda</i>	<i>Susan</i>	<i>Mike</i>	<i>John</i>
James	0	5	0	0	0	0
Mary	0	0	0	0	0	0
Linda	1	0	0	2	0	0
Susan	2	3	0	0	0	0
Mike	2	1	0	0	0	1
John	0	0	2	0	0	0

Table 6 Analytical Methods in Social Network Analysis

<i>Measures</i>	<i>Levels of measurement</i>	<i>Genre of methods</i>
Centrality	Node/actor/vertex	Descriptive
Centralization	Graph/network	Descriptive
Density	Graph/network	Descriptive
Structural equivalence	Dyadic pairs	Descriptive
Cliques	Subgroup	Descriptive
Dendrograms	Subgroup/whole network	Descriptive/visualization
Multi-dimensional scaling (MDS)	Subgroup/whole network	Descriptive/visualization
QAP	Graph/network	Explanatory
ERGM	Graph/network	Explanatory

methods (e.g., modularity, random graphs). Perhaps the most commonly used methods in Table 6 are the first four: centrality, centralization, density, and structural equivalence. The following paragraphs focus on those four measurements, assuming the binary undirected networks as the input data for simplicity.

Degree centrality of a given node i in binary undirected graphs is simply the summation of lines incident to the node. In Table 2, the row margins or the column margins of the nodes are the degree centralities of the nodes. This is because in an undirected network, the column margin always equals the row margin for each node. Degree centrality reflects the extent to which a given actor i is connected with other actors in a network, with the high centrality indicating high connectivity with other network actors. For example, Table 2 shows that James has the highest connectivity with other actors, whereas John has the lowest connectivity.

While centrality measures the connectivity of each individual node in a network, centralization is an indicator reflecting the differentials in degree centrality among nodes in a network. Centralization is a network-level measurement, as opposed to centrality, which is a node-level measurement. Network centralization ranges from 0 to 1, with 0 indicating complete equality in degree centrality among nodes and 1 indicating complete unequal or extreme hierarchy in degree centrality among all the nodes. In real-life examples, one can picture a classroom environment where the teacher commands all lecturing, leaving little room for students to interact with each other. In stark contrast, a teacher can organize many group discussions, partitioning students into study groups, and encourage discussions or problem-solving within each group. In the former situation, the centralization measure of the classroom interaction network would approach 1,

while in the latter situation, the centralization would approximate 0.

Network density is another important barometer reflecting the connectivity at the entire network level. Its computation involves dividing the actual dyadic pairs by the total mathematical maximum number of dyadic pairs between N actors in a given network. With that, it ranges from 0 to 1, with network densities close to 0 indicating isolations between actors in a network, and network densities close to 1 suggesting a great level of dyadic connections between network actors.

The last important network measurement introduced here is the structural equivalence, which operates at dyadic level. Structural equivalence measures to what extent a given dyadic pair (e.g., Actors A and B) in a given network are in structurally equivalent positions. Real-life examples of structural equivalence include two professors advising the same set of students on their research theses or two students being advised by the same professor. The nodes or actors in a network do not have to be individual persons, they can be aggregated entities. For example, two vendors furnishing the same goods to the same retailer would be in structural equivalence. Structural equivalence often reveals social and economic competition or political rivalry rather than social cohesion or harmony. For example, two job seekers for the same job often find themselves in a fierce competition to gain favoritism from their potential employer.

Applications

Equipped with a sound theoretical perspective and a set of well-defined methodologies, social network analysis affords a powerful analytical lens to various social science disciplines. Beyond sociology, study fields such as

criminology, public health, management science, economics, political science, and even psychology fruitfully apply social network analysis to advance their respective research topics. The following paragraphs offer a brief history of social network analysis in its origin discipline—sociology—followed by a concise introduction of its applications in several disciplines.

Social network viewpoint has a long tradition in sociology that studies social relations, social roles, and social interactions. In the late 19th century, founding figures of sociology such as Georg Simmel, Emile Durkheim, and Max Weber advocated for a structural view in explaining human behaviors. In the 1930s, psychiatrist Jacob Moreno focused on how individuals' well-being is linked to their relations with other individuals. Working with Helen Jennings, Moreno developed *sociometry* to provide a visual illustration of social network structure between individuals. Later, they founded a journal called *Sociometry* to publish articles examining social networks and their consequences on human behaviors and psychological states. During the 1970s, Harvard University-trained Edward Laumann educated a group of prominent social network scholars, such as Ronald Burt, Peter Marsden, David Knoke, and Joe Galaskiewicz, during his tenure with the University of Michigan. In addition, Harrison White at Harvard was conducting social network analysis, advising many brilliant social network scholars such as Peter Bearman, Philip Bonacich, Ronald Breiger, Kathleen Carley, Bonnie Erickson, Claude Fisher, Mark Granovetter, and Berry Wellman.

During the 1980s, Nan Lin at SUNY Albany fruitfully applied social network perspective to analyze labor market outcomes. He later developed positional generator measurement that captures the social resources flowing in individuals' social networks. Continuing in this line of work, Yanjie Bian at Minnesota Sociology reexamined the issue of social ties and job search in the Chinese labor market, finding strong ties, not weak ties, matter in China for a successful job search. More recently, University of California, Irvine (UCI) has become the epicenter of social network analysis. Thanks to efforts from Linton Freeman, the UCI School of Social Sciences developed a PhD concentration in social network analysis. Many mathematicians in social network analysis graduated from the program, such as Stephen Borgatti, Martin Everett, Tom A.B. Snijders, Stanley Wasserman, and Philippa Pattison. International researcher Wenhong Zhang from Shanghai University also visited the school and has become one of the catalysts in the development of social network analysis in China.

Social network analysis has long roots in facilitating studies of work, labor market, and organizations. For

example, social network analysis reveals the commonly held belief that to secure a successful job search, it is not only who the candidates are, but also who they know that matters. Furthermore, the ties that connect job candidates and their helpers also matter in landing a job. While strong-tie friends produce emotional supports, weak-tie contacts are the ones who really help the candidates because they provide fresh nonredundant information of job opportunities. To obtain early promotion or sizable pay raises, employees need to establish social connections with a variety of different clusters of coworkers. They then can reap the information and control benefits afforded by their social networks to advance their career trajectories. Organizations, being the collective entities, also engage in network relations to advance their strategic interests. For example, organizations commonly form partnerships to tap into new markets, to jointly develop new technology, or to deal with governmental regulations.

Social network analysis has been fruitfully applied to study criminology topics, deciphering terrorism networks, and understanding public health risks such as the spread of sexually transmitted diseases. Recently, political scientists applied social network analysis to better understand voting, the passage of legislature bills, presidential campaigns, and congress lobbying. While social network analysis facilitates studies of substantive issues in diverse social science disciplines, development in graph theory in mathematics and computer engineering also advances social network analysis from descriptive measurements to explanatory modeling. Exciting developments in big data of computer sciences provide social network scholars with an opportunity to delve into online social media networks, being able to scrape, store, and analyze large social media network data.

SOCIAL NETWORK ANALYSIS: METHODS AND APPLICATIONS

The book *Social Network Analysis: Methods and Applications* by Stanley Wasserman and Katherine Faust provides a broad perspective on the topic of social network analysis (SNA). It features detailed discussions about a variety of concepts related to research design within SNA. In this entry, the overall direction and theme of the book are being presented, followed by the structure and main lines of the discussions.

Overall Direction and Theme

The book *Social Network Analysis: Methods and Applications* is classic in the field of SNA. It introduces and deliberates various concepts that are still imperative for conducting state-of-the-art social network research. The book may serve as a textbook, as it encompasses a number of interesting examples as well as data sets (which are presented in Part 1 and Appendix B). At the same time, this book can be useful for reference purposes, as it follows a clear and systematic sequence of topics. Furthermore, it is not written for a specific academic discipline; rather, it is broad and abstract enough to be useful for a wide audience.

That said, it is worth noting that the field of SNA has made tremendous advancements since the book by Wasserman and Faust was first published in 1994. A plethora of new research avenues have opened since then. Also, new concepts have emerged, and new technologies are assisting researchers in conducting SNA. Still, the book is a relatively complete source when it comes to explaining the basics of SNA.

Structure of the Book

The book is made up of six main parts and a short epilogue. The first part focuses on networks, relations, and structure. It positions SNA in the broader, interdisciplinary research context and introduces basic network concepts such as nodes and ties. It also features a reading guide that helps the reader in finding his or her way through this volume. Importantly, this first part also elaborates the nature of data for SNA, which introduces varieties of SNA about which a researcher needs to be aware. To facilitate working through the example of the book, data sets are also provided and described by the authors in this part.

Part 2, which deals with (mathematical) representations of social networks, further elaborates the topic of data. The reader learns how relational data can be structured and stored in a data set. Furthermore, the algebraic

notation that is used throughout the book is introduced here. In the second chapter of this part, Wasserman and Faust introduce a long list of SNA concepts that form the basis for much of the rest of the book. For example, graphs and parts of graphs (e.g., dyads, triads, walks) are defined and illustrated. Further elaborating the structure of SNA data from before, this part also introduces basic matrix operations that are needed to do SNA. This part is essential to make sense of the rest of the book. As mentioned earlier, the book does not target a specific discipline, so the terms often remain quite abstract. Reading this part, however, helps to make them adequately clear and to establish a sound basis for comprehending more complex network concepts.

The third part of the book introduces structural and locational characteristics of networks. This part features four chapters, each of which discusses a prominent strand of social network research: centrality and prestige, structural balance and transitivity, cohesive subgroups, and affiliations. This part may serve as a useful reference to comprehend current SNA work, as many of the concepts listed here now belong to the common body of knowledge in the field of SNA (e.g., the diverse conceptualizations of centrality).

Part 4 introduces a different flavor of SNA that is not derived from graph theory (which was briefly introduced in Part 2). This part on roles and positions introduces the concept of structural equivalence, which was later developed into the approach of blockmodeling (which is also covered in this part). Wasserman and Faust have also discussed relational algebra, which is necessary to understand both structural equivalence and blockmodeling. Lastly, following the development of the broader literature in SNA, they have concluded this part by introducing generalizations of structural equivalence, for instance, by discussing regular equivalence.

Part 5 revisits two major SNA concepts that had been mentioned in Part 2 (both in the book and in this entry): dyads and triads. The basic toolbox for analyzing these structures via dyad and triad censuses has been introduced here. Following this theme of analysis, Part 6 then ventures into statistical models for the analysis of social networks. The book ends with an epilogue that speculates about future directions of social network research. Appendix A lists software packages for SNA, although the list may now be quite dated.

In sum, *Social Network Analysis: Methods and Applications* discusses a wide variety of concepts for research designs that include relational or structural features. With the increased usage of social network research designs since the 1990s, this book became an important reference point and structured the ensuing academic discourse.

SOCIAL NETWORK ANALYSIS SOFTWARE PACKAGES

Social network analysis (SNA) has been gaining momentum since the beginning of the 21st century in many fields, including sociology, economics, anthropology, educational research and other fields, and more recently, in pedagogical practice. Advances in computer technology and software applications have been a driving factor for this growth. This entry presents two SNA software packages, one designed for researchers and one geared toward educators and practitioners. The first package, UCINET, developed in 2002 by Lin Freeman, Martin Everett, and Steve Borgatti, is a software package for the analysis of social network data. According to its developers, it comes with the NetDraw network visualization tool, which enables graph visualizations. The second package is a web-based software application, called the SNA Toolkit, which is specifically designed with educators in mind, in order to allow them to explore the social dynamics and analyze social network data within their classrooms.

Before delving into the specifics of each package, this entry briefly discusses the importance of social relationships and systematic data collection for researchers and practitioners, as both software packages enable systematic data collection to study social relationships from a social network perspective. Although SNA can be used in a variety of fields, this entry discusses it primarily in the context of educational research and practice. UCINET in specific offers a wider range of tools that can be used by researchers in many other fields, beyond educational research.

Importance of Social Relationships

Classrooms are one of the main sources of socialization for students. Strong and positive social relationships and community are beneficial to everyone in the classroom. Positive social relationships empower students and make them feel more involved. Students experience a more enhanced sense of belonging if they interact with their peers consistently. Peer social relationships also lead to better academic performance. Positive social interaction can also help students feel welcomed in the classroom, especially traditionally marginalized and underserved students, such as students with disabilities. For example, even though students with autism spectrum disorder may lack certain social skills to make friends, constant training and peer interaction can improve their academic and social inclusion. Overall, social relationships are beneficial for all students in their academic and social life in classrooms. Therefore, collecting systematic data about the social position of students within their classroom social networks is highly important, both from a research and pedagogical perspective. SNA software packages provide a set of tools to do so.

Importance of Systematic Data Collection

Systematic data collection plays a big role in many fields, including education. When designing new policies or making instructional changes, schools typically analyze data to do so. As schools and classrooms become more diverse, systematic data collection ensures that every voice is heard. When using systematic data collection, teachers analyze the performance of students beyond mere test scores. This process allows teachers to get a more comprehensive understanding of each student's strengths and challenges. It helps the teachers to teach more effectively. With the data, they know what to emphasize, what to reteach, and how to split students in groups more efficiently. With systematic social network data collection and analysis, educators and researchers can inform teaching and school policy, respectively, and generate a more socially responsive classroom and school community. The remainder of this entry discusses UCINET and the SNA Toolkit, as two software packages that enable researchers and educators, respectively, to systematically collect and analyze social network data.

UCINET

UCINET requires training and prerequisite knowledge on SNA methods and procedures, so seems to be aimed at researchers rather than practitioners. According to its developers, UCINET provides a comprehensive

package for social network data analysis, as well as other one-mode and two-mode data. According to its founders, the UCINET software package can read and write differently formatted text files, as well as Microsoft Excel files, and can handle a maximum of around 32,000 nodes, although practically speaking many procedures become slow around 5,000–10,000 nodes. SNA methods that researchers may perform with the package include centrality measures, subgroup identification, role analysis, elementary graph theory, and permutation-based statistical analysis. In addition, UCINET has strong matrix analysis routines, such as matrix algebra and multivariate statistics. A powerful feature of UCINET is the integrated NetDraw program for drawing diagrams of social networks. To use UCINET, a full program installation is required on one's computer. According to the current information on UCINET's website, the program may be downloaded and used free for 60 days. For longer use, fees apply.

There are two main sources for training on how to use UCINET. The first is a book by Stephen Borgatti, Martin Everett, and Jeffrey Johnson titled *Analyzing Social Networks*, in which all data sets mentioned are analyzed within UCINET. The second source is a 2019 publication by Christoforos Mamas titled *Learn to Conduct Descriptive Whole Social Network Analysis Within an Educational Setting in UCINET With Data From the Inclusive Education Project (2015–2018)*. This brief guide provides step-by-step instructions on how to use UCINET to complete descriptive whole SNA.

The SNA Toolkit

The SNA Toolkit is a web-based software application that does not require installation on one's computer. The SNA Toolkit was designed and developed for educators and no prior SNA knowledge is required. A simple sign-up to the website gives free individual access to the Toolkit. Once a user has signed up, they can then use their credentials to log in into the Dashboard. The Dashboard is where users can "create" their class by adding their students, create a survey by asking relational (weighted and nonweighted) and demographic questions, and generate a link to the survey to send to their students for completion. Upon students completing the survey, the teacher has instant access to the results. The Toolkit is programmed, based on the results, to generate two reports: a classroom report and an individual student report. In the classroom report, a graph visualization for each relational question is included as well as a number of descriptive SNA metrics, such as density, average in-degree and out-degree centrality, and reciprocity. In the individual student

report, a graph visualization of the student's ego-network is generated as well as a number of metrics, such as in- and out-degree centrality.

On the Toolkit, a question bank is also offered to educators. At the moment, two weighted questions (Who are your friends in the classroom? and Who do you play with during recess?) are offered. Students are given a list of their classmates, which the teacher preloads onto the survey, and they get to select their friends or recess partners. Upon selecting a classmate, the system generates the weight given to these two questions, which the teacher can define. For example, the default weight given to the friendship question is: very good friend, good friend, sort of a friend. For the recess question, the three options given are: every day, once/twice a week, once/twice a month. The two non-weighted questions that are offered to educators are (1) Who do you ask for help on school work? and (2) Who do you talk to when you are having a bad day at school? In this case, the survey respondent only has to select any one of their classmates. In all questions, students are free to select as many classmates as they wish or even none. The network is bounded to the classroom, which means the students may not select any peers from outside their classroom. This is a potential disadvantage of bounded SNA but the teacher may add an additional open-ended question for students to add any contacts outside of their classroom.

To the best degree possible, simple language is used within the Toolkit's interface, so that educators can easily navigate through the dashboard and the reports. At the moment, the language of the interface is English. The metrics are all described without the use of jargon. For example, classroom network density is defined as the percentage of the total number of actual connections out of the number of all possible connections. If we imagine that there are 100 possible connections in a classroom of x number of students, density represents the actual number of those connections. So, if 20 connections exist out of a 100, the density of the network would be 20%. Similarly, the average degree centrality is the average number of connections within the classroom. For example, in one classroom of 30 students, on average, students may have six friends, which would mean that the average degree centrality would be 6. In-degree centrality shows how many individuals nominations each student received. For example, if the friendship in-degree centrality of a student is 5 that means that five classmates selected that student as their friend. The friendship out-degree centrality shows the number of nominations sent out by one individual student. For example, if a student selects seven classmates as their friend, their out-degree centrality would be 7.

Table 1 Characteristics of UCINET and the SNA Toolkit

	UCINET	SNA Toolkit
Target user audience	Researchers	Educators
Knowledge level	SNA knowledge required	SNA knowledge not required
Software installation	Required	Not required
Functions	Extensive number of nodes	Limited number of nodes
Data visualization tool	Yes	Yes
Cost	Free for 60 days	Individual use free

In sum, each SNA term used within the student and classroom reports is explained in simple language.

Comparison of Characteristics

Table 1 provides a comparative overview of the characteristics of each package. Users may decide that one or both are best for their work.

Both SNA software packages provide the necessary tools for social network data analysis. UCINET provides a more complete set of tools that can be employed by researchers to conduct descriptive and inferential SNA. The SNA Toolkit is a more basic web-based software package that is tailored for educators and classrooms or schools. There is some degree of flexibility to it, but most functions are predetermined in order to enable educators to systematically collect social network data to understand the social dynamics within their classrooms and inform their everyday instructional decisions. Both UCINET and the SNA Toolkit are periodically updated with new versions and new tools.

SOCIAL SUPPORT THEORY

Regarding the definition of social support, little consensus exists among researchers and theorists. Social support is characterized by the structure of interpersonal relationships, such as size, reciprocity, and accessibility. It also refers to functions served by the members in one's social network. Despite the variability in definitions, one commonality is that social support requires the existence of social relationships, which provides resources such as emotional or information support. Understanding various tenets of social support may help researchers to identify important research questions and appropriate research methods to address these questions.

Despite differences in defining the concept, studies across disciplines, including education, health, and psychology, have shown that social support buffers the negative impacts of life stress and promotes well-being. In fact, results from the World Happiness Report in 2016 show that social support, income, and healthy life expectancy are the three predictors associated with subject well-being. This entry focuses on three ways social support has been conceptualized: (1) interpersonal relationship (or social connectedness), (2) the individual's perception of being supported, and (3) functions of social support. The following sections describes research under each string of social support theory.

Social Support as Interpersonal Relationship

Theorists and researchers who study social support as interpersonal relationships focus on the structure of one's social network. This line of research builds on the assumption that features of social networks are associated with the quality of social support one receives. Various features of social networks have been studied, including social network density, size, and diversity. One example is the network characteristics of individuals with intellectual and developmental disabilities (IDD). Researchers have found that people with IDD have a narrow social network, which mainly consists of paid staff and family members. However, research has also shown that network characteristics are not always related to positive outcomes. For example, studying a group of individuals with diabetes who try to lose weight, researchers have found that for women, network size is not related to weight loss. Women with an extensive support network are less likely to attend clinic sessions or complete their homework assignments. For men, network size is positively correlated with weight gain. One speculation is that women who have large social network may have more obligations to family and friends. These findings point out another line of theoretical inquiry on social support, as described in the next section, that emphasizes the difference between perceived support and network characteristics.

Perceived Social Support

Findings on the negative correlation between network size and health outcomes prompt further investigation on the perceived social support (also referred to as *social support satisfaction*). Different from social support theory emphasizing social network, social support satisfaction refers to the degree to which an individual is satisfied with supports received from one's network. The assumption behind this line of research is that it is essential to distinguish between support given to someone and that person's perception of the support provided. Consider the case of teacher–student relationships. A high school student may have several teachers throughout the day (i.e., support network). Yet, the student may perceive a low level of support from the teachers. Some researchers argue that perceived social support is what buffers stress. It is the perception of individuals who believe that people care about them and are willing to help them that contributes to well-being. In other words, the value of social support is knowing that one is loved and supported in all circumstances.

Functions of Social Support

The third line of social support theory concerns the various functions provided by one's social network. In 1974, Thomas Weiss proposed six functions: attachment, social integration, opportunity for nurturance, reassurance of worth, a sense of reliable alliance, and guidance. Researchers have expanded on Weiss's work and proposed functions, including emotional, instrumental, informational support, and companionship. *Emotional support* refers to sympathy, caring, understanding, and reassurance received through social networks. *Instrumental support* entails the provision of tangible, concrete support or assistance, such as financial assistance. *Informational support* refers to the provision of information (e.g., information related to job opportunities) or advice. *Companionship support* refers to having a person with whom to share activities, such as going to the gym. The assumption underlying this perspective is that social support provided by one's network has its greatest effect when the support provided matches the specific needs of an individual. For someone who has recently lost a job, encouragement from friends in the form of emotional support and the provision of instrumental support (e.g., helping with resume) may be the most beneficial.

Integrating Various Perspectives on Social Support

Increasingly, researchers and theorists have proposed the importance of studying both the structural (e.g., network size) and functional aspects (e.g., provision of emotional or informational support) of social support. One argument underlying this integration is that evidence supports the importance of both aspects of social support on positive human development. Furthermore, studies have shown that contextual factors, such as developmental stage and gender, need to be considered when examining the impact of social support, as evidence has shown that the aging population tends to have a more selective social network.

SOCIOGRAMS

Sociograms are visual representations of a set of interpersonal relations within a group. They contain nodes (dots) and edges (lines), where nodes often represent individuals (organizations, nations, or other entities) and edges indicate relationships among them. A sociogram depicts how the individuals in a group are related to each other. It makes the structure of social networks readily visible and measurable, enhancing the interpretation of relations in the group. Given the simplicity and readability, sociograms have been widely used to represent social relationships in many branches of science. They help to discover and present group structure and are often used to identify cohesive subgroups in a network. Sociograms may also display the evolution of networks over time. This entry summarizes the key features of sociograms, provides an overview of the historical development of sociograms, describes the main types of layouts, discusses advances in dynamic network visualization, and refers to software for developing sociograms.

Sociogram Features

Figure 1 offers an example of a sociogram of marriage relationships in 14th-century Florence. Each circle (node) represents a different family. Each line (edge) represents a relationship between families—in this case, a marriage between family members. The sociogram conveys a sense of social closeness (or distance) between members based on connections to other units in the network. It can provide a sense of prominence or centrality within the network. In this case, the Medici family is the most central family in this network, which helps to explain why they were such powerful agents in this community. Sociograms can also convey elementary features of the network, such as the number of ties (or degree) that each family has or the path distance from one family to another.

Figure 1 Marriage Connections Among Renaissance Florentine Families

Source: Padgett, J. F. (1994). *Marriage and Elite Structure in Renaissance Florence, 1282–1500*. Paper delivered to the Social Science History Association. Public domain network data; recreated in R for this entry.

Sociograms are capable of conveying much additional information. While this network is a nondirected network, for other networks, one could add arrows to the lines to indicate the sending and receiving of ties. Strength of ties can be illustrated through increasing the thickness of the lines. One could also display different types of relationships by using different colors for the lines. Likewise, nodes could be depicted in different colors or shapes to designate different sets of actors. One example is a bipartite (or two-mode) network in which two sets of nodes interact with one another, such as people (Mode 1) connecting to one another via their co-membership in social clubs (Mode 2). Nodes may also be resized according to structural properties such as centrality. Finally, there are many possibilities for how to place the individual nodes in two-dimensional space. Those possibilities are discussed after a brief discussion of the history of sociogram development.

The History of Sociograms

The sociogram has evolved from hand-drawn charts, through computer-generated diagrams, to interactive visuals. The evolution is mainly driven by researchers' need to convey more information and the increased capabilities of the available visualization tools. Jacob L. Moreno was the first to use a graph that contained nodes and edges to display social relations in the 1930s. He used a variety of features of nodes and edges (i.e., colors, arrows, and shapes) to symbolize attributes of

actors and relationships. He advanced the network visualization by creating a symbolic system for developing sociograms. The sociogram became widely used by community sociologists who mapped out elite networks in small groups. These early graphs were relatively simple, and the success of graph was determined by the artistic skills and analytic eye of the author.

The state of the art in sociograms progressed remarkably after the incorporation of quantitative information in producing images in the 1940s and 1950s. One major challenge of sociogram is to locate the nodes on the page. Factor analysis was the first and most common computational tool used to assign locations to the nodes. This procedure allowed researchers to obtain x and y coordinates for each node based on shared connections between nodes. This effectively standardized the processes of drawing a sociogram and made it possible to replicate the images.

The availability of the computer in the 1960s dramatically facilitated the standardization of sociograms and their move from illustrative art to methodological tool. In 1966, Edward O. Laumann and Louis Guttman used multidimensional scaling (MDS) to locate nodes on the page and plotted the first network graph with a three-dimensional appearance. In the early 1970s, Richard D. Alba, Myron P. Gutmann, and Charles Kadushin developed the program SOCK, which is designed to generate node-and-edge graphics automatically, and produced the first fully computer-generated network diagrams. Since then, programs that automatically produce network images emerged at a rapid rate.

The introduction of the Internet and personal computers in the mid-1990s opened up many new possibilities for sociograms. Modern technology provided new tools that allow for more powerful and elegant images. The development of fast and efficient algorithms has also become a major driver advancing the sociogram. General-purpose network analysis programs offered increasingly sophisticated techniques for producing network images. These new programs made it possible to visualize and analyze very large networks as well as dynamic network properties. Recently, the growth of R programming language and RStudio software further facilitated the graphical presentation of social networks, enhancing the speed and aesthetics of modern graph layouts. R also made dynamic and interactive network visualization easy and popular.

Sociogram Layouts

The technological advances in sociogram development have mainly focused on designing new and better layouts, which refer to the placement of nodes in relation to one another. One strategy is to place nodes based on the characteristics or features of the nodes, independent

of how those nodes are connected to one another. An example is a bipartite graph, which might include one set of nodes (people) on the left side of the graph and the other set of nodes (social clubs) on the right side of the graph in order to show the relationships between those two groups. Another possibility is a hierarchical layout, whereby nodes are placed along a continuum based on some characteristic of the node, such as status or authority, like one might observe in an organizational chart. Nodes might also be placed geometrically. A circle graph is an especially popular layout in which nodes are located in a circumference and edges are drawn as chords that connect the corresponding nodes. Node placement around the circumference may also be organized by node characteristics. For example, a circle graph displaying connections between countries will often place those countries next to one another if they are on the same continent.

More sophisticated techniques place nodes close to one another based on similarity in their connections to other nodes. This can be done in two ways. The first is referred to as MDS. Similar to factor analysis, MDS attempts to capture correspondence between units based on shared connections to others. A single factor solution offers a score for each unit, which estimates how close (or far) that unit is from other units. Adding a second factor (or dimension) yields a second score, which can be combined with the first to serve as x and y coordinates on a graph. This approach thereby estimates social distance between units based on latent dimensions of shared connectivity.

While MDS is very useful, it can result in the overlapping of nodes when those nodes have identical connections to others, which is a problem for visualizing the network. Force-directed layouts offer a useful corrective. A force-directed algorithm simulates a network graph by assigning forces among the set of edges and the set of nodes. The edges operate like rubber bands, pulling nodes closer to one another. The nodes operate as oppositely charged particles, repelling one another. The algorithm iterates until it identifies optimal spacing between nodes. The result is an aesthetically pleasing sociogram in which all edges are of almost equal length, and there are as few overlaps and edge crossing as possible (Figure 1 is an example). There are many different types of force-directed layout algorithms, but the most popular ones are Kamada–Kawai and Fruchterman–Reingold.

Algorithms are also useful for identifying and labeling subgroups within a network. Figure 2 provides an example of a network of friendship ties between monks from the classic Sampson monastery study. In addition to showing the friendship connections between monks, a community detection algorithm was used to label subgroups. The algorithm (in this case, *walktrap*) estimates modularity, which refers to the density of ties

Figure 2 Friendship Relationship Subgroups Among Monks

Source: Sampson, S. F. (1968). A novitiate in a period of change: An experimental and case study of social relationships (Dissertation, Cornell University). Public domain network data; recreated in R for this entry.

among subgroup members relative to ties among out-group members. The algorithm iterates to maximize the ratio of within-group *versus* between-group density, thereby identifying cohesive subgroups. In addition to walktrap, community detection algorithms include fast greedy, leading eigenvector, and Louvain.

Dynamic Network Visualization

For the most part, network layouts have been devoted to static networks. Traditional sociograms are effective for small static networks while often unreadable when the network is dense, large, or dynamic. The fundamental problem is that static representations require at least two dimensions to represent proximity and that leaves no effective space to represent time. Recent tools have placed more emphasis on dynamic networks, for example, using the interchange of messages as a function of time, which makes dynamic network visualization possible.

The most basic approach to dynamic network visualization is the flipbook, whereby multiple sociogram time slices are presented sequential to illustrate change over time. A slightly more sophisticated alternative is the time prism, which adds a third dimension to the sociogram layout such that time slices are observed as horizontal layers. Network movies offer a more effective alternative to visualize dynamic networks. To account for temporal change, a time-space representation might be used to plot the network as a multislice graph, which generates a movie of the network. As the image moves from one time slice to the next, the nodes shift into the new position revealing change in the individual relationships and aggregate network structure.

Network movies were pioneered through the development of SoNIA software (social network image animator) to develop videos playable in QuickTime. More recently, advances in network movie making have been incorporated into the R statistical software platform via packages such as *networkDynamic* and *ndtv*. These programs are designed to deal with new challenges that include integration of network movies with javascript and trying to address the challenge of anchoring nodes to allow smoother transitions from one time slice to the next.

Visualization Tools

Several tools have been created for analysis and visualization of social networks. UCINET is easy-to-use software designed to provide network metrics, identify clusters, and draw diagrams for small and mid-sized networks (fewer than 5,000 nodes). Pajek is built for the analysis and visualization of large networks that may have hundreds of thousands of nodes. Gephi is an interactive visualization and exploration platform, which enables users to explore network graphs by interacting with the representation. NodeXL is an add-on template for Excel that allows for visualization of sociograms. Most social network analysis is now conducted via the R statistical software platform. A number of popular R packages have been developed for analysis and visualization of social networks, including *igraph* and *statnet*. R also allows users to construct interactive sociograms through the use of *visNetwork* and *shiny*. These interactive graphs are useful for posting html applications that allow users to engage with and manipulate sociograms online. The growing use of R promotes data and code sharing, which improves the reproducibility and transparency of sociogram.

SOCIOMETRIC TESTS

Sociometric tests are research instruments used to map social relations and to configure a social structure. These tests are part of a research technique called *sociometry* that belongs to quantitative research methods aiming to measure social relationships. A sociometric test typically concludes with a graphic representation labeled as a *sociogram*, which graphically and mathematically captures relational patterns between group members by showing the strength of inter-member ties. Sociometric tests are relevant instruments in designing social science research, including studies in social psychology, educational psychology, health-care management, business and economics, and so on. Such type of tests can be largely applied in different disciplines and sectors that deal with inquiries aiming to measure the cohesiveness between team members or even between actors of a larger system. This entry presents historical notes on sociometry and sociometric tests, procedural steps in applying sociometric tests, and nuances, applications, and limitations of sociometric tests.

Origins of Sociometry and Sociometric Tests

Sociometry and the sociometric method for mapping and measuring interpersonal relations/attractions were developed since 1934 by psychiatrist and group psychotherapist Jacobs Moreno, one of the pioneers in the field of group dynamics. Moreno was fascinated by the unneighborly phenomenon that he noticed between neighbor women living in bungalows. He noticed both intergroup and intragroup tensions, which he believed were due to an inadequate social organization of young women groups. Then, Moreno used the self-reporting method (i.e., self-confessing) to collect data on friendship preferences between neighbors. He used a questionnaire to ask the women which could be the five best neighborhood acquaintances with whom they would feel more harmony. After collecting the responses, Moreno regrouped women as per their preferences and, as a result, the overall level of the community's cohesion increased. Since then, sociometric tests are widely applied in different disciplines and sectors for improving human relations, satisfaction, and productivity in both personal life and workplace.

The Procedural Steps of a Sociometric Test

To design a sociometric test, one needs at least a group, researcher, questionnaire or interview, and natural

setting where the researcher observes the group dynamics (i.e., actions and reactions under particular circumstances).

The application of the sociometric method starts with a natural or participant observation, where the researcher diagnoses relational problems between group members. For instance, when in a football team the coach observes disputes among team players, the coach tries to reorganize the team in order to boost morale and cohesiveness. However, the social reorganization would function better if the coach would possess more accurate data. For this purpose, the self-reporting method is used after administering relevant questions toward group members, especially toward the ones directly involved in disagreements. Thus, the researcher asks the group members one or more questions about the other members. Questions can be asked through the means of a questionnaire or interview.

Questions can be both positive and negative. Positive questions are applied when the aim is to understand the social cohesion. Negative questions are applied when the objective is to discover the social distance between less empathic members. An example of a positive question is the following: *Who are your four best classroom friends with whom you feel more empathy?* An example of a negative question is the following: *Who are your four classroom friends you tend to avoid the most, or attempt to socialize with as little as you can?*

Then, the participants are asked to provide a ranking of their preferences. The data can be manipulated by hand or in a computer. There is plenty of dedicated software that can be used for analyzing group dynamics. The analysis provides insights to the researcher through different charts. A bar graph shows the number of acceptances and rejections that each member has received. This also shows the popularity of group members that is better manifested through a target graph. With the latter graph, the sociometric test provides quantitative data about members that are perceived as influencers, rejected, neglected, controversial, and average. When software is used, other metrics can be obtained about received/given acceptances and rejections in terms of value and density. Leadership traits and popularity can be inferred as well.

The last configuration in a sociometric test is the sociogram or a graphic representation of ranked choices (e.g., first friendship preference, second friendship preference). Choices can be either positive (i.e., order of acceptances) or negative (i.e., order of rejections). The sociogram serves as a diagram of relationships among group members. Diagrams are equipped with nodes/circles representing members and arrows

representing choices, thus, showing who likes/dislikes whom. The researcher can intervene on the sociogram to reorganize patterns and reshape groups. The purpose is to enhance interpersonal attraction, cohesion, and productivity.

Nuances, Applications, and Limitations of Sociometric Tests

Sociometric tests are various but their conceptual structure is common. They can be manually applied or can be software-based. The applications range in multidisciplinary fields. Wherever social systems are present, sociometric tests can be applied. Still, some confusion arises due to the terminology, as shown in the following sections.

Sociometer Theory

Researchers have shown that people's self-esteem depends on the degree of their inclusiveness in teams. When they are rejected, they manifest low levels of self-confidence. This model is a derivative of the sociometric test searching for details related with psychological consequences of individuals.

Social Network Analysis

Sociograms provide group-level social network information. Nevertheless, with social network analysis, a researcher is able to make an in-depth analysis of larger systems. Some examples include mapping stakeholders of a business firm, analyzing the number and strength of ties between citizens, or quantifying the closeness between doctors and patients. Concrete examples of social networks are Facebook, LinkedIn, Instagram, and Viber, to name a few. Equipped with sophisticated software, they can provide data about the number and strength of relationships between members of the platforms.

The main limitation of sociometric tests is that they show only the "what" dimension of social relations. In other words, they help the researcher to understand who likes/dislikes whom in a group but do not provided insights on the reasons (i.e., the "why" dimension). For more explanatory insights, other tests are needed to complement the sociometric tests.

SOFTWARE, FREE

Statistical software is an enabling component of conducting educational research. In particular, it makes statistical routines such as linear regression, data visualization, data manipulation, or other data-related tasks easier for users to perform. There are a variety of statistical software that users can choose from. These include general purpose software such as SPSS (IBM Corp., 2019), Stata (StataCorp, 2019), SAS (SAS Institute, 2017), R (R Core Team, 2021), Python (Rossum, 1995; Van Rossum & Drake, 2009), and Julia (Bezanson, Edelman, Karpinski, & Shah, 2017). Furthermore, thematic coding of qualitative studies are also commonly used to aid in the coding element using software such as NVivo (QSR International, 2020). This entry focuses on quantitative software as these are more numerous, but the principles can be applied to qualitative software (or more generally any software) as well.

In addition to general purpose statistical software, there are numerous specialized pieces of software that are designed to perform one type analysis or methodology. Some common specialty statistical software include MPlus for latent variable modeling (Muthén & Muthén, 1998–2017), flexMirt for item response theory modeling (Cai, 2013), G*Power3 for estimating statistical power from common simple statistical designs (Faul, Erdfelder, Lang, & Buchner, 2007), and Optimal

Design for estimating power for experimental designs (Raudenbush, 2011).

Within the general purpose and specialty statistical software groups, the software generally falls into two broad categories: software that are freely available for users to use and those that require a fee to use. For example, SPSS, SAS, and Stata all require users to purchase a license to use the statistical software. General purpose statistical software such as R, Python, Julia and specialty software such as G*Power3 and Optimal Design are free software. Free software is usually available to download and install from a website and users can use the software without limitations.

This entry first focuses on differentiating between free and paid software. Free software can further be separated into free and open-source software. Strengths and weaknesses within free software are also explored in more detail in this entry.

Paid Versus Free Versus Open-Source Software

The distinction between free and paid software is whether the software license has a cost associated with it. In particular, if the software requires a fee to be paid, then it is paid software. If the usage of the software does not require a fee, then it would be free software. Within the free software paradigm, the focus of this entry, there is a more subtle distinction between free and open-source software that has important implications.

The distinction between free and open-source software is related to whether the source code is available or not. A common definition for open-source software is that the source code is freely available, but also that the source code can be inspected, modified, or enhanced by anyone. Free software, however, could be freely available to download, install, and use, but the source code may not be able to be seen. If the source code is unable to be inspected, this is often referred to as *proprietary* or *closed-source software*. In these instances, the development team is the only one who can legally access, modify, enhance, or distribute the source code.

Examples of free or open-source software may help to show differences in these approaches. Open-source statistical software include R, Julia, Python, and the packages associated with them. In contrast, statistical software such as G*Power3 and Optimal Design are free software, but the source code associated with them to implement the features is not available outside the development team. Furthermore, it is possible to have free software that is not open source, but the inherent nature of open-source software is such that it is always free. In contrast, software that is paid software is

always closed source, such that the source code would not be openly available to its users. Free software could be either open source or closed source, depending on the development team's preferences.

What Is Source Code?

In the previous section, the term *source code* was used, but what exactly would represent source code? According to opensource.com, source code is the code that developers use to implement specific features within a piece of software and in which many users of the software do not see. If the software is a command line or code based software (e.g., R, Python), the source code would not be the code that users use to perform a specific task. Rather, the source code would be the code that a developer wrote to implement that routine.

A specific example may be helpful. Linear regression is a common analysis that is performed in educational research. This command in R is `lm()` and the user interacts with this code by first typing the `lm()` command in a script or within the terminal in R. The source code for the linear regression implementation in R can be viewed within an R session by typing `lm` without any parentheses around it. This source code processes the users' specifications via function arguments to conduct the desired analysis.

R is an open-source language; therefore, the source code is directly viewed by anyone who wants to see the source code. However, there is source code underlying any software, and this code runs when the user requests a specific routine. For example, within SPSS, a linear regression analysis can be performed in at least two ways by an end user. One is through the graphical user interface and menu structure (e.g., Analyze > Regression > Linear) or through the SPSS syntax, REGRESSION. Whichever method is used, there is source code behind the scenes that is implementing this analysis; however, the primary difference between R and SPSS is that SPSS is a paid, closed-source software. This means that a user has to purchase a software license to use the routine, and also since it is closed-source, the user is unable to see the specific source code used to run the routine behind the scenes.

Strengths of Open-Source Software

The strengths of open-source software are explored explicitly in this subsection. The benefits of the open-source software stem from the ability to directly view, modify, enhance, study, or distribute the source code. Having access to the source code can improve users' collaboration with the developer. This can lead to improvements to the software, including better

documentation, enhancing usability, or even fixing errors to the implementation of the software routines. The fixing of errors in the implementation of a software routine is an important distinction for open-source software as this would not directly be possible within a closed-source software project. Instead, the user would need to contact the developer directly to try to explain the problem and hopefully get a fix in the next release of the software.

Furthermore, open-source software can be extended to add additional functionality on top of an existing open-source software project. As the original open-source project is freely distributed and the source code is accessible, there is no need to re-implement the functionality of the original software project. The new functionality can be added directly, which from a developer standpoint can increase productivity to focus on the new elements rather than re-implement a problem that already has a solution.

Weakness of Open-Source Software

The primary weakness of open-source software is that the software is distributed and licensed as-is without any warranty or support. From the user perspective, this puts more burden to learn the software themselves as the developer makes no commitment to answer usability questions. The support and warranty for free closed-source software is also most likely distributed and licensed as-is. Therefore, there is likely not a large difference in the support and warranty for the source code of free and open source compared to free and closed-source software.

Another potential weakness of open-source software could include the ability of the developer to fix errors in a timely manner. As discussed earlier, the software is often distributed as-is; therefore, the developer is under no obligations to provide a fix for potential errors. The developer may also not be a trained software developer, which could make the software less flexible or more prone to errors. These issues need to be considered when using open-source software. Such issues may also be found in free closed-source software; however, in this scenario, the source code cannot be viewed to evaluate whether the source code does have an error or not.

Some open-source software may provide support as an add-on service that users could pay for, but the software is still considered open source (i.e., the source code is made accessible). This idea is similar to support provided from paid software whereby users often are able to opt in to receive additional support in addition to paying for the software. Some paid software may also provide free support when one purchases the

software, but this is not necessarily required as part of the paid software.

Software Licenses

Much of the distinction between paid, free, and open-source software comes down to the software license that is distributed with the software. There are largely two buckets that licenses fall into: those that are free and open *versus* those that are proprietary. Within these ecosystems, there is quite a bit of variety to the software licenses and many slightly different versions of licenses. This entry is not able to give a deep dive of all the software license options, but a few specific and more common software licenses are discussed and compared.

The primary differences between the two large groups of software licenses come down to what actions are typically allowed with respect to the source code. Software distributed under a proprietary license typically are closed source and do not allow the source code to be viewed, distributed, or modified. This is in contrast to the free and open licenses, which require the software to provide the source code.

Free and Open Licenses

There is quite a variety to free and open licenses, but all of these licenses require that the source code be released, viewed, modified, and distributed. There are numerous subtle differences across the variety of licenses available, but these can be broken down into two broad categories. One group is referred to as *permissive licenses* (e.g., MIT license, Apache license, BSD licenses, Mozilla Public License), and the second group is referred to as *copyleft licenses* (e.g., GNU General Public License [GPL] or Affero General Public License). A more thorough list of free and open-source licenses can be viewed at the Open-Source Initiative.

Permissive Licenses

Permissive licenses are open-source licenses that give broad permissions to use the software. In particular, there are no limitations on using, modifying, or redistributing the software. The notable difference with permissive licenses to copyleft licenses is that the permissive licenses place very few, if any, restrictions on how the software can be redistributed. For example, software with a permissive license that is free and open source can be used within closed-source software or released under a proprietary license. The hallmark of permissive licenses is that, in general, the software can

be used however the user desires with very few restrictions.

There are many instances of permissive licenses used in open-source projects, for example, Python uses a permissive license that uses their own Python Software Foundation license and also licenses some with BSD licenses. Julia also uses the MIT license for their software project. These permissive licenses give broad use for the software to those who wish to use, build, enhance, view, or distribute part of all of the source code.

Copyleft Licenses

Copyleft licenses are similar to permissive licenses; however, these licenses have one important distinction. If a copyleft license is used, such as the GPL, there are greater restrictions on how the software can be distributed. In particular, software with a copyleft license must remain open source, free, and with the same license. For instance, if software is built that uses functionality from a GPL licensed software, the new software must also be open source with the source code released. Furthermore, implied within the last example, software that has a copyleft license cannot be used inside software that uses a proprietary license or requires a fee to use the software. The copyleft licenses are also a type of *share-alike* license whereby the license is designed to restrict new software that builds off of software with a copyleft license to be released with the same or similar type of license.

Similar to the permissive licenses, copyleft licenses are used frequently within open-source work. For example, R uses the GPL v2 license for its source code.

Proprietary Licenses

Proprietary licenses limit the usage of the software and source code. Users are often asked to agree to an end-user license agreement to use the software. These agreements typically limit who can use the software and restrict the sharing of the software or releasing of any source code. Furthermore, ownership of the software is retained by the publisher. Examples of proprietary software within educational research are SAS, SPSS, MPlus, Stata, and NVivo.

Software such as Optimal Design and G*Power3 follow a proprietary free license. In this situation, the source code is not shared, but the software is freely downloaded and used by end users. Users agree to not distribute or modify the source code, however; therefore, these software would fall best under a proprietary license even though they are free to download and use.

Package Ecosystems of Open-Source Software

The open-source licenses of R, Python, and Julia have allowed software developers, hobbyists, and others to build additional functionality on top of each software. This is made possible because of the open-source licenses that these software have chosen to adhere to. Most, if not all, of the software packages that have been developed to enhance R, Python, or Julia are also open source with permissive or copyleft licenses.

All of these package ecosystems continue to evolve over time. As of 2021, there are over 17,000 software packages that were written to extend functionality of R, over 200,000 Python packages, and about 4,000 Julia packages. Much of the functionality that has been added to these general purpose languages would not have been developed for the platform without the distributed effort of the many developers who have contributed their time and expertise. This is an example of the open-source community presenting additional benefits over the closed-source development process.

Future Outlook

Free software is a diverse and thriving area of software development. There are differences within free software that are important for the use of those software in the future. Much of these differences stem from the license that the software is released with, whether the software is a free and open-source license or a proprietary license. Both of these types of licenses have their strengths and weaknesses, but the difference largely comes down to whether the source code is released, able to be viewed, or can be redistributed. If it can, then the software uses a free and open license; if not, then the software uses a proprietary license.

Using free and open licenses have many benefits, for instance, allowing any user to view, modify, incorporate fixes, or build new functionality on top of existing source code. This has directly led to the creation of package ecosystems on top of the primary open-source package for R, Python, and Julia to add specialty functionality. Stand-alone free software that is not open source will always have a place in the software ecosystem, but the proliferation of open-source software will likely continue as the benefits seem to outweigh any potential weaknesses.

SPAGHETTI PLOT

The purpose of the spaghetti plot is to present the trajectory or trend of data. This display can take the form of a graph or a figure, depending on the data. Numerous long lines that curve and intersect give the appearance of noodles, hence the name, spaghetti plot. Typically, whether data are to be presented over time or over space (such as in a map) will determine whether the spaghetti plot takes the form of a graph or a figure. A graph displays individual responses over time for psychological or physiological (interval or ratio) variables. In a figure, the physical path of the variable of

interest is important to display to provide an indication of how the variable's path changes through space. This entry explains the usage of the spaghetti plot in the graph and figure forms and the rationale for its use, provides examples, and presents the advantages and disadvantages of this type of visual data presentation.

In graph form, the spaghetti plot typically reflects longitudinal, repeated measures of individual raw scores (see Figure 1). This is plotted on a chart where the dependent variable, or variable of interest, is on the y-axis, while time is on the x-axis. The dots for a participant's data points are connected to form a line. Depending on the research design and purpose of the study, another variable of interest, other than time, can be displayed on the x-axis. The spaghetti plot is distinct from a line graph as the points on a line graph present summarized data. It is also different from a scatterplot, which is frequently used to present discrete data points that reflect a pattern in the overall data but does not permit comparisons of individuals' responses over time.

Examples of graphical spaghetti plots can be found in medicine, psychology, education and management, whereby the outcome variable is tracked over days, months, or years for numerous individuals. The outcome variables are, for instance, psychological or physiological variables such as weight, physical symptoms, neurological outcomes, biological outcomes, cognitive functioning, and psychological symptoms. The purpose is to determine whether the outcome variable trajectory presents itself in a similar manner for the participants over time. The trend of an individual's data is of interest, as well as that of the entire sample or subsample. Although it is typical to employ the spaghetti plot to illustrate the measured variable more than twice, it is also employed when there are only two points of data for each participant.

Spaghetti plots presented in a figure are designed to present individual data, as well, but not over time. In a figure, the objective is to illustrate the actual environment in relation to the individual data. Examples of data presented in a figure can be found in management, human factors and ergonomics, and engineering, where movement or flow is illustrated via paths on a map. For instance, movement in an office floor plan may be important to track (see Figure 2). In meteorology, each line may reflect different weather pressures or different actions of weather systems illustrating distinct paths for these weather phenomena over a map.

The spaghetti plot provides a visual display of trends, differences between participants, missing data, and outliers. This can be beneficial to illustrate whether there are changes due to the temporal sequence of the data (certain patterns that occur at different points in

Figure 1 Example of Spaghetti Plot Illustrating Longitudinal, Repeated Measures of Participants' Scores Each Reflecting the Total Free Recall Over Four Trials

time), can illustrate whether subgroups of data naturally form, and display outlier data. The closer the lines follow one another, the easier it is to view the trend, and the greater assurance that a trend exists. To make it easier to follow individual paths, labels for each line can be incorporated. If labels cannot be utilized, as the number of lines make them difficult to follow, color can be applied to distinguish between different subgroups based on a predetermined variable such as gender or age. Alternatively, each participant's data can be given a unique color, permitting the observer to follow each participant's data trajectory. Additional information can be superimposed on the graph, such as a line representing an average or the best-fit linear regression line. This is frequently illustrated as a black, slightly bold line to ensure it is noticeable. If the sheer number of lines makes it difficult to follow distinct trends, separate panels of spaghetti plots, all with identical axes can be created to isolate and compare different potential trends. Alternatively, combining a subset of participants' scores and plotting that subset in the appropriate units, for instance, can be employed; for very large data

sets, this can help to add clarity to the visual display, although not all participants are represented in the plot.

The disadvantage of the spaghetti plot is that trends, patterns, and missing data can be difficult to discern when samples are large and there are many overlapping lines. Therefore, the ability to see patterns is hampered, and the advantages of the spaghetti plot are lost. Another disadvantage is that because the spaghetti plot requires a visual exploration of the data, errors can be made in their interpretation. In the absence of statistical analyses of the data, error could be introduced, as observed trends may be nonexistent.

The spaghetti plot is an important tool to illustrate and gather information regarding where the data deviate, as well as whether individual data in a sample follow the same trajectory. Used as a graph or as a figure makes it a versatile tool for numerous disciplines.

SPEARMAN RANK ORDER CORRELATION

For ordinal-level data, the Spearman rank order correlation is one of the most common methods to measure the direction and strength of the association between two variables. First put forth by British psychologist Charles E. Spearman in a 1904 paper, the

nonparametric (i.e., not based on a standard distribution) statistic is computed from the sequential arrangement of the data rather than the actual data values themselves. The Spearman rank order correlation is a specialized case of the Pearson product-moment correlation that is adjusted for data in ranked form (i.e., ordinal level) rather than interval or ratio scale. It is most suitable for data that do not meet the criteria for the Pearson product-moment correlation coefficient (or Pearson's r), such as variables with a non-normal distribution (e.g., highly skewed) or that demonstrate a somewhat nonlinear tendency.

Although Pearson's r indicates the strength of the linear relationship between two variables, the Spearman rank order correlation shows the strength of the monotone associations. A monotonic relationship is one in which all x and y variables are arranged in ascending order and are compared for their differences in ranks. In other words, the statistic determines to what degree one data set influences another data set. An increasingly positive monotonic relationship would be one in which as x increases in rank (and value), y also increases (or stays the same) in rank, and the data pairs are concordant with one another. In contrast, an increasingly negative monotonic relationship exists when as x increases in rank (and value), y decreases (or stays the same) in rank. In this case, the data pairs are discordant with one another and exhibit large differences between their respective ranks. In contrast to Pearson's r , the Spearman rank order correlation does not differentiate between linear and monotonic associations because of the ordinal level scale of the data. This property enables the Spearman rank order correlation to be a suitable nonparametric alternative to the Pearson's r when assumptions regarding linearity cannot be met or are unknown.

This entry discusses several aspects of the Spearman rank order correlation, including methods for computing, the influence of tied rankings, and statistical significance and significance testing.

Computation

The Spearman rank order correlation measures the degree of association of ordinal-level data by examining the ratio of the sum of the squared differences in the ranks of the paired data values to the number of variable pairs. Computationally, the Spearman rank correlation coefficient (r_s) is defined by the formula

$$r_s = 1 - \frac{6 \sum d^2}{N(N^2 - 1)},$$

where d is the difference in statistical ranks between the paired variables x and y , $\sum d^2$ is the sum of the squared differences between the ranks of the paired variables, and N is the number of paired data values. As with the Pearson's r , values of r_s range from a minimum of -1.0 to a maximum of 1.0 . Increasingly negative r_s values indicates a negative monotonic relationship between the ordered pairs, and x and y are inversely related to one another (i.e., as one variable increases, the other tends to decrease). Conversely, increasingly positive r_s values indicates a positive monotonic relationship, and x and y covary in the same direction (i.e., as one variable decreases, the other is apt to also decrease). The closer the Spearman rank correlation coefficient is to the extremes (1.0 or -1.0), the stronger the association between the variables. If no association exists between the variables, then r_s is equal to or near 0 . The statistical strength of the Spearman correlation has been demonstrated to be as robust as that of the parametric Pearson's r , especially for data sets with considerable range in values and reduced frequency of tied ranks.

In the Spearman rank correlation coefficient, the value of the 6 in the numerator stems from a conversion done to produce a scale with a similar interpretation to that of the Pearson's r . To understand the need for the conversion (as outlined by D. Griffiths), take into account the extreme cases of the rankings where the relationship is perfectly positively or negatively monotonic. If the rankings for each ordered pair (N) are identical, then the sum of the differences between the rankings for variable x with ordered pair y ($\sum d^2$) will be 0 and the value of r_s will be 1 . For example, the ranks of the pairs $(1,1)$, $(2,2)$, $(3,3)$, $(4,4)$, and $(5,5)$ do not differ and illustrate a positive monotonic relationship with a perfectly positive correlation coefficient ($r_s = 1$). In contrast, if the rankings for each ordered pair (N) directly oppose one another, then the sum of the differences between the rankings for variable x with ordered pair y ($\sum d^2$) will be equal to $N(N^2 - 1)/3$. For example, the ranks of the pairs $(1,5)$, $(2,4)$, $(3,3)$, $(4,2)$, and $(5,1)$ differ considerably and demonstrates a negative monotonic relationship, whereby x and y are inversely related to one another and r_s will be more negative with increasing N . Consequently, the lower range of r_s will be dependent on N and the scale quantifying these associations will fluctuate. By finding an equation that passes through the extreme points in either direction from zero (i.e., $(0, 1)$ and $(N(N^2 - 1)/3, -1)$ for this data set), the scale of the Spearman ranked correlation coefficient is adjusted to a standard scale. The resulting equation is $y = -6/N(N^2 - 1)x + 1$, where the slope of the line is $-6/N(N^2 - 1)x$ and the y

intercept is 1. This transformation produces a coefficient then that is not dependent on the number of ordered pairs (N) and varies similarly to the Pearson's r , between -1 and 1 .

Tied Rankings

As with other statistical techniques employing ordinal-level data, the Spearman rank correlation coefficient can be substantially influenced by the incidence of tied rankings. For example, a data set examining the relationship between annual income and vehicles owned would in all likelihood have a large number of tied ranks because the latter variable will tend to elicit a more limited response (most likely values would be between 0 and 3, with 1 and 2 vehicles owned being more common). As the number of tied ranks increases, the larger the difference between the sum of the square of ranks from the sum of the square of N (the number of paired data values) and the larger the effect there will be on r_s . In these cases, a correction factor is needed to minimize the effect of tied ranks and produce an uninflated, more realistic representation of r_s . One common method used to correct for tied ranks is to sum the number of tied positions and divide by the number of tied scores, thus assigning each of the tied scores the mean rank value. For instance, a data set with the values of 1, 3, 6, 6, 6, 6, 7, and 9 would have the ranks of 1, 2, 3, 3, 3, 3, 7, and 8, respectively; thus, the tied values of 6 all receive an equal ranking of 3. Applying the correction factor, each of the tied rankings would instead be assigned a value of 4.5 (i.e., the sum of the tied positions is $3 + 4 + 5 + 6 = 18$ divided by the number of tied scores, 4). However, the effect of tied ranking on r_s is only significant when the fraction of tied ranking to the total number of values is sufficiently large, often a quarter or more of the entire data set. Computer statistical packages (e.g., IBM® SPSS® [PASW] 18.0, an IBM company) typically will automatically make these adjustments, if necessary.

Statistical Significance

The Spearman correlation coefficient describes the strength of the association between the two ordinal variables, but it does not show whether that relationship is statistically significantly different from 0. Because the sample correlation coefficient (r_s) estimates the population correlation coefficient (ρ_s), a test statistic is needed to determine the degree of confidence that the relationship found from random sampled pairs is truly representative of the entire

population. This step is particularly important when using relatively small sample sizes where there is an increased probability that a nonzero correlation coefficient results through chance sampling from an otherwise uncorrelated data set. The test for statistical significance examines whether the null hypothesis is confirmed or rejected in favor of an alternate hypothesis. The null hypothesis is that no relationship exists between the two variables x and y in the population data set and the correlation is zero ($H_0 : \rho_s = 0$). If the null hypothesis is true, then the two variables do not covary and are independent of one another. Conversely, if the null hypothesis is false, then the two variables are not mutually exclusive, and the alternate hypothesis that the two variables are significantly correlated within the population must be accepted. The alternate hypothesis (H_a) is either one of two forms, depending on the problem under consideration. For situations in which prior knowledge concerning the relationship between the two variables is unknown, a nondirectional or two-tailed significance test is applied, and the alternate hypothesis is that a relationship does exist between the two variables ($H_a : \rho_s \neq 0$). However, if the variables are anticipated to covary in one direction, then a one-tailed significance test is used and the alternate hypothesis is that the variables are related in either a positive ($H_a : \rho_s > 0$) or negative ($H_a : \rho_s < 0$) direction.

To test the significance of the Spearman rank correlation coefficient (or the Pearson's r), either a Z or t distribution is usually applied depending on the size of the sample population. Significance testing for larger sample sizes (usually when $N > \sim 30$) will use the Z or normal distribution, a probability density function with a mean equal to zero, and a standard deviation equal to one. For the Z distribution, the significant correlation test is governed by the value of the Spearman correlation coefficient and the number of degrees of freedom (i.e., the sample size minus one population variable being estimated, the population correlation coefficient) such that

$$Z_{r_s} = r_s \sqrt{n-1}.$$

For smaller sample sizes, the Student's t distribution is more appropriate than the Z distribution, because the deviations from the normal distribution increase with decreasing degrees of freedom. The t distribution test statistic is also dependent on the strength of Spearman correlation coefficient and sample size and is commonly written as

$$t = r \sqrt{\frac{(n-2)}{(1-r^2)}}.$$

The larger the Z or t value, the less likely the relationship between the two variables is random and the alternate hypothesis should confidently be accepted in favor of the null hypothesis.

The Z or t scores obtained from significance testing can then be converted to a p value using a probability table that signifies the proportional area under a normal or Student's t distribution curves, respectively. The probability value or p value represents the probability of rejecting the null hypothesis that no relationship exists between the variables when in fact, it is true (i.e., a Type I error). Large Z and t scores generally yield progressively smaller p values and, thus, decrease the likelihood of making a Type I error. For example, suppose the relationship between two variables produce a Spearman rank correlation coefficient of 0.50 based on a sample size of 22. Because the sample size is relatively small, a significance test statistic and probability table based on the Student's t distribution is used. The computation produces a t equal to 2.6 and an associated p value of .017, suggesting a small probability that the null hypothesis is true ($H_0 : \rho_s = 0$) and that the two variables are most likely significantly correlated. Large Spearman rank correlation coefficients ($>.50$) in conjunction with larger sample sizes will generate p values closer to 0 and indicate a statistically significant relationship; however, the researcher must determine whether that relationship is meaningful and justified.

SPEARMAN–BROWN PROPHECY FORMULA

Charles Spearman and William Brown separately derived a formula to predict the reliability of a test when its length was altered by the addition or subtraction of parallel items. Each presented their formula in 1910 in Volume Three of *The British Journal of Psychology*. Because their articles were published at the same time, the formula is known as the Spearman–Brown prophecy formula.

The basic premise of classical test theory is that an observed test score consists of the sum of the following two components: true score and error score. For any individual examinee, the two cannot be separated, but for a group of examinees, the variance attributed to each source can be estimated. Test reliability, which is an important characteristic of test score quality, is defined as the ratio of true score variance to observed score variance.

By definition, error scores are random perturbations—they covary zero with each other as well as with true scores. It is well established within statistics that the variance of a sum is equal to the sum of the variances plus two times the covariances.

Consider a test to which items are added that measure the same construct equally as well as the items already in the test (parallel items). When an item is added, the true score variance of the test is increased by the true score variance of the item as well as two times the sum of true score covariances. The error variance of the test is increased by the item error score variance, but because error scores have zero covariance with everything else (by definition), the true score variance of a test increases more rapidly than the error score variance. Thus, adding parallel items increases the reliability of a test.

An early important use of the prophecy formula allowed the estimation of score reliability from a single test administration. For example, when using the split-half reliability calculation method, a single test is divided into two halves with equivalent properties and the reliability of the half tests is calculated by correlating the two. The Spearman–Brown formula allows the test developer to estimate the reliability of the full-length test from the reliability of the test halves. Additionally, the formula allows estimation of full-length test reliability when any number of individual items are added to or subtracted from a test.

The Spearman–Brown formula relies on the assumption of strictly parallel tests or test items. Parallel tests or items are those that have identical properties,

measure the same constructs, and have the same level of difficulty. The Spearman–Brown prophecy formula will only produce a valid estimation if the change in the length of the test is derived from parallel components. If an increase in test length is accomplished by adding items of a lesser quality, the Spearman–Brown formula will overestimate the reliability of the longer test. If the new items are statistically better than the average items of the original test, then Spearman–Brown will underestimate the reliability.

The Spearman–Brown prophecy is expressed in the following equation:

$$\hat{r}_u = \frac{kr_{AB}}{1 + (k-1)r_{AB}},$$

where k is the factor by which the length of the test is changed or the ratio of the new test length to the old test length, r_{AB} is the reliability of the original test, and $\hat{r}_u$ is the estimated reliability of the test k times as long as the original test.

When a test developer wishes to estimate reliability from a test that is doubled in length or when $k = 2$, the equation simplifies to

$$\hat{r}_u = \frac{2r_{AB}}{1 + r_{AB}}.$$

Consider a researcher who wishes to estimate the impact of adding 30 additional equivalent items to a 20-item test that has yielded a reliability of .50. The new 50-item test will be 2.5 times as long as the old test; it will increase by a factor of 2.5. Using the Spearman–Brown prophecy formula, the answer is

$$\hat{r}_u = \frac{2.5(.50)}{1 + 1.5(.50)} = \frac{1.25}{1.75} = .71.$$

The estimated reliability of the new test is .71.

Another form of the equation allows the estimation of the number of items needed to achieve a desired level of reliability of test scores when the original test reliability is known. When solved for k , the Spearman–Brown formula is

$$k = \frac{\hat{r}_u(1 - r_{AB})}{r_{AB}(1 - \hat{r}_u)}.$$

The resulting k equals the factor by which the test should be changed to achieve a desired full test reliability of $\hat{r}_u$.

Suppose that a 20-item math test is producing a reliability of .60; how many comparable items would need to be added to the test to achieve a reliability of at least .80? Using the form of the equation that solves for the factor k , the answer is

$$k = \frac{\hat{r}_u(1 - r_{AB})}{r_{AB}(1 - \hat{r}_u)} = \frac{.80(1 - .60)}{.60(1 - .80)} = \frac{.32}{.12} = 2.67.$$

The test would need to be increased by a factor of 2.67. Taking the factor of 2.67 times the original test length of 20 items requires a total of 54 items, so 34 items would need to be added to achieve a reliability of .80.

Practical considerations must be noted when using the Spearman–Brown formula. The formula demonstrates that net change in reliability is a function of the reliability of the original test. Adding items to a test that begins with low reliability will yield a larger change in reliability than a test that begins with a higher reliability. Thus, as the test reaches higher levels of reliability, the addition of parallel items yields diminishing returns.

SPECIFICITY

The accuracy of a test in making a dichotomous classification might be evaluated by one of four related statistics. Of these four statistics, specificity is used to evaluate the probability of correctly identifying the absence of some condition or disease state. For example, specificity might be used in a medico-legal setting to describe that a particular test has 95% probability of detecting that a head-injured patient is not malingering. Specificity is calculated as the proportion of true negative cases divided by all cases without the condition.

Calculating Specificity Scores

Specificity is calculated based on the relationship of the following two types of dichotomous outcomes: (1) the true state of affairs and (2) the outcome of the test or collection of tests. The true state of affairs is known either via experimental assignment of some condition

or through classification based on some gold standard test. The outcome of the test is typically referred to as being positive (indicating the condition is present) or negative (the condition is not present). Based on these two types of dichotomous outcomes, there are four possible outcome variables, which are defined as follows:

True negative = the number of cases with a negative test outcome that *do not* have the condition

True positive = the number of cases with a positive test outcome that *do* have the condition

False negative = the number of cases with a negative test outcome that *do* have the condition (Type II error)

False positive = the number of cases with a positive test outcome that *do not* have the condition (Type I error)

Specificity is computed from the pool of individuals who do not have a particular condition or disease. Specificity is the number of true negative cases divided by the number of true negatives plus the number of false positives. This is distinct from sensitivity, which is computed as the number of true positive cases divided by the number of true positives plus false negatives.

The specificity of a test is typically not fixed but might vary depending on the cutoff used to define a negative test outcome. To demonstrate this, consider an example in which cognitive performance was measured from 100 head injury cases, 50 of which are instructed to perform to the best of their true ability level on measures of cognition (symptom validity test) and the other 50 are instructed to perform poorly (malingering). Table 1 shows, from left to right, simulated data showing cognitive performance levels and the corresponding number of patients scoring at that performance level who were instructed to perform their best. If a negative test is defined as being any patient with a performance level of 40 or higher on the symptom validity test, then 35 of the 50 patients instructed to perform their best would have a negative test outcome (sample size from the groups with scores of 40 or 50). Given this cutoff, then, the specificity of the procedure would be calculated as: $[35 \text{ (true negatives)} \div [35 \text{ (true negatives)} + 15 \text{ (false positives)}]] = 70\%$. In contrast, if a negative test is defined as a performance level of 30 or higher, then 45 of the 50 patients instructed to perform their best would have a negative test outcome (resulting in a specificity of 90% $[45 \div [45 + 5]]$).

The patients instructed to perform poorly are not listed in Table 1 because they would by definition either be true positive or false negative cases, which are not part of the specificity calculation. They would instead be pertinent to the calculation of sensitivity. This example demonstrates how specificity and sensitivity are

Table 1 Example Showing Performance Levels Among Head Injury Patients Instructed to Perform to the Best of Their Ability

<i>Symptom Validity Test Score</i>	<i>Number of Patients</i>
20	5
30	10
40	15
50	20

independent measures because they are calculated on two different samples of individuals (those without or with a particular condition).

Specificity in Research Design

Specificity is typically used to demonstrate or evaluate the accuracy of a test for correctly ruling out the presence of some condition or disease state. This measure of a test's accuracy in classification is especially important in settings where a false positive is extremely costly. Consider the example of head-injured patients and malingering. If a patient is classified on the basis of some test as malingering, then this information might be used in the medico-legal setting to deny that patient financial compensation for his or her condition and thereby limit his or her ability to obtain services for treatment. In addition, there is a significant social stigma in being assigned such a classification. Because of these costs, it is imperative that the number of false positives be minimized, thereby maximizing specificity.

Specificity is not the only relevant measure of test accuracy. Although specificity provides information about the accuracy of a procedure for ruling out the presence of some condition, it does nothing to indicate that test's ability to identify a condition accurately. The accuracy in making a positive test outcome would be defined by sensitivity, which is described in a separate entry of this encyclopedia. Also, specificity is not the most pertinent measure of test accuracy in clinical settings where decisions are being made about an individual's test outcome and the true diagnoses or classification is unknown. In this setting, what is of greater interest is the confidence in interpreting an individual test outcome, which is defined by positive and negative predictive values. Unlike specificity, predictive values take into account the population base-rate of the phenomenon of interest.

SPHERICITY

Sphericity is an assumed characteristic of data analyzed in repeated measures analysis of variance (ANOVA). Sphericity refers to the equality of variances of the differences between treatment conditions. Violations of the sphericity assumption do not invalidate a repeated measures ANOVA but do necessitate using corrected F ratios.

To illustrate sphericity, imagine you were conducting a study administering placebo, a low dose of alcohol, and a high dose of alcohol to young adults and measuring subjective ratings of alcohol intoxication. You wish to analyze your results using a repeated measures ANOVA, but to do so you must check whether the sphericity assumption is violated. Sphericity can be measured by the following:

1. Comparing each pair of treatment levels
2. Calculating the differences between each pair of scores
3. Calculating the variances of these differences
4. Determining whether the variances of the different treatment pairs are significantly different

For the sphericity assumption to hold up, the variances of the different treatment pairs must be about equal, illustrated in the following:

$$\begin{aligned}\text{Variance}_{\text{placebo/low dose}} &\approx \text{Variance}_{\text{placebo/high dose}} \\ &\approx \text{Variance}_{\text{low dose/high dose}}\end{aligned}$$

Assessing Departures From Sphericity With Mauchly's Test

Mauchly's test is a statistical procedure that might be used to determine whether the sphericity assumption has been met for a given data set. Repeated-measures

ANOVA performed with the IBM® SPSS® (PASW) 18.0 statistical program (an IBM company) will automatically include Mauchly's test. If the Mauchly's test statistic is not significant (i.e., $p > .05$), then it might be assumed that the variances of the differences between treatment conditions are roughly equal, and the sphericity assumption has been met. However, if the Mauchly's test statistic is significant (i.e., $p < .5$), then the variances are not equal and the assumption of sphericity has been violated.

Some caution is in order on using Mauchly's test to check for violations of sphericity. This test might be underpowered with small sample sizes, which might lead to violations of the sphericity assumption going undetected. Furthermore, Mauchly's test does not provide information regarding the degree to which sphericity has been violated.

Correcting for Violations of Sphericity

There are corrections that might be used when the sphericity assumption has been violated, although they result in the loss of some statistical power. The most commonly used are the Greenhouse–Geisser correction (developed by Samuel Greenhouse and Seymour Geisser), the Huynh–Feldt correction (developed by Huynh Huynh and Leonard Feldt), and a hybrid of the two. All three corrections decrease the degrees of freedom and thereby increase the p value needed to obtain significance.

These corrections first require generating a value known as epsilon. Epsilon varies between $1/(k - 1)$ (k = number of repeated treatments) and 1. The closer epsilon is to 1.0, the closer data are to meeting the sphericity assumption. The lower limit of epsilon naturally varies based on the number of repeated treatments. For example:

When $k = 3$, the lower limit of epsilon = $1 / (3 - 1) = 0.5$.
When $k = 5$, the lower limit of epsilon = $1 / (5 - 1) = 0.25$.

The Greenhouse–Geisser correction generates a conservative estimate of epsilon and thus might generate an overly conservative correction. The Huynh–Feldt correction generates a more liberal estimate of epsilon, and this correction might be more appropriate when the Greenhouse–Geisser estimate of epsilon is greater than 0.75. However, it has also been argued that the Huynh–Feldt estimate of epsilon is too liberal (overestimates sphericity), and thus it might be more appropriate to average the epsilon values obtained from both and use that averaged value for adjusting degrees of freedom.

Another alternative is to use a multivariate ANOVA (MANOVA) for repeated measures testing, as the MANOVA is not dependent on the sphericity assumption. The MANOVA is less powerful than the repeated measures ANOVA, but it might be preferable when study sample sizes are large and epsilon values are low.

SPIRIT 2013 STATEMENT

The SPIRIT 2013 statement was an international collaboration to develop clear and comprehensive guidance for preparing a full protocol for a clinical trial. The statement continues to evolve with extensions to enhance research protocol development in numerous areas.

Although a comprehensive and detailed protocol is an essential component of high-quality research, significant issues have been identified with many available protocols. For example, protocols have often failed to include information on randomization and allocation concealment processes, have not distinguished between primary and secondary outcomes, have not provided power calculations for the planned analyses, have not included plans for analyses that were reported in subsequently published study papers, or have not explicitly noted possible conflicts of interest for researchers and/or funders. A protocol that lacks full transparency is challenging for reviewers (grant reviewers for funding decisions; research ethics committee/institutional review board [REC/IRB] reviewers for ethical decisions) to accurately evaluate the trial. Furthermore, incomplete protocols may result in inconsistent trial

conduct by researchers who lack essential procedural information. To address these issues and to provide clear guidance on the core requirements for protocols, a multidisciplinary international group of methodological experts and researchers collaborated to issue recommendations.

This entry begins by reviewing the purpose of research protocols and then discusses the Standard Protocol Items: Recommendations for Interventional Trials (SPIRIT) initiative in general and the SPIRIT 2013 statement in particular, including extensions.

Research Protocols

Research protocols are intended to provide clear, comprehensive, and transparent details of how a study is to be conducted. The protocol should not only outline the methodology but should also include a description of how all relevant ethical principles (e.g., participant protection, data protection, disclosures of conflict of interests) will be managed. The critical importance of clear and comprehensive protocols for clinical trials has become increasingly accepted in recent years.

Protocols serve a number of different purposes for different audiences at all stages of the research process. For example, in the early phases, a protocol provides research funders with a clear description of the proposed method to inform their decision-making regarding supporting the project. In advance of commencing the study, the protocol informs the relevant REC/IRB of the study's methods and analysis plan as well as how the project adheres to ethical principles. During trial implementation, the protocol provides all members of the research team with a detailed set of instructions on how to conduct the trial. Finally, those conducting systematic reviews and meta-analyses who wish to include the trial can examine protocols in order to check for possible sources of bias or deviations from protocol in the reported analyses.

The SPIRIT Initiative

The SPIRIT Initiative was launched in 2007 and was co-funded by the Canadian Institutes of Health Research, National Cancer Institute of Canada, and Canadian Agency for Drugs and Technologies in Health. The authors of the SPIRIT statement followed best practice recommendations for developing guidelines for health research reporting. An initial Delphi consensus survey involved key stakeholders who were expert in the development and use of clinical trial protocols. The experts included a broad range of the core professionals involved in clinical trials: researchers, methodologists, statisticians, and

senior study coordinators from academia, pharmaceutical industry, and government; members of RECs/IRBs; representatives of both funding and regulatory agencies; and editors of major health-care journals. In addition, two systematic reviews were conducted to examine existing protocol guidelines and empirical evidence supporting the importance of specific checklist items. Finally, two face-to-face consensus meetings were held to develop and finalize the SPIRIT 2013 statement.

SPIRIT 2013 Statement

The SPIRIT 2013 statement was published in a number of leading international medical journals (e.g., *Annals of Internal Medicine*, *BMJ*, *Lancet*) to provide researchers with high-quality standards for trial protocols. The statement comprises three documents to guide the reporting of clinical trial protocols:

1. A 33-item checklist, which presents the recommended items to address in a clinical trial protocol.
2. An explanatory paper (SPIRIT 2013 Explanation and Elaboration), which details the rationale and supporting evidence for each checklist item. In addition, the paper provides clear guidance and detailed examples from actual protocols.
3. A diagram that provides a template of recommended content for the schedule of participant enrollment and allocation, timelines for interventions and assessments.

Checklist

The 2013 checklist comprises a series of items grouped under a number of core areas.

Administrative Information

The title of the trial; where it has been or will be registered; the version of the protocol; the funding source and types of financial, material, and other support should be stated. Detailed information is needed on the roles and responsibilities of all the protocol contributors as well as the trial sponsors and funders. The governance (e.g., membership and role of coordinating center, steering committee, end point adjudication committee, data management team) of the trial needs to be stated explicitly.

Introduction

The background and rationale for the study and its specific objectives or hypotheses should be outlined. In

addition, the nature of the trial design (e.g., parallel group, crossover), allocation ratio (e.g., equal), and framework (e.g., superiority, equivalence, noninferiority trial) need to be provided.

Methods: Participants, Interventions, and Outcomes

A description of study settings and the inclusion/exclusion criteria for participants should be presented. The intervention should be outlined in sufficient detail to facilitate replication, and information on intervention process (e.g., criteria for discontinuing intervention, extent to which other relevant concomitant care is permitted during trial) is required. The primary, secondary, and other outcomes, including the specific measurement variables, analysis metric (e.g., change from baseline), method of aggregation (e.g., mean), and time point for each outcome, should be stated. The time schedule of enrollment, interventions, assessments, and visits for participants is required; a schematic diagram of the participant timeline is recommended. The rationale and basis of the sample size as well as the recruitment strategies to achieve sufficient participant enrollment should be stated.

Methods: Assignment of Interventions (for Controlled Trials)

The method of generating the allocation sequence (e.g., computer-generated random numbers), and list of stratification factors are required. The mechanism and personnel (e.g., who generates allocation sequence, who enrolls participants, who assigns participants to groups) for implementing the allocation sequence should be stated. Furthermore, the blinding (masking) process should be described.

Methods: Data Collection, Management, and Analysis

Detail on the data collection method should include the plans for assessment and collection of data at each time point as well as validity and reliability of properties of all measures. The plans for data management in terms of data entry, coding, security, and storage, and any related processes to promote data quality (e.g., double data entry) are required. The statistical methods for analyzing primary and secondary outcomes, planned additional analyses (e.g., subgroup analyses), and statistical methods to manage missing data should be specified.

Methods: Monitoring

The composition of the data monitoring committee, summary of its role and reporting structure, a statement of its relationship (e.g., independent) to the sponsor, and any competing interests should be outlined. A description of all planned interim analyses and trial stopping guidelines are required. The process of collecting, assessing, reporting, and managing all reported adverse events should be outlined. Similarly, the process for auditing the trial conduct needs specification.

Ethics and Dissemination

The plans for seeking REC/IRB approval need to be stated; furthermore, the process of communicating important protocol amendments (e.g., change in analyses) to relevant parties (e.g., RECs/IRBs) should be provided. Details on the consenting/assenting process for participants should be clear, as should the details on how personal information is managed to protect confidentiality before, during, and after the trial. A declaration of interests (e.g., financial) for all principal investigators is required. The details of who has access to the data should also be provided. In addition, details on the provisions, if any, for ancillary and posttrial care, and for compensation to those who suffer harm from trial participation are required. The dissemination plan and policies should be clear, including plans for making the data open access.

Appendices

Details on the information leaflets and consent forms should be provided. Finally, plans for the collection, laboratory evaluation, and storage of biological specimens for analysis should be outlined.

SPIRIT Electronic Protocol Tool and Resource

The SPIRIT Electronic Protocol Tool and Resource (SEPTRE) is a web-based software platform that makes it easy to create, manage, and register high-quality protocols for clinical trials. Each field in SEPTRE is based on the SPIRIT 2013 guidance for developing high-quality protocols. It was developed to save time and promote transparency by enabling users to easily register their protocol on ClinicalTrials.gov, track amendments, and generate a SPIRIT formatted document.

SPIRIT Extensions

Since the publication of the 2013 statement, a number of extensions have been published by the group to provide guidance to researchers regarding some specific issues not addressed in the original statement and checklist. The development of these extensions followed a similar process to the development of the original 2013 statement and adhered to the Enhancing Quality and Transparency of Health Research (EQUATOR) Network's framework for guideline development. Systematic reviews were conducted and Delphi groups were held with experts and key stakeholders to refine preliminary checklists. The extensions have been published in high-impact international journals to ensure they reach the research community.

SPIRIT PRO

In 2018, an extension was developed to address the absence of recommendations in the 2013 protocol content relating to patient-reported outcomes (PROs) such as self-rated health or activity levels, symptoms or health-related quality of life. PROs are integral to psychological research and can inform clinical decision-making regarding treatment options. The final SPIRIT-PRO Extension recommends an additional 16 items (11 new items [extensions] and 5 elaborations for existing items) that should be routinely addressed in the SPIRIT checklist for all clinical trial protocols in which PROs are a primary or key secondary outcome.

SPENT

The SPIRIT 2013 checklist focused on clinical trials that provide estimates of average intervention effects; however, such studies do not address intervention response heterogeneity and often exclude those with comorbid conditions and/or concurrent treatments. Furthermore, clinical trials may not be possible for patients with rare diseases.

To address these issues, researchers often use n-of-1 trials to measure intervention effects and to understand individual variation regarding intervention response. The SPENT (SPIRIT extension for n-of-1 trials) guidance was developed in 2019 for n-of-1 trials as such considerations were not part of the original SPIRIT recommendations. SPENT has developed a 14-item extension of SPIRIT for n-of-1 trial protocols, a checklist for n-of-1 protocol abstracts, and additional guidance for eight SPIRIT items where trialists could encounter issues specific to n-of-1 trials. This extension was developed in collaboration with the Consolidated Standards of Reporting Trials (CONSORT) guideline

developers; CONSORT is an initiative that emerged in the mid-1990s to enhance trial reporting standards.

SPIRIT TCM

Researchers examining the effectiveness of Traditional Chinese Medicine (TCM) noted that the application of the SPIRIT 2013 statement to TCM trial protocols was challenging, due to the theory and the characteristics of TCM interventions. Therefore, an extension to the original SPIRIT was developed in 2019 to ensure high-quality trial design with TCM. Seven items from the SPIRIT 2013 statement were modified, and the extension defined the concept of TCM pattern and described three major TCM interventions (Chinese herbal formulae, acupuncture, and moxibustion), with examples and explanations.

SPIRIT-AI

The SPIRIT-AI and CONSORT-AI initiative is an international collaborative effort to improve the transparency and quality of clinical trial reports evaluating interventions involving artificial intelligence (AI). SPIRIT AI involves an 11-item extension and 3 elaborations specific to AI interventions. Both the CONSORT and SPIRIT extensions built upon existing recommendations to address considerations specific to AI health interventions. Both extensions adhered to the EQUATOR process were published in leading international journals in 2020, and the subsequent guidelines are endorsed by key medical journals for the reporting of clinical trials for AI interventions.

SPLIT-HALF RELIABILITY

Measurement is fundamental to almost all forms of research and applied science. To conduct quantitative research, scientists must measure at least one variable. For example, researchers studying the effect of social rejection on self-esteem must measure participants' self-esteem in some way. Similarly, to apply scientific knowledge, practitioners often rely heavily on measurement. For example, school psychologists measure children's academic and cognitive aptitudes to place them in appropriate classes and to identify potential academic difficulties. Given the importance of measurement, researchers and practitioners must evaluate the quality of the measurement tools that they use. Reliability is a key facet of measurement quality, and split-half reliability is a method of estimating the reliability of a measurement instrument.

Reliability

Briefly stated, reliability reflects the precision of scores obtained from a measurement instrument—how closely participants' scores on the instrument correspond to their real characteristics. Unfortunately, many factors can interfere with measurement in any scientific domain, some of which are unsystematic sources of measurement error. Such factors artificially inflate some participants' scores and deflate others' scores in a random, or unsystematic, way. In behavioral research, these factors can include guessing, poorly written items, fatigue, misreading test items, and temporary mood states.

Consider, for example, a participant in a study involving a measure of trait self-esteem (i.e., the degree to which a person sees himself or herself in a generally positive way). Imagine that the participant actually has a high level of trait self-esteem, generally having a positive view of himself or herself. Unfortunately, one or two of the self-esteem questionnaire's items are worded in a confusing manner (e.g., "I rarely feel as if I don't have low self-esteem"). Such items can elicit confused responses that do not reflect accurately the person's truly high level of self-esteem, thereby introducing error and imprecision into the measurement process. As an index of measurement precision, reliability reflects the degree to which test scores are free of unsystematic measurement error.

Reliability cannot be known directly, so it must be estimated. Much as a person's self-esteem is not directly observable and must be estimated from his or her test scores, reliability is not directly observable and must be estimated from a set of test scores. As a fundamental

facet of reliability, measurement error cannot be known in reality—researchers cannot truly know the degree to which a respondent's scores are affected by fatigue, confusing wording, mood states, or any of the many factors potentially affecting test scores. Consequently, reliability must be estimated from the scores obtained on the measurement instrument itself. Split-half reliability is one of many approaches to estimating the reliability of scores on a measurement instrument.

Computing and Interpreting Split-Half Reliability

The split-half method of estimating reliability is most directly applicable to instruments that have multiple items. Indeed, many instruments in behavioral research are tests, questionnaires, inventories, or surveys that include two or more items.

Consider the hypothetical set of responses in Table 1. Imagine that a researcher wishes to estimate the reliability of a four-item test of trait self-esteem, in which each item presents a statement relevant to self-esteem (e.g., “I often feel that I am a good person”). People respond to each item using a seven-point scale indicating their level of agreement with the statements (e.g., 1 = strongly disagree, 4 = neutral, and 7 = strongly agree)—thus, larger numbers reflect greater self-esteem. Peoples' responses are summed to create a total score indicating their level of trait self-esteem. Of course, many good tests include negatively keyed items, for which an endorsement or agreement reflects a low level of the characteristic being measures (e.g., “I rarely feel like I'm a good person”). Such items must be reverse scored before scoring the scale and evaluating reliability. As shown in Table 1, Person 2 has the highest level of self-esteem and Person 4 has the lowest. Being aware that scores on the instrument might be affected by

measurement error, the researcher estimates the reliability of these scores.

The split-half method of estimating reliability can be viewed as a three-step process. First, the test is divided into two subtests, and participants' scores are computed for each subtest. For example, the “split 1” columns in Table 1 present peoples' scores for two subtests—one subtest formed by summing the odd items and one formed by summing the even items (ignore the “split 2” columns for the moment).

Second, the Pearson correlation between the two subtests is computed. This “split-half correlation” reflects the consistency between the two parts of the test. In this regard, note the discrepancy between the two subtests—the differences among peoples' scores on the first subtest are somewhat inconsistent with the differences among their scores on the second. Specifically, on the first subtest, person 2 has the highest score, followed by person 3, and then person 1; however, on the second subtest, persons 2, 3, and 1 have identical scores. That is, subtest 1 indicates differences in these three peoples' self-esteem, but subtest 2 indicates no differences in their self-esteem. This inconsistency between the subtests suggests an imperfect test; a very strong test should include subtests that were strongly consistent with each other. Indeed, the correlation between the two halves is .57 (recall that correlations can be as large as 1.0, indicating perfect consistency). Although this correlation is not a perfect 1.0, it is large enough to indicate a fair degree of consistency—in both subtests, person 4's score is smaller than the other peoples' scores. Because it arises from consistency between parts of a test, split-half reliability is an “internal consistency” approach to estimating reliability.

Third, the split-half correlation is entered into an equation producing the estimate of reliability. The

Table 1 Split-Half Reliability Example Data

Person	Item				Total Score	Split 1		Split 2	
	1	2	3	4		1 & 3	2 & 4	1 & 4	2 & 3
1	3	5	3	3	14	6	8	6	8
2	6	3	5	5	19	11	8	11	8
3	5	6	2	2	15	7	8	7	8
4	2	2	3	2	9	5	4	4	5
Mean	4.00	4.00	3.25	3.00	14.25	7.25	7.00	7.00	7.25
SD	1.58	1.58	1.09	1.22	3.56	2.28	1.73	2.55	1.30

Note: SD = standard deviation.

equation is a form of the Spearman–Brown prophecy formula, tailored to the split-half approach:

$$\text{Split-half estimate} = \frac{2r_{\text{SH}}}{1 + r_{\text{SH}}},$$

where r_{SH} is the split-half correlation obtained in the previous step. Thus, for the previous example, the split-half estimate of reliability is .73:

$$\text{Split-half estimate} = \frac{2(.57)}{1 + .57} = \frac{1.14}{1.57} = .73.$$

This result is an estimate of the reliability of the test scores, and it provides some support for the quality of the test scores. In theory, reliability ranges from zero to 1.0, with higher values reflecting better reliability. In psychological measurement, experts cite reliability of .70 or .80 as being acceptable for research purposes, with even higher reliability being desirable when using test scores for decisions about individuals (e.g., when assigning students to classes on the basis of aptitude scores). Based on these guidelines, the example's test scores are reasonably reliable for research purposes.

A split-half estimate of reliability can be obtained from some statistical software packages. For example, if item-level responses are entered into IBM® SPSS® (PASW) 18.0, an IBM product, then the “Scale . . . Reliability Analysis” procedure offers the “split-half” model as an option. SPSS automatically creates subtests by grouping the first half of the items together and the second half of the items together (note that this is not an ideal method of creating subtests).

Problems and Contemporary Practice

Although split-half reliability was important in the evolution of measurement theory, it is now reported infrequently. Indeed, during the past few decades, the use of split-half reliability has been decreasing while the use of other methods (e.g., coefficient alpha) has been increasing. This trend arises from at least three problems with the split-half method of estimating reliability.

First, subtests can be formed in many ways that can produce dramatically different estimates of reliability. Subtests can be formed not only by combining odd items and combining even items (as was done for the previous example), but also by first-half and second-half (as is done by SPSS), by random assignment of items to halves, and by various other methods. For example, the “split 2” columns in Table 1 present subtest scores for a different method of creating subtests. Specifically, the first item was combined with the fourth item, and the second item was combined with the third item. The correlation between these subtests is

.68, which produces an estimated reliability of .81; this estimate is larger than the estimate obtained from the previous split. In contrast, combining item 1 and 2, and combining items 3 and 4 (as is done by SPSS) produces a split-half correlation of only .09 and an estimated reliability of only .16—dramatically lower than the other estimates. Because the many ways of splitting a test can produce varying estimates of reliability, there is no single value that can be taken as *the* split-half estimate of reliability.

A second problem with split-half reliability is that it does not account for measurement error unique to a single testing occasion. As an internal consistency approach to estimating reliability, the split-half method reflects the item-by-item effects of random measurement error (e.g., items that are confusing or do not fit with the rest of the items, the effect of fluctuating attention, and guessing on some items but not others); however, it does not reflect error affecting responses to the entire set of items. For example, it does not reflect the possibility that a respondent's temporary sad mood artificially deflates her score across all the items on a measure of trait self-esteem. That is, temporary mood states might affect a person's responses to the entire test, but internal consistency estimates such as split-half reliability will not reflect the effects of this form of measurement error.

A third problem is that the accuracy of split-half reliability as a method for estimating reliability depends on several assumptions that are unlikely to be valid in research applications (e.g., the assumption that subtests have identical standard deviations). Because the underlying assumptions might not be true, the split-half approach might not provide good estimates of reliability in many research contexts. Note, however, that all methods of estimating reliability rest on certain assumptions; this is not unique to split-half reliability.

Considering the problems associated with the split-half method as a way of estimating reliability, contemporary researchers tend to use different methods. Specifically, researchers are much more likely to use coefficient alpha (also called Cronbach's alpha), which avoids some problems associated with the split-half approach (e.g., the problem of splitting a test into halves) and is available through statistical software such as SPSS and SAS. Nevertheless, split-half reliability has played an important role in the evolution of reliability theory and in applied measurement.

SPLIT-PLOT FACTORIAL DESIGN

It is often inconvenient, costly, or even impossible to perform a factorial design in a completely randomized fashion. An alternative to a completely randomized design is a split-plot design. The use of split-plot designs started in agricultural experimentation, where experiments were carried out on different plots of land. Classical agricultural split-plot experimental designs were full factorial designs but run in a specific format. The key feature of split-plot designs is that levels of one or more factors are assigned to entire plots of land referred to as whole plots or main plots, whereas levels of other factors are assigned to parts of these whole or main plots. These parts are called subplots or split-plots. Split-plot designs thus have two types of experimental units, whole plots and subplots. The smaller experimental units, the subplots, are nested within the larger ones, the whole plots.

A Sample Design

Consider an experiment in which the effect of different types of nitrogen and grain varieties on the grain yield is investigated. Usually, it is convenient to treat entire plots of land (the whole plots) with the same type of nitrogen, whereas different grain varieties can typically be planted on small plots of land (the subplots) obtained by splitting each whole plot that was treated with one kind of nitrogen only. In this experimental setup, the first factor, the type of nitrogen, is called the whole-plot factor because its levels are applied to whole plots. The factor grain variety is called the

subplot factor of the experiment because its levels are applied to the subplots. A schematic representation of a split-plot design involving type of nitrogen as the whole-plot factor and grain variety as the subplot factor is displayed in Figure 1. The four levels of the whole-plot factor are denoted by $N_1 - N_4$, whereas the three levels of the subplot factor are represented by $G_1 - G_3$. The split-plot design in this example has only one whole-plot factor and one subplot factor. Nevertheless, split-plot factorial designs with more than one whole-plot factor and more than one subplot factor can be constructed too. An example of a design with two whole-plot factors is given in the following discussion.

Design Layout

The layout of a split-plot design resembles that of a randomized block design. The key difference between split-plot designs and randomized block designs is that, in randomized block designs, the factor level combinations are randomly assigned to the experimental units in the blocks. In split-plot designs, a completely random assignment is impossible because all the subplots within one whole plot must be treated with the same level of the whole-plot factor(s). Because of this restriction on the assignment of factor-level combinations to the plots, only a restricted form of randomization is possible. The restricted randomization is carried out in

N_3	N_1	N_2	N_4

Note: The design has eight whole plots, each of which is split into three subplots.

two steps. First, the whole-plot factor-level combinations are randomly assigned to the whole plots. Next, the subplot factor-level combinations are randomly assigned to the subplots within each whole plot. This is done so that each subplot factor-level combination appears once in every whole plot.

Analysis

In the analysis of data from split-plot designs, the whole plots act as the levels of a blocking factor. Therefore, along with the effects of the whole-plot and subplot factors, a random effect is included in the statistical model for each of the whole plots, and advantages similar to the ones for block designs can be obtained using split-plot designs. For example, the effect of the grain varieties in Figure 1 is obtained from the differences between the yields within each whole plot. These differences eliminate the whole-plot effect, so that the effect of the grain varieties is measured with greater precision than the effect of the type of nitrogen. The calculation of the effect of the nitrogen type is not as precise because it involves computing and comparing average yields over all the subplots within a whole plot, and errors between subplots in different whole plots are usually larger than errors between subplots in a single whole plot. For this reason, the effect of the whole-plot factor, type of nitrogen, is tested against the whole-plot error, and the effect of the subplot factor, grain variety, is tested against the subplot error. An attractive feature of split-plot designs is that interaction effects between a whole-plot factor and a subplot factor can be estimated with the same precision as the subplot factor effects, so that they are also tested against the subplot error. Thus, a split-plot design is an excellent design option if powerful inference is desired regarding the subplot factors and the interactions between whole-plot factors and subplot factors.

In a classic split-plot analysis, the whole-plot and subplot factors are treated as categorical, and the analysis of variance (ANOVA) model used to analyze the split-plot data can be written as

$$Y_{ijk} = \mu + \delta_{i(j)} + \alpha_j + \beta_k + (\alpha\beta)_{jk} + \varepsilon_{ijk},$$

$$i = 1, \dots, w; j = 1, \dots, a; k = 1, \dots, b,$$

where Y_{ijk} is the response for the j th type of nitrogen and the k th grain variety in whole plot i , μ is the overall mean, $\delta_{i(j)}$ is the random effect of the i th whole plot nested within the j th level of the whole-plot factor, type of nitrogen, α_j is the main effect of the j th type of nitrogen, β_k is the main effect of the k th grain variety, $(\alpha\beta)_{jk}$ is the interaction effect of the j th type of nitrogen and the k th grain variety, ε_{ijk} is the random error, a denotes

the number of whole-plot factor levels, b is the number of subplot factor levels, and w is the number of whole plots at each whole-plot factor level. In this example, a , b , and w equal 4, 3, and 2, respectively. To make the split-plot model estimable, the factor effects α_j , β_k , and $(\alpha\beta)_{jk}$ are subject to the constraints

$$\sum_{j=1}^a \alpha_j = 0, \sum_{k=1}^b \beta_k = 0,$$

$$\sum_{j=1}^a (\alpha\beta)_{jk} = 0 \text{ for all } k,$$

and

$$\sum_{k=1}^b (\alpha\beta)_{jk} = 0 \text{ for all } j.$$

The effects α_j , β_k , and $(\alpha\beta)_{jk}$ are fixed effects. They are referred to as whole-plot factor effects, subplot factor effects, and whole-plot-by-subplot interaction effects, respectively. The remaining effects in the model, $\delta_{i(j)}$ ($i = 1, \dots, w; j = 1, \dots, a$) and ε_{ijk} ($i = 1, \dots, w; j = 1, \dots, a; k = 1, \dots, b$), are random effects. They are called the whole-plot errors and subplot errors, respectively. The whole-plot errors $\delta_{i(j)}$ are assumed to be independently normally distributed with zero mean and variance σ_δ^2 . The subplot errors ε_{ijk} are assumed to be independently normally distributed with zero mean and variance σ_ε^2 . It is also assumed that each of the whole-plot errors is independent from each of the subplot errors. Under these assumptions, responses from observations in different whole plots are independent, whereas responses from observations within the same whole plot are correlated. The assumed correlation structure is special in the sense that, although two observations in a given whole plot are correlated in advance of the experiment, they are independent once a whole plot has been selected. This correlation structure is usually referred to as a compound symmetric structure.

A general ANOVA table for a classic split-plot factorial design with one whole-plot factor and one subplot factor is displayed in Table 1. In the table, the whole-plot and subplot factors are denoted by A and B , respectively, and a , b , and w denote the number of levels of factor A , the number of levels of factor B , and the number of whole plots at each whole-plot factor level, respectively. The number of observations in the split-plot design equals $N = abw$, whereas the total number of whole plots equals $q = aw$.

A key characteristic of split-plot designs is that the whole-plot factor effects, α_j , are estimated less precisely than the subplot factor effects, β_k . This implies that split-plot designs result in a small power for detecting whole-plot effects and a high power for detecting

Table 1 ANOVA Table for a Classic Split-Plot Factorial Design With One Whole-Plot Factor, A, and One Subplot Factor, B

Source of variation	SS	df	MS	E(MS)

Total	44,452,679.83	23			

subplot effects. Because the interaction effects between a whole-plot factor and a subplot factor, $(\alpha\beta)_{jk}$, are estimated precisely as well, split-plot designs also have a high power for detecting these. Ignoring the split-plot nature of the experiment and analyzing the data from a split-plot factorial design as if they were data from a completely randomized factorial design leads to an underestimation of the variance of the whole-plot factor effect estimates and to an overestimation of the variance of the subplot factor effect estimates and the whole-plot-by-subplot interaction effect estimates. Therefore, ignoring the split-plot nature of the design results in declaring whole-plot effects to be significant too often and declaring subplot effects and the whole-plot-by-subplot interaction effects to be significant not often enough.

The data for the split-plot design depicted in Figure 1 are shown in Table 2. The table clearly shows that the same type of nitrogen was used for every observation in a given whole plot, whereas every grain variety was used exactly once in every whole plot. The corresponding ANOVA table is displayed in Table 3. In the ANOVA table, the effect of the whole-plot factor, type of nitrogen, is tested against the whole-plot error. The effect of the subplot factor, grain variety, is tested against the subplot error, as is the interaction effect between the type of nitrogen and grain variety. The main effect of the subplot factor is highly significant, as well as the interaction effect. The main effect of the whole-plot factor is not significant.

Application

Split-plot factorial designs are applied not only in agriculture but also in many other application areas. Obviously, the whole plots and the subplots then no longer correspond to plots of land. For example, one experimental factor in many industrial experiments is an oven temperature. Typically, an oven has enough space to accommodate several experimental units, to which other factors are applied. In such experiments, each run of the oven plays the role of a whole plot, whereas the different positions in the oven are similar to the subplots in classic agricultural split-plot designs. Another typical situation where split-plot designs are used is in prototype experimentation. Consider for example a wind tunnel experiment where the factors under investigation are the front ride height of a car (studied at two levels), the car's rear ride height (studied at two levels as well), and the driving condition (studied at three levels). A duplicated, completely randomized factorial design would require building 24 different prototypes and putting a new prototype in the wind tunnel

for every single experimental run. Using the split-plot design with 24 observations schematically visualized in Figure 2 would require only eight prototypes to be built. Each of the eight prototypes would then be tested under each of the three driving conditions successively. The two levels of the front ride height are denoted by FRH_1 and FRH_2 . The two levels of the rear ride height are denoted by RRH_1 and RRH_2 . The three driving conditions are denoted by DC_1, DC_2, DC_3 . In this design, the prototypes serve as the whole plots of the design, and the front ride height and the rear ride height are the whole-plot factors. Finally, split-plot designs also are often used in robust parameter design, where the researcher is interested in the precise estimation of interactions between control factors and noise factors. From these applications, it is clear that a more general name would be appropriate for split-plot designs. Several authors have used the term split-unit design as an alternative to split-plot design.

In some settings, for instance those involving large numbers of experimental factors, split-plot factorial designs will not be feasible. In such cases, fractional factorial split-plot designs or response surface designs run in a split-plot format can be considered. Industrial fractional factorial split-plot designs with few whole plots and runs are often analyzed graphically using

Figure 2 Classic Industrial Split-Plot Design

Notes: FRH_1 and FRH_2 , RRH_1 and RRH_2 , and DC_1 , DC_2 , and DC_3 represent the levels of the factors' front ride height, rear ride height, and driving condition, respectively. The design has eight whole plots, each of which contains three observations and corresponds to a prototype.

normal probability plots or half-normal probability plots. The analysis of data from response surface split-plot designs is done using a generalized least squares regression approach.

Experimental settings also exist where split-split-plot designs or strip-plot designs (which are also called strip-block or criss-cross designs) are more convenient than split-plot designs. Both split-split-plot designs and strip-plot designs are natural extensions of split-plot designs, which were also originally used in agricultural research but can be useful in other application areas too. Split-plot, split-split-plot, and strip-plot designs belong to the family of multistratum designs.

SPSS

SPSS is a software package (that originally stood for *Statistical Package for the Social Sciences*) published by IBM. It is a potent tool for quantitative researchers to use to accurately analyze numeric data. Because of its user-friendly interface (no programming is necessary and all commands are menu-driven), SPSS is likely the most popular statistical package for students and quantitative researchers. In this entry, the purpose and functions of the three main file types within SPSS are reviewed, and some tips for using each are provided.

Users

Partly because SPSS has been around since the mid-1970s, it has been used widely across numerous disciplines, extending far beyond just the social sciences it was originally named to serve. It is common in health-care sciences as well as psychology and other social sciences. Its longevity and broad base of users means there are many credible and free resources available to guide both novice and experienced quantitative researchers in its use, including animated movies of

successive screenshots with narrated step-by-step instructions from expert users, including some recorded by university academics as part of their coursework, but made available freely via YouTube and other viewing platforms, as open educational resources (OERs). In addition, there are many embedded user tutorials included in the software itself.

Most universities and many health-care facilities have a corporate subscription to the software, meaning that staff and higher degree research students can use it without personal cost. In addition, SPSS offers a 30-day free trial to users, which can enable it to be used in short projects nested within either industry or educational institutions that do not offer a corporate subscription to all its employees or students.

Advantages and Disadvantages

Because of its wide user base, co-investigators and research students' supervisors are often familiar with the program and comfortable guiding a novice researcher in its use. In addition, the data entry format's resemblance to the even more widely known and used Microsoft Excel software program also fosters rapid acclimation to the software for new users. The screen displays used for both data entry and data analysis are reasonably intuitive and thus are user-friendly to navigate and operate. Further advantages of SPSS include the frequent updates and strong technical support through IBM.

There are of course some disadvantages, including some higher order statistical testing that SPSS does not handle as well as other programs such as R software, where users can program the software themselves to perform specific functions. Some other statistical processing programs offer more sophisticated chart display functions than those available in SPSS, which can produce higher quality graphs, diagrams, and tables that more clearly display in journal articles, theses, or presentations at seminars or conferences.

File Types

Within the SPSS software, there are three types of files: data file (.sav), syntax editor file (.sps), and Viewer file (.spv). This section discusses each of these file types in turn and provides tips for using each.

Data File

The first type, data file, which ends with the suffix .sav, presents like an Excel spreadsheet, with rows and columns in which numeric data can be entered. It is

also possible to take existing Excel files and upload them into the SPSS program.

The data file can be viewed in either a data view, most commonly used for data entry, or a variable view, which is most commonly used for creating new variables and stipulating their properties. In the data view, each row represents a new *case* or patient for instance, and each column is another data point about that case. So, the first row is the first patient, and the first column might be the first variable of age in years for that patient, the second column might be the second variable of highest educational level achieved, the third might be their marital status, the fourth might be gender, and so on.

The data file is the heart of the user's analysis, and it is vital to save it frequently as the user enters the data, with a date naming convention as described later in this entry. It is also crucial to save the data file in multiple locations to avoid loss of work if a device becomes lost, damaged, or corrupted. It is also advisable that not all locations be cloud based, to enable continued progress when an Internet connection is not available and given the slightly higher vulnerability to hacking of cloud storage. All locations need to be password protected, especially if the data are about participants who could be identified from the variables included in the data file.

Careful consideration should be brought to bear on the design of the data file, as it may become quite wide for studies with numerous columns/variables. If data will be manually entered into SPSS from handwritten surveys, then the data file should be laid out in a similar order as the written survey, for ease and accuracy of data entry. Similarly, if data are being pulled from other systems, for instance, electronic medical records or other facility databases, then aligning the order of variables to the order in the source systems can be advantageous. Often data come from online survey platforms, such as Qualtrics or Survey Monkey. Most of these allow a download in an Excel format, which can then be uploaded directly into SPSS. Some online survey programs even allow downloads as an SPSS file. Figures 1 and 2 show a data file with raw data that has been download from Qualtrics, first in variable view and then in data view.

Once all data entry has been completed, data cleaning needs to occur. This step is crucial to complete and have checked by another researcher, prior to using SPSS for data analysis (e.g., for running statistical tests). The user will again need to be sure to save all successive modifications of the data file, with date and time stamps, and an indication as to which data cleaning steps have been taken in each subsequent modification. Missing data need to be identified in the data cleaning

Figure 2 Data File in Data View

stage, and a decision made as to how it will be handled. Cases with missing data may be excluded from the data analysis. Alternatively, the missing value for an isolated variable may be deemed acceptable, particularly if it is demographic data to describe the sample, rather than a predictor variable or an outcome variable.

When the data have been obtained from an instrument with multiple items that need to be scored and summed to arrive at a composite score that represents a value for that variable, then the absence of an answer for one item may make it difficult to calculate the composite score, which is often the critical outcome variable in social science and health-care science research. SPSS can assist in this situation by calculating the average of the participant's scores on the other items and

then inserting that average score into the item that had no data from the participant. Alternatively, the average score for the entire sample for that item number may be used instead. SPSS should also be used to run frequency distributions on all variables, which will assist in identifying outliers that may have resulted from data entry mistakes.

Syntax Editor File

The second type of file is a syntax editor file, which is used by SPSS to record the programming language it used to run the specific statistical tests the user has directed it to run, within the parameters the user has selected. This file type ends with the suffix .sps. This file

type is generated when the user directs SPSS to run tests but usually directs it to do so from *within* the data file. When the user directs SPSS to run a test, he or she will need to stipulate which variables to use from the data file, so viewing them before selecting them is prudent.

Once the statistical tests are executed, the program will create a new .sps file that records the exact syntax used for the test that was run. For auditability, the user should always save the .sps file. Many researchers also recommend copying and pasting the syntax used into the third type of SPSS file, the Viewer file. While SPSS provides some information in the Viewer file of how the testing was conducted, it is not as detailed as that provided in the syntax editor file.

The appeal of SPSS, to novice researchers especially, is the intuitive drop-down menu options available from the tool bar at the top of both data file types and syntax editor file types. Dialogue boxes also prompt the user to make relevant selections among numerous options, and these selections are based on decisions that can be partially guided by embedded contextual help within the program. However, input from an experienced quantitative researcher or a statistician is also highly advisable and may be obtained from co-investigators, research students' supervisors, or a meeting with the statistical consulting teams available in most universities and hospitals. Lastly, there are a vast array of helpful how-to textbooks as well as many OERs such as online videos and slideshow files.

Statistical consulting is best undertaken at the beginning of the project when the tentative research design has been decided. Consultation with a statistician may result in numerous changes to the phrasing of the research question, the operational definitions of variables, the instruments used to measure variables, or the unit of measurement used. It is critical to have this statistical consultation *before* one begins collecting data, and indeed before one even applies for ethical approval, if any data will be collected from human or animal participants. Mistakes in how to measure, collect, or analyze data can be fatal to a project. The research protocol should stipulate which types of statistical tests will be run on which variables within the data set that will be collected, to demonstrate an ethical and rigorous analysis process. It is inappropriate and unethical to collect data and then decide afterward how to analyze it.

Viewer File

The third type of file is a Viewer file, indicated by .spv in the file type. It is sometimes also called an *output file*. This file is generated automatically whenever the user runs a statistical test. Some information about

what variables were used and what tests were run are automatically captured each time in this file. However, it is also advisable to copy and paste the exact programming language string from the syntax editor file, to enable replication of the testing, which is inevitable in rigorously conducted quantitative research. Co-investigators and research students' advisors will often want to audit the novice researcher or student's work to see exactly how tests were executed to ensure all decisions were appropriate choices. The Viewer file is also where any tables or graphics that were *ordered from the menu* will display; these can then be copied and pasted into publication or thesis manuscripts.

It is considerably easier to review the statistical testing that was done, if each test is run on its own and then each relevant Viewer file is saved and named for the statistical test conducted and the variables upon which those tests were conducted. While it may be tempting to just keep running test after test after test, the Viewer file very quickly becomes lengthy and cumbersome, despite a left vertical pane that contains a table of content view. Lengthy Viewer files make it far more difficult to locate tests for later auditing and/or replicating, which is nearly always necessary.

For example, if you were running a statistical test to determine whether age correlates with scores on the Beck Depression Inventory (BDI), you will firstly need to determine whether your distribution was normal for each of the variables involved. You would do this by instructing SPSS to run a frequency distribution on the variable of age, and to produce a graph of same, and then to tick the options to ask it to overlay a bell curve diagram on top of that displayed distribution. These tests would be best saved as their own Viewer file. As mentioned, copy and paste the exact syntax used from the .sps syntax editor file into the Viewer file, so you have documented *how* you ran the test, immediately next to the results you obtained from running that particular test, with those selected parameters.

You would then repeat those steps for your other variable of the scores on the BDI, and again save this as a separate Viewer file. Lastly, after determining the normality (or not) of the distribution of both variables, you would then select the appropriate correlation test from the drop-down menu in SPSS, again selecting output formats of a table and graph. This correlation test would also deserve its own Viewer file, clearly titled as such in the file name.

Including the date on which the test was run as part of the file name is also advisable, especially if tests need to be rerun after further data cleaning processes. Dates formatted from the largest to the smallest unit of time (year, month, and date) will order themselves sequentially in the folder in the user's directory, to show

subsequent testing in order of date. The default setting in file directories places files named with numbers above those named with letters and orders them from lowest to highest (or can be reversed to highest, to put the most recent test on top). Military time can be added after the date, for further specificity and auditability. A time stamp on the work can become critical when doing progressive analyses in a single day, to easily identify the best and final run, after having sorted through any earlier problems.

So for the earlier example, you might have three output files titled as *2021_03_22 at 1423 Age_Freq Dist* and *2021_03_22 at 1438 BDI Freq Dist*, and lastly, *2021_03_22 at 1522 Age BDI Pearson Corr*. Then when your co-investigator, consulting statistician, or supervisor reviews your work and advises you to adjust one of your decisions, perhaps to select a different type of correlation, you can rerun the test and save that output file with the new date and time, for instance: *2021_03_28 at 0928 Age BDI Spearman Corr*.

STANDARD DEVIATION

In the late 1860s, Sir Francis Galton formulated the law of deviation from an average, which has become one of the most useful statistical measures, known as the standard deviation, or *SD* as most often abbreviated. The standard deviation statistic is one way to describe the results of a set of measurements and, at a glance, it can provide a comprehensive understanding

of the characteristics of the data set. Examples of some of the more familiar and easily calculated descriptors of a sample are the range, the median, and the mean of a set of data. The range provides the extent of the variation of the data, providing the highest and lowest scores but revealing nothing about the pattern of the data. And, either or both of the highest and lowest scores might be quite different from the scores in between. The median is the single middle score (or average of the two middle scores) that tends to be used to compensate for unusually high or low scores, but again, it still provides little information about the overall characteristics of the data. The mean is probably the most familiar, as well as easily calculated, descriptor of a given set of numbers. As individuals, we like to know where we fit in comparison to most other people. Countless surveys have been conducted, for example, to determine what “most” people earn or the taxes that most people pay. It is also useful to gauge a school’s educational success by determining whether test scores are above or below average. On a more personal level, it can be interesting to know the average height of the players on one basketball team compared with another. However, although the mean is quick and easy to calculate, it is also subject to distortion by even a single extreme score, or outlier, in the data set. For example, the mean of a set of data can be the same; the mean height of two teams of basketball players might both be 7 feet tall. But, the variability of the players’ heights on each team could be quite different. The height of players on team 1 ranges from 6 feet 9 inches to 7 feet 3 inches. The height of team 2 might realistically cluster around 6 feet tall, but one of their players is 7 feet 6 inches tall. A comparison of the means alone hides the fact that most of team 2 is much shorter than team 1. To obtain insight as to which team might be more likely to win tonight’s game, more information is needed about the true variability of the players’ heights.

To understand that variability, statisticians calculate the standard deviation, which is especially important to research because, although the other measures described previously are useful, the standard deviation provides a more accurate picture of the distribution of measurements. This statistic is an indicator of the distance of individual measurements from the mean score. A low standard deviation indicates that the data points are clustered tightly around the mean value, whereas a high standard deviation indicates that the data are less precise and spread across a large range of values.

For example, Table 1 provides the IQ scores of two samples. In these two samples, both groups have the same mean score of 100; however, the variability of

group 2's data around that mean is about 30% less than the variability of group 1. In this case, a single standard deviation for groups 1 and 2 equals 4.1 and 2.8 IQ points, respectively. This means 2 standard deviations are twice that amount (i.e., 8.2 and 5.6), and 3 standard deviations are three times that amount (i.e., 12.3 and 8.4). Applying these data to a normal curve illustrates the difference in the dispersion of the two samples (see Figure 1). The data from group 1 cluster more tightly around the mean, producing a tall narrow curve, whereas the greater dispersion of data from group 2 produces a shorter broader curve by comparison.

Unlike the closely related measure variance, the standard deviation is expressed in the same units as the data. In the example, the data are IQ scores from two samples; therefore, the standard deviation is a number that represents IQ points. As shown in Figure 2, the standard deviation is specifically divided into three segments: three standard deviations both above and below the mean value. In a normal bell-shaped curve, each standard deviation represents a percentage of the sample scores, which is occasionally referred to as the 68–95–99.7 rule. That is, when normally distributed, 34.1% of the scores will fall above the mean score and 34.1% will fall below the mean for a total of 68.3% (accommodating for rounding error) of the scores within ± 1 standard deviation from the mean. The second standard deviation encompasses 13.6% of the scores such that 95.4% are within ± 2 standard deviations from the mean. Last, the third standard deviation

Figure 1 Differences in the Normal Curve as a Result of Differences in Distribution of the Data Are Illustrated for the Example of Groups 1 and 2

Figure 2 The Relationship of the Standard Deviation and the Normal Distribution of Data as Illustrated by the Group 1 Data Set

Table 1 Group Example of Data Distribution, the Mean, and the Difference of Standard Deviations

Participant	IQ Scores	
	Group 1	Group 2
1	95	95
2	95	97
3	97	99
4	97	99
5	100	100
6	100	100
7	100	100
8	105	103
9	105	103
10	106	104
Mean	100	100
Standard deviation	4.1	2.8

encompasses 2.1% of the sample scores, making up a total of 99.7% within ± 3 standard deviations from the mean. This leaves only 0.3% of scores falling at the two extremes of the normal curve, which means only 3 scores of 1,000 will range beyond ± 3 standard deviations from the mean. So, roughly two thirds of the scores in a normal distribution are within one standard deviation of the mean.

In mathematical terms, Figure 3 represents a compilation of steps, combined into a single equation, that

$$\sqrt{\frac{\sum(X - M)^2}{N - 1}}$$

Where X = The Individual score

M = The mean of the sample (the group of scores)

N = The sample size

Figure 3 Steps, Combined Into a Single Equation, That Are Needed to Calculate the Standard Deviation

are needed to calculate the standard deviation. However, this equation can be broken down into seven steps (but only six simple calculations). Knowing the individual steps for calculating the standard deviation can be useful for removing the mystery and fear surrounding this number, and for understanding its purpose. These steps are as follows:

1. Calculate the mean of your data set
2. Subtract that mean from each of the scores in your data set to determine the individual deviation of each score from the mean
3. Square each of those individual deviations
4. Sum all of the squared deviations
5. Divide that sum by one less than the sample size ($N - 1$)
6. Last, take the square root of that result
7. That final number equals the standard deviation of your data set

Because most data sets are much larger than the example here of two groups of 10, it is fortunate that most spreadsheet and statistical programs include a function that will easily calculate the standard deviation of a set of data. The computer calculation will provide this information for between-group comparisons or for repeated measurements within the same group(s). These calculations are also typically provided as an item contained in the results of other more in-depth statistical analyses (e.g., t tests or analysis of variance).

Although the description and ease of calculating the standard deviation makes this single number seem like the answer to understanding all the important aspects of the data, there are also key limitations to

interpreting precisely what this number means. One of the most important considerations is to know that the standard deviation provides information only about the measurements taken from the sample group(s) that was selected as representing all the possible measurements that could ever be made of that same type. The earlier example of IQ scores is a case in point. The two samples selected in Table 1 are not truly representative of IQ scores of an entire population. The actual standard deviation has been determined by sampling very large numbers of people, testing large numbers of different samples, and testing samples representing a wide range of ages and other characteristics that would be typical of the population as a whole. Therefore, the standard deviations in Table 1 are only an estimate of the true variability within that population. The accuracy of that estimate increases depending on the sample selection and how well the sample represents the population of interest. The accuracy is also highly subject to the size of the sample studied. Larger samples tend to have less variability and be somewhat more representative of an entire population. Somewhat related to the importance of the size of the sample is the number of different samples that are tested. Testing many smaller samples, fewer larger samples, or best of all, testing many large samples, will all improve the accuracy of the estimate of the true variability in a population. The important thing is, as long as these limitations are understood, the standard deviation is still a valuable statistic important to understanding characteristics of the data and to interpreting the results of testing.

STANDARD ERROR OF ESTIMATE

Standard error is the estimated standard deviation of an estimate. It measures the uncertainty associated with the estimate. Compared with the standard deviations of the underlying distribution, which are usually unknown, standard errors can be calculated from observed data.

First, this entry will explain how estimates are obtained. Then, the entry discusses how the standard errors of estimates are derived, with an emphasis on the differences between standard errors and standard deviations. Two examples are used to illustrate the calculation of standard errors of a parameter estimate and standard errors of a future outcome estimate, respectively. Finally, the relationship between standard errors and confidence intervals is discussed.

Estimate

One main purpose of research designs is to make inferences about a population. Many population characteristics are described by numerical measures or can be translated into numerical values. Numeric descriptive measures of a population are called parameters of the population. Common examples of parameters include the percentage of voters supporting candidate Mr. Jones, the average weight of 1-month-old babies, the variance or standard deviation of the annual income of fresh college graduates in year 2008, the correlation coefficient between annual income and years of education, and the increase of average annual income associated with 1 more year of education. In many cases, it is infeasible to sample the whole population, and the sampled information might not be 100% accurate; thus, the true values of the parameters are unknown and need to be estimated. An estimate is an approximation of the true parameter value using specific rules when sampled information is incomplete, noisy, or uncertain. The rule to calculate an estimate is called an estimator, which could be a formula or a procedure. Different estimators give different estimate values for the same parameter, and many statistical methods have been developed to evaluate the good and bad qualities of estimators.

Another main purpose of research design is to make predictions for future events. Often, future events can be characterized by numeric values, such as the highest temperature of an area next week, the life expectancy of someone who has already lived to 80, and the cure rate if a new treatment is applied. The true values of the measurements of future events are unknown until the event happens. Statistical regression models study

the relationship between the specific measurements (outcome) and other related variables (predictors) based on historic data, and then estimate the future values. The estimate of a future value is called a prediction. Although the true values of the regression coefficients are fixed, different models give different predictions for the same future value. Even with the same model the predictions will vary because the regression coefficients, which measure the relationship between the predictors and the outcome, are estimated from a particular sample and vary from sample to sample.

Standard Error of Estimate

The differences between the true value and its estimates are called errors. The exact value of an estimate depends on the estimating procedure as well as the sample used to calculate the estimate. Because the sampled data are a random sample of the underlying population, the estimates vary from sample to sample even when the same estimating procedure is used, especially when the sample size is small. When the sample size goes to infinity, the estimate converges to its expectation, which might or might not be the same as the true value being estimated. The difference between the expectation of an estimate and the true value is called bias. Some estimating procedures produce unbiased estimates, whereas others do not. Both randomness in the sample and bias lead to difference between estimates and the corresponding true value, that is, errors.

The standard deviation of the estimate for a parameter or a future value can be illustrated with the following steps. First, sample a population multiple times. Second, calculate the estimate based on each sample. Third, take the difference between the estimates and the true value, thus a sample of errors is obtained. When the number of samples goes to infinity, the distribution of the errors can be observed. The standard deviation of the errors is the positive square root of the variance of the errors, that is, the expectation of the squared difference between the error and the mean of the error distribution.

In real life, sampling infinite times is infeasible. The error distribution is usually not observed, and the standard deviation of the errors is unknown. Thus, many statistical methods have been developed to estimate the standard deviation of the errors. The estimated standard deviation of the errors in an estimating procedure is called the standard error of the estimate, which is sometimes abbreviated as standard error or SE or S_E . It needs to be pointed out that standard errors are only estimates of the standard deviation of errors, not the standard deviation itself. For example, when an

estimate is divided by its standard error instead of its standard deviation, the resulting test statistic follows a Student t distribution instead of a normal distribution, which will be explained in more detail using the examples in the following two sections. When sample size is large enough, the Student t distribution converges to the normal distribution and standard errors converge to standard deviations as a measure of the uncertainty. Here, whether the sample size is “large enough” or not depends on the particular estimating procedure and the parameter or future measurement being estimated.

Given the standard error of an estimate, then the standard error of its linear functions can be calculated accordingly.

$$SE(X + c) = SE(X)$$

$$SE(cX) = cSE(X),$$

where X represents the estimate and c is a constant.

Standard Error of Estimates of Parameters

Take the standard error of the mean estimate as an example. First, notations are set up. A sample of n independent observations, $X_1, X_2, \dots, X_n$, is taken from a population with mean μ and variance σ^2 . A widely used estimate of the population mean is the average of all observations

$$\bar{X} = \frac{1}{n} \sum_{i=1}^n X_i,$$

where $i = 1, \dots, n$. The mean estimate $\bar{X}$ is normally distributed with mean μ and variance σ^2/n if the distribution of X_i is normal. However, the assumption that X_i follows normal distribution is not always necessary in deriving the distribution of $\bar{X}$. When the sample size is moderately large ($n > 30$), by central limit theorem, $\bar{X}$ from independent identically distributed samples converges to a normal distribution with the same mean and variance σ^2/n . Through some transformation, $(\bar{X} - \mu) / (\sigma^2 / \sqrt{n})$ converges to a standard normal distribution (mean zero and variance one).

The standard deviation of the population is σ , which can be estimated by the sample standard deviation, which is denoted as s in the following equations. That is, the standard deviation based on the observed sample, which serves as an estimate of the population standard deviation σ , is

$$s = \sqrt{\frac{1}{n-1} \sum_{i=1}^n (X_i - \bar{X})^2}.$$

The standard error of the mean estimate can be calculated as

$$SE(\bar{X}) = \frac{s}{\sqrt{n}}.$$

Note that the standard error of the mean estimate is different from the standard deviation of the mean estimate,

$$SD(\bar{X}) = \frac{\sigma}{\sqrt{n}}.$$

Here, $SD(\bar{X})$ will not be known unless σ is known. When people substitute $SD(\bar{X})$ with $SE(\bar{X})$ in calculating $(\bar{X} - \mu) / SD(\bar{X})$, the resulting statistic $(\bar{X} - \mu) / SD(\bar{X}) = (\bar{X} - \mu) / (s / \sqrt{n})$ follows a Student's t distribution with mean zero, variance one, and degree of freedom $n - 1$, instead of a standard normal distribution. Analysts cannot replace the standard deviation with the standard error directly because additional uncertainty is added when an estimate of the standard deviation is used instead of the true standard deviation itself.

Standard Error of Future Outcome Estimates

Take the simple linear regression with one predictor as an example. Suppose the expectation of Y , $E(Y)$, and X have a linear relationship,

$$E(Y) = \beta_0 + \beta_1 X,$$

where β_0 and β_1 are regression coefficients with fixed but unknown true values. When a series of $X_i, Y_i, i = 1, \dots, n$, is observed, because of the randomness associated with each individual Y_i , the linear relationship becomes

$$Y_i = \beta_0 + \beta_1 X_i + \epsilon_i,$$

where the residuals ϵ_i are assumed to follow a normal distribution with mean zero and constant variance σ^2 . The least squares estimators of the regression coefficient, $\hat{\beta}_0$ and $\hat{\beta}_1$, are obtained by minimizing the sum of the squares of residuals. The explicit forms for the least square estimators are

$$\hat{\beta}_1 = \frac{\sum_{i=1}^n (X_i - \bar{X})(Y_i - \bar{Y})}{\sum_{i=1}^n (X_i - \bar{X})^2}$$

$$\hat{\beta}_0 = \bar{Y} - \hat{\beta}_1 \bar{X}.$$

Note that although β_0 and β_1 are constants, $\hat{\beta}_0$ and $\hat{\beta}_1$ are estimated from the sample and vary from sample to sample, that is, $\hat{\beta}_0$ and $\hat{\beta}_1$ are random.

For future observations with $X = X^*$, the corresponding Y values can be estimated as $\hat{Y}^* = \hat{\beta}_0 + \hat{\beta}_1 X^*$.

The error of the prediction $\hat{Y}^*$ is calculated as $\hat{Y}^* - Y^*$, where $Y^* = \beta_0 + \beta_1 X^*$ is the expected value of the future outcome corresponding to X^* . Through some algebra, it can be proved that the standard deviation of the errors is

$$SD(\hat{Y}^*) = \sigma \sqrt{\frac{1}{n} + \frac{(X^* - \bar{X})^2}{\sum_{i=1}^n (X_i - \bar{X})^2}}.$$

Because σ^2 can be estimated by the sample mean square error (MSE)

$$S^2 = \sum_{i=1}^n \{Y_i - (\hat{\beta}_0 + \hat{\beta}_1 X_i)\}^2 / (n-2),$$

the standard error of $\hat{Y}^*$ can be calculated as

$$SE(\hat{Y}^*) = S \sqrt{\frac{1}{n} + \frac{(X^* - \bar{X})^2}{\sum_{i=1}^n (X_i - \bar{X})^2}}.$$

As pointed out earlier, $(\hat{Y}^* - Y^*) / SD(\hat{Y}^* - Y^*)$ follows a standard normal distribution, whereas $(\hat{Y}^* - Y^*) / SE(\hat{Y}^* - Y^*)$ follows a Student's t distribution with degrees of freedom $n - 2$.

Express Standard Errors as Confidence Intervals

Standard errors provide measurements of uncertainty in an estimate and are widely used. In the previous examples, the estimate divided by its standard error follows a Student's t distribution, and the uncertainty of the estimate can also be expressed with confidence intervals. For example, when $(\bar{X} - \mu) / SE(\bar{X})$ follows a Student's t distribution with degrees of freedom $n - 1$, the 95% confidence interval for μ is $(\bar{X} - SE(\bar{X})t_{.975, df=n-1}, \bar{X} + SE(\bar{X})t_{.975, df=n-1})$, where $t_{.975, df=n-1}$ is the 97.5th quantile of the Student's t distribution with degree of freedom $n - 1$. Because $\bar{X}$ and $SE(\bar{X})$ are random and depend on data, the 95% confidence interval is also random and vary from sample to sample. If sampling is repeated multiple times and the 95% confidence interval is constructed each time, 95% of the intervals will cover the true μ value.

If the data are sampled from a normal distribution or the sample size is moderately large ($n > 30$), the confidence intervals based on standard errors can use quantiles from normal distributions. For example, for large n , $(\bar{X} - \mu) / SE(\bar{X})$ converges to a standard normal distribution. Then, the 95% confidence interval for μ is calculated as $(\bar{X} - SE(\bar{X})Z_{.975}, \bar{X} + SE(\bar{X})Z_{.975})$, where $Z_{.975}$ is the 97.5th quantile of the normal distribution. Specifically, interval $(\bar{X} - SE(\bar{X}), \bar{X} + SE(\bar{X}))$ covers true μ 68% of the time, interval

$(\bar{X} - 1.96SE(\bar{X}), \bar{X} + 1.96SE(\bar{X}))$ covers true μ 95% of the time, and interval $(\bar{X} - 3SE(\bar{X}), \bar{X} + 3SE(\bar{X}))$ covers true μ almost all the time.

When the distribution of the estimate divided by its standard error is unknown, conservative confidence intervals for the true value can be calculated, where the standard errors are derived using relationships such as Chebyshev's inequality.

STANDARD ERROR OF MEASUREMENT

The standard error of measurement is a statistic that indicates the variability of the errors of measurement by estimating the average number of points by which observed scores are away from true scores. To understand standard error of measurement, an introduction of basic concepts in reliability theory is necessary. Therefore, this entry first examines true scores and error of measurement and variance components. Next, this entry discusses the standard error of measurement and its uses. Last, this entry comments on methods for reducing measurement error.

True Score and Error of Measurement

When psychological tests are administered, points on items measuring the same construct are aggregated to generate the raw score for each respondent. The raw score, or observed score, can be conceptualized as the sum of two distinct components, the true score and the error of measurement. The true score is caused by systematic influence that produces consistency to the observed score on the test. Note that the true score does not speak to the true standing of an individual on the construct; instead, it only indicates the unchanging portion of the observed score. The error of measurement is a result of chance influence that produces random variation to the observed score on the test.

**Observed score =
true score + error of measurement**

The concepts of the true score and the error of measurement can be illustrated with the next example. Consider an examinee who takes an ability test and assume that the same test can be administered multiple times without him or her remembering the test items. The examinee's observed score might be influenced by factors such as his or her true ability level, test-taking skills, lucky guessing, and fatigue. The portion of the observed score contributed by the ability level and the test-taking skills is invariant across different possible administrations of the test, as long as his or her ability and test-taking skills remain unchanged. This consistent portion of the observed score is defined as the examinee's true score. Note that the true score might be influenced by his or her level of the construct, that is, his or her ability level, as well as factors that are irrelevant to his or her level of the construct, such as his or her test-taking skills.

In contrast, fatigue and lucky guess might vary on different administrations of the test, so their effects are transient rather than systematic. The portion of the observed score associated with these transient factors is the error of measurement. The error of measurement is random, being positive sometimes and negative other times, and when the same test is taken by the examinee for a large number of times, the average of the error will approach zero. In other words, the average of those observed scores will approximate the true score.

Variance Components

The amount of variation in observed scores on a test from a population of interest can also be partitioned into two components: variation caused by true scores and variation caused by an error of measurement. When expressed in terms of variance components:

$$\text{Observed score variance} = \text{true score variance} \\ + \text{error variance}$$

The reliability of a test is defined as the extent to which the observed score variance is caused by true score variance. With the same amount of observed score variance, the larger the true score variance, or the smaller the error variance, the more reliable a test is. Reliability can be expressed as follows:

$$\text{Reliability} = \frac{\text{true score variance}}{\text{observed variance}} \\ = 1 - \left(\frac{\text{error variance}}{\text{observed variance}} \right).$$

Reliability can be understood as the degree to which a test is consistent, repeatable, and dependable. The reliability coefficient ranges from 0 to 1: When a test is perfectly reliable, all observed score variance is caused by true score variance, whereas when a test is completely unreliable, all observed score variance is a result of error. Although the reliability coefficient provides important information about the amount of error in a test measured in a group or population, it does not inform on the error present in an individual test score. The standard error of measurement is used to determine the effect of measurement error on individual test scores so as to aid decision making on individual outcomes. Serving in a complementary role to the reliability coefficient, it also functions as another important indicator of the psychometric quality of a test or measure.

Standard Error of Measurement

The standard error of measurement is the standard deviation of error of measurement in a test. It is closely associated with the error variance, which indicates the amount of variability in a test administered to a group that is caused by measurement error. The standard error of measurement (*SEM*) is expressed as

$$\begin{aligned} SEM &= \sqrt{\text{error variance}} \\ &= \sqrt{\text{observed variance} \times (1 - \text{reliability})} \\ &= \text{standard deviation of observed scores} \\ &\quad \times \sqrt{1 - \text{reliability}}. \end{aligned}$$

The standard error of measurement is a function of both the standard deviation of observed scores and the reliability of the test. When the test is perfectly reliable, the standard error of measurement equals 0. When the test is completely unreliable, the standard error of measurement is at its maximum, equal to the standard deviation of the observed scores. An additional advantage of the standard error of measurement is that it is in the original unit of measurement. With the exception of extreme distributions, the standard error of measurement is viewed as a fixed characteristic of a particular test or measure. Whereas the Pearson product-moment coefficient measure of reliability is commonly used for the calculation of the standard error of measurement, others have argued that the intraclass correlation coefficient is a more appropriate one to use. This is additionally complicated by the fact that different formulas can be used to calculate the intraclass correlation coefficient. Still others have pointed out that the standard error of measurement can be calculated from the square root of the mean

square error term in a repeated-measures analysis of variance (ANOVA).

Given that the overall variance of measurement errors is a weighted average of the values that hold at different levels of the true scores, the variance found at a particular level is called the conditional error variance. The square root of the conditional error variance is the conditional standard error of measurement, which can be estimated with different procedures.

In the previous example of the test taker, with multiple administrations of the same test without the memory and practice effect, his or her observed test scores will form a normal distribution with the mean at the true score, and the standard deviation of his or her observed test score will approximate the standard error of measurement. This is an approximation because the standard error of measurement is estimated on a group instead of on an individual. Indeed, the estimate is an overall value for the whole test, and researchers have shown that standard error of measurement can be different at different levels on the scale score (i.e., conditional standard error).

Probabilistic Statements Around True Scores

With the standard error of measurement, probabilistic estimates can be generated around true scores, using the normal curve and the standard normal table. Given a true score, confidence intervals can be constructed around the true score to estimate the probable range of observed scores. When a given true score is determined as the cutoff score for decision-making, individuals with true scores at or above the true score level can nevertheless obtain observed scores below this cutoff. To account for the effect of measurement error, confidence intervals can be created to estimate the cutoff for observed score so that one can ensure that a certain percentage of individuals (e.g., 68%, 95%, etc.) whose true scores are higher than the true score cutoff will be selected. The confidence interval can be created using the following formula:

$$\text{Confidence interval} = \text{true score} \pm z \times SEM,$$

where z is the z score associated with the desired probability level, which is available in standard normal tables. For example, when an IQ true score is determined as the cutoff of eligibility for an academic program, and the standard error of measurement is known in the relevant population, setting the cutoff observed score to one standard error below the cutoff true score can ensure that 68% of test takers whose true scores are above 100 will be selected.

Using standard error of measurement, one can also estimate the likelihood with which an observed score

comes from a given true score by calculating the corresponding z score, using the following expression:

$$z = \frac{(\text{observed score} - \text{true score})}{SEM}.$$

After obtaining the z score, one can look up the probability associated with the z score from a standard normal table. For example, when an observed score is two standard errors higher than a true score of interest, the z score associated with the probability is 2, and there is only around a 2.5% chance that the observed score came from an individual having the said true score.

Probabilistic Statements Around Observed Scores

When an observed score is known, confidence intervals might be placed around the observed score to estimate the probability of obtaining a certain true score. For example, one might wish to find out the probable range of a test-taker's true score given his observed score. The correct estimate of the confidence interval around observed scores, presented by Harold Gulliksen, is slightly more complex and does not involve standard error of measurement. However, the standard error of measurement is often used to place confidence intervals around observed scores in practice, despite cautionary notes by some authors against such use. Gulliksen suggested the use of $\text{Observed score} \pm z \times SEM$ to estimate true score, noting that this interval provides "reasonable limits" of true score estimates if precise probability statements are not made. The use of standard error of measurement to create intervals around observed scores can be a good approximation if the reliability is reasonably high and if the observed score is close to the mean of the reference group. Given these two conditions for approximation, it is somewhat misleading when confidence intervals are constructed around the observed score to create probabilistic estimates of the true score.

Difference Between Observed Scores

When testing the significance between two observed scores, the standard error of measurement is not applicable because difference scores are less reliable than single scores. Instead, the standard error of measurement of score difference is used:

$$SEM_{\text{difference}} = \text{Standard deviation of observed scores} \sqrt{2 - \text{reliability}_1 - \text{reliability}_2}.$$

If the difference between two observed scores is more than two standard errors for score difference, one can be 95% confident that the true scores are different between these two test takers.

Typical Use of Standard Error of Measurement

The standard error of measurement is used in industrial and organizational psychology in three typical ways. An applicant's test score can be compared with a cutoff true score to determine the likelihood of obtaining a score above or below the cutoff after retest. Scores between two applicants can be compared with each other to determine whether they are different from each other. Given the means of two groups, the difference between the means can also be compared using the standard error of measurement.

In the educational arena when high-stakes testing (e.g., college admissions or determination of qualification for special education services) is involved and test scores are used for classification purposes, errors of measurements are highly consequential. In such circumstances, it would be useful to report conditional standard error of measurement near the cutoff scores or critical values used for such decisions.

The Standards for Educational and Psychological Testing has recommended that both overall and conditional standard error of measurement be reported when test information is disseminated. In addition, these standard errors of measurements need to be provided in raw scores and original scale units as well as each derived score to be used in interpretation.

Preventing Measurement Error

Jum Nunnally and Ira Bernstein have indicated that it is usually better to prevent measurement errors from occurring in the first place than trying to assess their magnitude and effects after the fact. They suggest some useful steps to reduce measurement error, which include writing items that are clear, ensuring that test instructions are easily understood, and adhering to the prescribed conditions for test administration. Other recommended steps include making subjective scoring rules as explicit as possible and investing in the training of raters to do their jobs well.

STANDARD ERROR OF THE MEAN

The standard error of the mean is a number that represents the variability within a sampling distribution. In other words, it is how measurements collected from different samples are distributed around the mean of the total population from which the sample measurements could be taken. The mean of each sample of measurements, therefore, is an estimate of the population mean. Although the means from each sample provide an estimate of the mean of the entire population, measurements collected from numerous samples are quite unlikely to be equivalent. This raises the question of how well each sample mean represents the true population mean. That accuracy can be estimated by calculating the standard error of the mean, which provides an indication of how close the sample mean is likely to be to the population mean.

In random samples of the population, the standard error of the mean is the standard deviation of those *sample* means from the population mean. So strictly speaking, the functional difference between the two measures is that the standard deviation is used to calculate the variability of *individual measurements* around the mean of a sample, and the standard error of the mean is used to calculate an estimate of the variability of *the means of multiple samples* around the mean of the population. The formula for calculating the standard error of the mean (see Figure 1) is closely related to that of the standard deviation (for calculation, see Figure 3 in Standard Deviation entry) in that it is the standard deviation divided by the square root of the sample size. And, like the standard deviation (see Figure 2 in Standard Deviation entry), the means of 68.3%, or about two thirds, of all the sample means will be within ± 1 *standard errors* of the mean (rather

than ± 1 standard deviation), 95.4% will be within ± 2 standard errors of the population mean, and 99.7%, or almost all the sample means will be within ± 3 standard errors from the population mean (only 0.15% will be more than three standard errors either above or below the population mean).

For example, assuming the height of all individuals in a total population of 330 people was measured, the mean of those measurements would be the true mean of that entire population. Because it is rarely feasible to conduct an experiment that tests an entire population (and entire populations are typically much larger than this fictitious example), experimenters collect data from smaller samples that are randomly selected from the population. The size of the sample will influence the accuracy of the estimate of the true population mean. Looking at Figure 2, the graph on the left shows data for 6 samples of 5 individuals each and the graph on the right shows data for 6 samples of 50 individuals each. For both graphs, each vertical line (with the cross bars on the ends) shows the spread of the data in that sample (asterisks and circles represent

extreme values within each sample), and the heavy horizontal line is the mean height of the individuals in each sample. The horizontal dotted line on each graph illustrates the location of the true mean of the total population of 330 individuals. The means of each of the small samples (left side, $n = 5$) deviate from the true population mean much more than the means of each of the larger samples (right, $n = 50$). The means of the smaller sample sizes also show much more variability in the distance from the population mean. On both graphs, the calculated estimates of the deviation of those sample means from the population mean (i.e., the standard error of the mean) are shown just above the x -axis. Comparing the standard error calculations on each graph, it is easy to observe that the larger samples provide a more consistent and truer estimate of the population mean than the smaller samples. The larger samples deviate from about one half to two thirds of a standard error from the mean, whereas the smaller sample sizes vary from one half to more than two and a half standard errors from the mean. Clearly, when feasible, testing a larger sample will provide a better estimate of the population, although there are practical limits.

Another way to view the effect of the sample size on the standard error of the mean is to calculate the standard error holding the standard deviation constant (numerator, Figure 1) while increasing the size of the sample (denominator, Figure 1). For example, if the standard deviation is held constant at 20, and the standard error of the mean is calculated for sample sizes from 1 to 50 (see Figure 3), when the sample size is small there is a large difference in the estimate of the standard error of the mean. Small samples, as noted previously, do not

$$\sqrt{\frac{SD}{n}}$$

Where SD = The standard deviation of the sample

and n = The size of the sample

Figure 1 Formula for Calculating Standard Error of the Mean

Figure 2 The Effect of Sample Size on Accuracy of Estimating the Population Mean

Note: The population mean = 67.7 inches tall (dashed line).

Figure 3 The Function of Sample Size on the Standard Error of the Mean

Note: Holding the SD constant at 20.

necessarily provide a good estimate of the population mean and increasing the sample size can have a considerable effect on increasing the accuracy of the sample mean as an estimate of the population mean. However, as the sample size continues to increase, the difference in the standard error begins to level off. Increasing the sample size no longer has much effect on how well the sample represents the population and the benefits of a larger testing sample are diminished.

It bears repeating that the standard deviation is the deviation of individual observations from the mean of the sample, and the standard error is the deviation of sample means from the mean of the population. The standard error of the mean and the standard deviation are closely related and many consider the two as equivalent terms; as long as one is reported, plus the sample size, the other can be easily calculated. Although this is true, others argue against using the standard error of the mean to represent variability when publishing data because it is the standard deviation that describes the actual variability within the sample being reported, and the standard deviation is, by definition (see Figure 1), larger than the standard error of the mean. This argument contends that it is misleading to report the smaller standard error of the mean, which is only an estimate of how well the sample represents the true population mean. Whereas it is essential not to lose sight of the fact that the initial sample can only be an estimate of the population characteristics, as long as the distinctions between the two statistics are understood, both can provide important information about the characteristics of the sample and the population from which it was drawn.

STANDARDIZATION

Standardization is a term that is used in variety of ways in research design. The three most common uses of the term relate to standardization of procedure, standardization of interpretation, and standardization of scores.

Standardization of Procedure

Standardization of procedure is highly important in any kind of research design and essentially refers to experimental control. This is relevant for any test or experimental procedure and includes the standardization of instructions, administration (including manipulation), and measurement of variables of theoretical interest. Instructions need to be as clear as possible for the particular population. The presentation order of test material or experimental manipulations needs to be identical between people, trials, or conditions. Time constraints might be specified. In many test designs, instructions might also include ways of handling questions of participants. For some tests, oral instructions might include the consideration of rate of speaking, tone of voice, inflections, facial and bodily expressions, or pauses. For example, correct answers might be given away if smiling or pausing when a critical test item is being read out loud. In essence, this type of standardization tries to reduce the influence of any extraneous variable on the test or experimental performance of participants. A lack of standardization of procedure will lead to unreliable results, which in turn will threaten the validity of the test or experiment. The standardization of procedure as a term is more often

used in the context of test development (e.g., test instructions, item order, and time limits) than in experimental design. In experimental designs, researchers are concerned with internal and external validity, which is often treated as a separate topic.

Standardization of Interpretation

The standardization of interpretation refers to the standardized interpretation of obtained scores. This is of particular importance in test administration and interpretation. Here, the concept of so-called norm groups is central. Psychological tests have no predetermined standards against which performance of individuals or groups of individuals can be evaluated. Therefore, scores are typically compared with some norm, which is the performance of others obtained using the same test. Norms imply some form of normal or average performance. For example, if the typical 8-year-old child answers 10 questions of 50 correctly, then this would be the norm for 8-year-olds. Without knowing the average performance of a comparable group, the raw score of 10 correct answers is meaningless. The raw scores on tests could include the number of correct answers (or percentage of correct answers), number of errors or mistakes, reaction times, mean or modal response to some attitude item, or some other objectively measurable indicator relevant for the content of the test. In addition to such age norms, percentile ranks or grade norms are other typical examples. To obtain these norms, tests are administered to large and representative samples drawn from the population for which the test is being designed. This is an essential element of test standardization. The quality of the test norm depends on this so-called standardization sample chosen for norming the test. For example, if a test is developed to measure mental abilities for managers, it would be meaningless to norm the test on patients who underwent psychiatric treatment.

The utility and applicability of norms is hotly debated. Norms are important in many applied contexts (e.g., in mental health, educational, and work settings), where decisions need to be made about individuals falling above or below some particular normative criterion (e.g., for selecting individuals for therapy, students for university entry, or new employees likely to meet performance targets). However, norms often change over time and can be highly context specific. The Flynn effect (named after James Flynn) is the most well-documented case for the temporal instability of norms. IQ scores have been steadily increasing over the decades, requiring constant renorming of IQ tests. Using outdated norms could lead to invalid inferences about individuals. Similar problems exist in regard to

the applicability of norms across culturally and ethnically diverse populations. The interpretation of test scores can be highly misleading if inappropriate norms are used. In many societies, minority groups do not have the same access to education and professional development. If norms developed for majority group individuals were applied to minority group individuals, then inappropriate conclusions would be drawn if the test performance is influenced by these differences in educational opportunities (or other socioeconomic variables that put minority group members at disadvantage). Some critiques have therefore called for local norming (establishing norms based on specific local populations), and some have even suggested an abandoning of the use of test norms altogether. Although some of the criticism of norms is justified, abandoning norms would be counterproductive and problematic in practical settings. It would also open the door for more subjective and potentially discriminatory practices, which are the very issues that critics of norms are concerned with.

Standardization of Scores

The third use of standardization is in relation to individual or group scores. This is somewhat associated with the previous usage of the term, because one particular way of norming scores is to express raw scores in the form of z scores (sometimes called standardized scores). Individual scores are expressed in units that indicate the position of the individual relative to the distribution of scores in his or her group. A score of 0 would indicate that the individual has a score that is exactly at the mean of the group, whereas a score of 1.0 would mean that the individual scores one standard deviation above the mean for this group. Like scores based on some population norms, these z scores allow normative interpretations. Nevertheless, the ad hoc sampling of participants (typically using relatively small samples of university undergraduate students) together with often non-normal distributions of psychological variables in small samples precludes meaningful comparisons of z scores across studies and samples. One alternative is to compute so-called percent of maximum possible (POMP) scores, which express raw scores in terms of the maximum possible score. Any score can be converted into POMP scores by taking the raw score minus the minimum score and then dividing it by the possible scoring range. If test scores had binary response options, this would be equivalent to the percentage of correct answers. If multiplied by 100, the converted scores range between 0 and 100. This scoring method standardizes the scores so that they can easily be compared across alternative

scoring methods, populations, and instruments. They have the advantage of conveying immediate meaning. Many psychological tests have different answer scales and it is often not clear how a score of 3 on a scale from 1 to 4 compares with a score of 3 on a scale from 0 to 4. This arbitrariness of scaling hinders efforts to build a more cumulative science. However, POMP scores do not address the relative meaning of scores compared to some real or statistical norm. For example, a score of 55 only indicates that the individual could have reached a score of 100 but only achieved 55. It does not indicate whether 55 is a particularly high or low score on that construct.

Standardization to Adjust for Response Styles

Another application of standardization of scores is common in the psychometric and more recently in the cross-cultural literature, in particular if subjective evaluations of attitudes, personality, values, beliefs, or some other psychological construct are being measured using some form of rating scale. It deals with the same problem of score comparability, but this time the concern is the presence of response styles or biases that might distort observed scores. The two most commonly discussed response styles are acquiescent responding (also called yay-saying and its opposite nay-saying) and extreme responding (also called modesty responding). Acquiescent responding results in some upshifting or downshifting of mean scores independent of item content, whereas extreme responding is the selection of more extreme scores (either acceptance or rejection) than would be expected based on the true level of the underlying construct. Such tendencies can be expressions of individual differences or can be characteristics of cultural groups, indicating some cultural response or communication style. If individuals or groups are more likely to agree with items or endorse more extreme statements than they actually hold, this will certainly create problems in the interpretation of scores. In practical contexts, this might lead to the invalid selection of candidates in educational or occupational settings or incorrect diagnoses on self-rated mental health checklists. In research contexts, it might obscure real between-group differences, or more typically, will result in differences that are spurious and not related to the construct of interest. For example, it has been observed that Japanese participants typically use the middle category of a response scale, which is independent of item content. If we were to compare Japanese and U.S. samples (that typically do not show the same response style), many significant differences might be found reflecting this difference in response styles, but not differences in the measured psychological construct. It can

also lead to paradoxical findings if the scores of different subgroups with different response styles are combined and the data are being analyzed in the whole sample without considering the different score means in the subgroups. Imagine a researcher has measured the frequency of laughing each day and the number of times individuals cry during the week. There is a negative relationship in each group separately (the more you cry, the less you laugh). However, one group gives higher responses irrespective of item content (assuming that the overall emotional responsiveness is not different between groups). If the data from the two groups are pooled, the relationship between crying and laughing might become zero or even positive because of the different positions of the two groups. Therefore, ignoring response styles might lead to paradoxical relationships between constructs. Several standardization or score adjustment procedures have been discussed in the literature.

The first procedure has already been discussed, namely z transformation. If scores are z transformed in each group, it effectively removes any mean differences between the two groups and might circumvent the problems described in the crying/laughing example. This will work well in situations where researchers are conducting structure-oriented tests, that is, tests examining relationships between constructs using correlational techniques (correlation, regression, factor analysis, path modeling, etc.). However, this will not work if researchers are interested in examining means or true levels of the underlying variable (so-called level-oriented tests, e.g., t test and ANOVA). In this case, using z transformation will remove any between-group differences (because the mean will be standardized to zero in each group separately). It will also not work if there are individual differences in responding.

A second strategy that has been used frequently, especially in the personality and cross-cultural literature, is within-subject standardization or ipsatization. Each individual's score on each variable will be adjusted for the total mean across all variables for that person. This adjusts for overall personal tendencies to respond more positively or negatively, adjusting for acquiescence responding of individuals. If the standard deviation for each individual is used for adjustment, then it might also control for extreme responding. Therefore, each score is then expressed as the relative standing of that person on that variable in relation to all other variables that are used for within-subject standardization. The overall score for that person across all items is consequently zero. Using the crying versus laughing example again, if we standardized the responses of individuals, the adjusted score after ipsatization could be interpreted as the relative frequency of

laughing compared with crying (and vice versa). This has important theoretical and statistical implications. Theoretically, using within-subject standardization or ipsatization, a researcher would assume a limited resource, or fixed-size pie scenario. This might or might not make sense in particular areas of investigation. Using the crying/laughing example, we would assume that all people have the same level of emotionality and spend all their time either crying or laughing. In motivational research, it might be logical to assume that individuals have only a limited area of energy, and therefore there is a balance or trade-off for where this energy can be invested. However, a different motivation researcher might assume that some individuals have higher levels of motivation overall and would like to predict what personality variables are associated with this overall level of motivation. In this case, ipsatized scores would not be useful.

Another problem is that if all the scores are influenced by an unmeasured third variable, it might also obscure any differences and lead to paradoxical results after standardization. Standardizing the length of the body features of a mouse and an elephant might lead to the conclusion that the tail of the mouse is longer than that of the elephant. However, because both are related to the overall size of the animal, this statement is certainly incorrect (if scores are interpreted as absolute measures). This form of standardization therefore raises important theoretical questions about the meaning and interpretation of such scores.

Within-subject standardization is also problematic mathematically because it creates ipsative scores. It results in mean scores that are constant for each individual, and each score for an individual is linearly dependent on scores on all other variables, while being independent of the scores of other individuals. This implies mathematically that the sum of variances and covariances is zero in each row and column of the covariance matrix. This will create problems for factor analysis and other multivariate tests that require creation of an inverse matrix. This standardization also forces at least one of $k - 1$ (with k being the number of variables) covariance terms in each row and column to be negative, independent of the substantive relationship. This can have important theoretical consequences, because at least one negative correlation in a correlation matrix is not determined by the relationship between constructs or scores but by pure methodological artifacts. Furthermore, both the average correlation between all variables (which will be negative) and the relationship between standardized scores and external criterion variables (which will always sum up to zero) are known. The implications for standard statistical tests are wide-ranging. Reliabilities are affected, factor

analyses might yield uninterpretable loading patterns, and mean scores can be seriously overestimated or underestimated. Some of these effects are mitigated if a large number of unrelated constructs is used in research. Some guidelines say that ipsatization might work if it is based on at least ten unrelated constructs. However, from a practical perspective in that case, there would be little need for within-subject standardization. Using nonparametric tests, many of these aforementioned problems can be overcome. However, nonparametric tests are not as widely used, are less well understood, and are often less powerful and stringent. There have also been a lot of recent efforts to overcome some of these problems with more advanced multivariate methods (such as structural equation modeling). However, the results are somewhat mixed and it needs to be determined to what extent ipsative scores can be used with modified multivariate tests.

Another type of score adjustment that has been used primarily in the cross-cultural literature is within-culture standardization. Here, the score across all items and individuals within a group is used for adjusting each score of each individual within a sample. The idea is to remove cultural response styles. Again, if the standard deviation is used in addition to (or instead of) means for adjustment, the adjusted scores might also control for cultural extreme responding. This method raises somewhat similar theoretical problems, if the constructs are highly related. However, the statistical implications are less severe, especially if larger numbers of variables are being used.

Sometimes, double-standardized scores have been advocated in the cross-cultural literature. Here, the scores are first ipsatized and then these ipsatized scores are corrected using within-culture standardization. This strategy will remove both personal and cultural response styles, but the meaning of the resulting scores can be ambiguous. It also creates problems associated with ipsatized scores, and multivariate statistical tests might not run properly.

A final but less frequently recommended and used method is to use covariate analyses to adjust for the overall response tendency of the individual. Similar to within-subject standardization, the overall mean across all items or scores for an individual is created and then partialled in an analysis of covariance or partial correlation. This use of the covariate analysis has many of the same problems as ipsatized scores. In addition, it might create problems of singularity (where the criterion variable is perfectly related to the predictor variable, in this case the covariate variable is partialled first).

The use of these techniques has increased during the last three decades, even when accounting for

the increased publication rate. It certainly reflects the increased trend to use self-reports in psychological and social research, and it also demonstrates an increasing awareness among researchers about the problems of using raw scores to make cross-cultural or cross-ethnic comparisons. Nevertheless, the use of these score adjustment procedures is not without problems, and researchers should exercise caution when using them. For research purposes, it is better to model such response style factors and estimate the effect directly rather than controlling for it without knowing the exact extent and nature of it. It is also possible to use within-subject designs to control for individual differences in reaction to stimuli.

STANDARDIZED SCORE

There are times when it is important to compare the scores of different types of data that are scored in different units or to compare scores within a sample or a population. One common example is that students typically want to understand how their test score compares with the scores of the rest of the class. Or they might want to understand how their scores compare across different classes, which could each be scored using somewhat different methods. In either case, the challenge is somewhat like attempting to compare apples with oranges. A standardized score is calculated on an arbitrary (but universal) scale, which has the

effect of turning the apples and oranges into pears, scores that can be more easily evaluated and interpreted. In other words, a raw score can be converted from one measurement scale to another to facilitate data comparison. This entry discusses comparative and standardization methods.

Comparative Methods

Several different methods are used to create scores that are comparable with one another; however, some of the more familiar methods can have limited comparative accuracy. For example, there are 23 students who are each taking mathematics, history, and psychology mid-term exams. One student, Ben, scores a 53 in math, 77 in history, and 88 in psychology. Comparing these scores, it seemed to Ben that he is not very good at math. But these are raw scores that can tell us only the number of questions that were correctly answered on each examination. Without a frame of reference, it is not possible to determine Ben's standing in each class relative to the other students or to understand the relationship of his performance across his different classes. One way to understand Ben's performance compared with the other students is to use the range of examination scores within each class. In this example, the scores of all the students who took the math examination ranged from a low of 48 to a high of 57. This means Ben's score was just above the middle of that range, which might indicate his score is close to average when compared with the rest of the class. The history exam scores ranged from 75 to 99, so Ben's score was nearly at the bottom of that range, seeming to be a very poor score compared with the other students. And, the psychology scores ranged from 86 to 90, which puts Ben's score precisely in the middle of the range of his classmates' scores.

A somewhat more useful way of calculating scores for comparative purposes would be to calculate the percentage scores for each examination (i.e., number of correct answers divided by total possible correct answers, then multiplied by 100). This type of calculation might provide more equitable scores for a comparison within and between classes. Because the percentage scores (not to be confused with percentile scores) are dependent on the total number of questions on the examination, converting Ben's raw score of 53 on his math examination to a percentage might show that his score compares differently both within and between his classes than when using simple range values for comparison. Some might immediately think that calculating percentages solves the comparison problem: not necessarily and, most likely, not adequately for accurately understanding Ben's

performance within each class, or his overall performance when comparing across his classes. Ben's math exam had a total of 150 questions, so his raw score of 53 converts to 35%. His history test had 100 questions, so his raw score of 77 remains at 77%. And, his psychology test had 90 questions, turning his raw score of 88 to 98%. When comparing scores calculated as a percentage of the total instead of comparing raw scores, it seems that Ben's math score is even worse than he originally thought. *But*, Ben's math instructor creates very difficult exams and on this exam everyone in the class scored from 32% to 38%. Consistent with the comparison of the range of scores, his score of 35% falls precisely in the center of the class percentages, which could mean he is actually an average student. On the history exam, the other students scored from 75% to 99%. Ben's score of 77% is well below average, and it is still consistent with his ranking using the range of scores. But, on the psychology exam the other students scored from 92% to 100%, which indicates Ben's score of 98% is close to the top of the class, a fairly substantial increase from the comparison using the range of scores. However, that there are differences between the two comparison methods makes it very difficult to determine which set of comparisons are correct. Furthermore, while there are indicators of the spread of the scores from each exam using the upper and lower ends of either the raw or the percentage scores, neither method provides information about the variability of the scores. If only one student scored lower than Ben on the math exam and the rest scored very close to the top of the range, Ben's score would not be average after all. Although his score was *numerically* in the middle of both the range and percentage scores, he actually got the second lowest score of all the 23 students. And, because the range and the percentage scores are determined only within each group, both types of scores are insufficient for comparing Ben's scores from each of the classes. These simple examples illustrate some of the important pitfalls of using some of the possible methods of comparisons.

Standardization Methods

One way to avoid the problems described previously is to use standardized scores when comparing both within and across data sets. The standardized (or standard) score is a dimensionless quantity that can be calculated from any set of scores to transform them into equal units that facilitate a comparison within a particular group of scores or across different types of scores. The transformation process is called standardization, and it is one method for normalization of a data set. Although this calculation can be used for a

small sample as in these midterm examination examples, the larger the sample size, the more accurate the standardized score and the most accurate score is calculated from a population mean and standard deviation. However, in this case, Table 1 provides all the necessary information for calculating the standardized score based on the sample means of each of Ben's classes. A standardized score is easily calculated by subtracting the mean of the raw scores of the data set from an individual raw score. That difference score is then divided by the standard deviation of the raw scores within that data set (see Figure 1). Applying this formula to Ben's scores (using the mean and standard deviation from Table 1) provides a more accurate picture of his overall standing among his fellow students. The result of this standardization calculation is often called the *z* score (or normal score). The *z* score has a mean of zero and a standard deviation of 1. Applying the *z* score calculation to all of Ben's examination scores (see Figure 2) shows that Ben is almost one standard deviation above the mean (1 unit above average) on his math midterm examination, which indicates he performed much better than the other comparative

Table 1 Examples of Midterm Examination Scores and Different Scoring Methods Used for Comparative Purposes

	<i>Midterm Examinations</i>		
	<i>Math</i>	<i>History</i>	<i>Psychology</i>
Number of students taking examination	<i>n</i> = 23	<i>n</i> = 23	<i>n</i> = 23
Number of examination questions	150	100	90
Range of all students' raw scores	48–57	75–99	86–90
Ben's raw score (# of correct answers)	53	77	88
Ben's percentage score	35%	77%	98%
Mean raw score of the class	51	85	88
Standard deviation of scores from the mean	2.10	6.45	1.48
Ben's standardized <i>z</i> score	0.95	–1.24	0.00
Ben's standardized scaled score	12.85	–13.72	10
Ben's standardized <i>T</i> score	59.5	37.6	50.0

$$z = \frac{X - M}{SD}$$

Where z = The standardized z score

X = The individual raw score

M = The mean of the sample

SD = The standard deviation

For example,

Ben's Math Exam z score is:

$$.95 = \frac{53 - 51}{2.1}$$

Figure 1 Formula for Calculation of the Standardized z Score

methods (previously) suggested. Ben's psychology midterm score is exactly on the mean, or average, and his history midterm score is more than one standard deviation below the mean (negative z score). But, if Ben goes home to tell his parents about his midterm exams, it is unlikely that his parents will understand if he tells them he got a zero in psychology. That is where alternative standardization scores are useful.

Several alternative standardized scores are provided here, each of which is simply an extension of the z score calculation (see Figure 2). The scaled score is calculated by applying a simple linear transformation to the calculated z score. The scaled score equals $3(z) + 10$, a mean of 10 and standard deviation of 3. The T score (not be confused with the t test that has an entirely different purpose) was arbitrarily decided to have a mean of 50 and a standard deviation of 10; therefore, the formula to transform the z score is $T = 10(z) + 50$. Using a T score, it is a little easier for Ben to explain his average midterm score to his parents as a score of 50. Along with the z scores, Table 1 provides the standardized scaled scores and T scores for each of Ben's midterm examinations, and Figure 2 illustrates how these two scores are related to the z score. And then there is probably the most well-known example of this type of transformation, the standardized scores for IQ tests. Reporting a z score for the IQ score would be very upsetting to most parents because an average IQ would be zero, so applying a linear transformation where the mean is 100 and the standard deviation is 15 (see Figure 2) results in a more understandable score. The transformation of IQ scores can be calculated as $IQ = 15(z) + 100$ (Wechsler IQ), or $IQ = 16(z) + 100$ (Stanford-Binet IQ, not

Figure 2 The Normal Curve With Comparisons of Four Standardized Scoring Methods: z Scores, Scaled Scores, T Scores, and IQ Scores

Note: The example midterm scores are indicated and apply to the z score and T score axis labels only.

shown). Looking at Figure 2, the normal curve helps to understand where a particular score is in relationship to other scores, but there are also probability tables for each of the different standardized scores that can be used to find the corresponding percentile score. For example, looking up any of Ben's z , scaled, or T scores on the appropriate probability table (available on the Internet) can provide a percentile rank that is a more concrete way of understanding how many people scored above and below Ben's score. Because the scaled score and T score are linear transformations of the z score, the tables for all of these standardized scores provide the same percentile rank of 82.9 for Ben's math score, 10.6 for his history score, and 50.0 for his psychology score. Thinking back to the use of percentages, Ben's worst score, his math midterm examination, was only 35%, which was clearly not a good representation of Ben's mathematical ability. And, his best score, 98% in psychology, was really only average.

Scores resulting from different sets of data can take many different forms, and whereas there are some calculations that are commonly used to compare scores (e.g., percentage scores), they are not necessarily the most appropriate choice for accurate comparison of scores. The standardized score will provide the best picture of how scores compare both within and

between groups of data. The standardizations discussed here, the z score and the related scaled score, T score, and IQ score, are some of the most well-known and widely used standardization methods that allow for the most accurate comparisons of scores, although each rests on the original calculation of the simple z score. By examining these different transformations of the standardized score, it is easy to understand that other alternative transformations could be created to provide a score on yet another scale. Although the example of midterm examinations used here represents a very small sample ($n = 23$) and rather skewed sets of scores, it is sufficient to illustrate the *concept* of standardized scores. It is important to remember that the larger the sample size, the more likely it is that the calculated z score will represent the most accurate probability of the population.

STATISTIC

Statistic, a singular noun, has three meanings: (1) an observed number or event, (2) a mathematical operation (and the resulting number) performed on sample data, and (3) an operation (and the resulting number) obtained from a sampling distribution. The plural form for each of these three cases is *statistics*. A fourth meaning of the word *statistics* is a branch of mathematics devoted to the analysis, interpretation, and presentation of empirical data. Statistics, as a branch of mathematics, is a singular noun. In most contexts *statistics* (with an s) refers to this branch of mathematics, which

scientists and others use to analyze data from empirical studies.

In conversational use, *statistic* means a single number or a single event. The 84 in *84 people attended the reunion* is a statistic. *Statistic* sometimes conveys a sense of the impersonal. *His death was just a statistic* uses *statistic* in the same way as Josef Stalin's famous quote to Winston Churchill, "A single death is a tragedy; a million deaths is a statistic."

In the discipline of statistics, a descriptive statistic is a mathematical operation that captures some characteristic of a sample of observations. Each operation has a formula and, of course, each formula has a name. For a sample, the mean ($\Sigma X/N$) is a descriptive statistic, as is the median, standard deviation, and the 95th percentile, each of which has its own formula. Not only is the formula itself called a statistic, but the resulting numerical value can be referred to as a statistic. Thus, the expressions, $M = 98.28F$, standard deviation (SD) = 12 points, $z = -1.50$, and 95% confidence interval (CI) = 0.50, -2.25 each qualify as a statistic and are often referred to as sample statistics. The corresponding population characteristics are called *parameters*. Although almost all research reports focus on statistics calculated from samples, the purpose of research is to discover relationships among populations. Thus, the most satisfactory statistics are those that provide mathematically unbiased estimates of parameters. The sample mean qualifies; the sample mode does not.

A *statistic* is also a value from a sampling distribution. A sampling distribution is a collection of sample statistics derived from a mathematical formula rather than empirical observations. Both the graphical form of the collection and the mathematical formula that produces the collection are called sampling distributions. Sampling distributions that researchers commonly use include inferential statistics such as the t distribution, chi-square distribution, and the F distribution. Thus, t , χ^2 , and F values calculated from data are inferential statistics. In the same way that an expression such as $M = 98.2^\circ F$ or $SD = 12$ points is called a statistic, $t = 2.03$, $\chi^2 = 3.84$, and $F = 1.84$ are each called inferential statistics. The relationship of inferential statistics to research design is an intimate one. "An adequate experimental design involves not only a satisfactory plan for conducting the trial, but also an appropriate statistical method for evaluating the results. The two can ill be divorced" (Snedecor, 1946, pp. xv-xvi).

In general discourse, the word *statistic* is not a neutral word, and the connotation that accompanies it can be negative or positive, sometimes strongly so. Context and past usage determine the connotation. The phrase, *just a statistic*, conveys a negative tone of dismissal. The common expression, *you can prove anything with*

statistics, is similarly dismissive. The phrase *lies, damned lies, and statistics*, attributed to Disraeli but found first in the writings of Mark Twain, even equates statistics with falsehood.

On the positive side, the phrase, *statistically proven*, carries a tone of assurance. A statistically proven conclusion is one that is based on evidence, according to the speaker. A prediction made with *statistical certainty* is one that can be relied on.

Using the word's connotation in an argument is a common rhetorical device. However, citing actual statistical results is usually more effective and often can prevail against an argument that rests only on connotation.

STATISTICA

Statistica is a stand-alone software package that provides a complete statistics and data management environment that can work well with other software. Statistica (1991) grew out of a set of software packages and add-ons dating back to its original developer, StatSoft, in 1984. As of June 8, 2017, it is owned and developed by TIBCO Software, which released Version 14 in December 2020. The software provides a rich environment for single users and collaborating users to perform data management, statistical analysis, approval processes, and automation. This entry begins with a review of the statistics software environment and then

details various attributes of the software; it ends with a brief discussion of the future of Statistica.

Statistics Software Climate

The statistics software market is a mix of retail and freeware comprising *complete* packages such as Statistica, Stata, SAS, SPSS, and Minitab; complemented by programming languages, database software, spreadsheets, and numerous specialized stat packages. The complete packages offer data management and statistical tools that can meet most of the needs of most organizations.

The decade-long evolution of statistics software has involved improved user-friendliness; broader technical reach; gains in speed, automation, and data size capabilities; greater and lesser software fidelity; and enhanced multiuser environments. Meanwhile, software has remained more tool-based in organization, as opposed to problem-based, and governance has improved for safeguarding data, while relatively little for data analysis. The overall trajectory points to handling more data, greater execution speeds, more automation, rich multiuser environments, and new artificial intelligence tools.

Empowering people with push-button statistics software with no corresponding increase in governance is resulting in more statistical malfeasance. In the past, users with the training necessary to use the statistics software usually had sufficient training in statistics. Famous examples of statistical malfeasance include the Space Shuttle *Challenger* disaster and the election prediction of 1948, *Dewey Defeats Truman*.

The value proposition for statistics software is straightforward:

$$\text{ROI} = \text{Productivity/Cost,}$$

yet it can be difficult to accurately appraise. Estimating the productivity should include the synergy with other software and the user. The cost should include the shelf price, software development, maintenance, and errors.

Statistical Interface

There are multiple ways to interface with Statistica, including pulling drop-down menus, executing macros in Statistica Visual Basic (SVB) that can call another 11,000 functions in addition to those of Visual Basic, calling programming languages, scheduling automatic analysis (Monitoring and Alerting Server), accessing tools and results via the web or cloud, calling it from other software such as Spotfire and Spark, and using an

icon-based graphical user interface (GUI) in individual workspaces or multiuser environments (groupspaces). In addition, Statistica can deploy code, can send reports or messages, and offers a comprehensive manual. A complex analytics session can look like Figure 1, with two workspaces on the left: output and interactive decision making on the right.

The GUI enables users and groups of users to build processing flows or streams that provide a big picture and in a collaborative space. This interface permits the user to reflect in graphical pictures the conceptual flow of the steps in processing, analyzing, and presenting data. Data transformations and analyses are assigned nodes or icons in a toolbar. The nodes are pasted into a workspace and connected with arrows to represent a data flow through a sequence of processing operations. Users can create custom nodes to suit their needs, and there are nodes to call external code modules, including iron python, python 3.8.3, C#, spark scala, SVB, R, and H2O (Version 14 of Statistica). This accommodates user preferences and opens the package to existing custom code and the latest innovative ideas.

Figure 2 shows a simple workspace. The initial data set appears in the upper left corner. The data are prepared for modeling; they are modeled; and the results are sent to an output node (Reporting Documents) and can be sent to other software.

Figure 3 shows the potential of a workspace to remember past analyses, perform multiple tasks, and capture the big picture.

The menu interface is characterized by either a toolbar or a ribbon bar (Figure 4) across the top, which contain numerous options. This interface is interactive, prompting for the type of analysis required and for the variables to be included. It keeps the user closer to the underlying assumptions—that is, the user is reminded of what statistical model they are using and the assumptions that go with it. Statistica uses two separate statistics tabs: Statistics and Data Mining. While confusing, this separation is a common wrinkle in the industry, which might do better by grouping tools by purpose.

The usual graphical or tabular output options are embedded in the menus and groups of results can be stored in separate workbooks. This interface facilitates exploratory data analysis (EDA) and quick one-off analyses. Also, it can help users discover the best approach for a set of identical analyses and then save this approach into a SVB macro or select the best GUI node. Figure 5 provides a glimpse of the modeling options.

There are quick keys, short cuts, and multiple ways of performing certain tasks (Figure 6). Also, Statistica

Figure 6 Calculating Quick Statistics on the Fly

can record the actual keystrokes one enters via the keyboard into a macro.

After finding a solution with the GUI or menu interface, another way to leverage Statistica is to deploy the solutions using Java, C#, and other software code. Deploying code is particularly useful for embedding prediction or clustering models into other applications for scoring new data as it becomes available.

Accessing Data

Statistica can house data or connect to data repositories. Alternatively, it can import data *tables* from files or receive data cut-and-pasted from anywhere. Finally, it can use web crawling to collect data and can pull data out of documents, including PDFs.

Extracting data from relational databases for use in analytics processes can be complicated, and cloud storage applications and formats add further data connectivity challenges. Statistica can solve these operations through denormalization, data integration operations, and complex extractions. It supports data quality tools with fuzzy matching capabilities to handle complicated

data quality assessments and integration operations like reconciling multiple versions of the same customer name with different spellings. It offers a strong database query tool, flexible data import tools, and through the integration with other TIBCO Data Virtualization and access tools, can integrate and analyze most data formats. The Statistica Enterprise solution allows users to create reusable templates for all data access, integration, and analytics tasks. These templates can be deployed to create automated systems supported by Statistica's detailed and mature governance, versioning, security, automation, monitoring, and model management tools, which are common in regulated industries, for example, in pharmaceutical and medical device manufacturing.

Preparing Data

Statistica can be used to prepare data for general purposes. The main and advanced endeavors for data management are cleaning the data; identifying concerns; creating new variables; categorizing variables by structure or purpose; identifying missing data patterns;

running simple tests on data quality; and generating metadata, which is data to describe the data—as in the data encyclopedia and data dictionaries. Beyond general-purpose preparation, additional work is usually required to bring the data up to an analyzable form for more technical statistical tools. For example, some tools will work better when missing values are replaced using an imputation technique tailored to the situation.

Statistica's Tools

Statistica offers numerous vetted statistics tools, including the following:

artificial neural networks (ANN; regression and classification)	naïve Bayes, k-nearest neighbors)
association rules	multidimensional scaling
boosted trees	multivariate adaptive regression splines (MARS)
canonical analysis	parametric and non-parametric tests
correspondence analysis	principal component analysis
design experiments (DoE) tools	quality control and process control charts
discriminant function analysis	random forests
distribution fitting and simulation	reliability and item analysis
factor analysis	sample size and power analysis tools
forecasting	sequence, association, and link analysis
generalized additive model (GAM)	Six Sigma tools
goodness of fit	structural equation modeling (SEM)
Gaussian discriminant analysis (GDA) models	summary statistics
independent component analysis, clustering (generalized expectation maximization, k-means, tree)	survival analysis (life tables, Kaplan–Meyer, Cox proportional hazard)
interactive trees (C&RT; CHAID)	text analytics
linear and nonlinear regression tools	time series
log linear	variance components
machine learning (support vector machines,	web crawling/document retrieving
	weight of evidence

Statistica includes tools to produce publication-quality graphics. These include standard two- and three-dimensional graphs: scatterplots, histograms, means with error plots, surface and line plots, matrix plots, icon plots, and many others. The graphs can be edited to add, for example, lines, labels, or points, and brushing actions (interactive labeling, marking, and data exclusion) facilitate investigating outliers and performing EDA.

Statistica's Design Is for Speed

Statistica is multithreaded, a design which enables it to use all available processors. Also, the scripting languages (VB, Python, IronPython, and C#) can access all of the capabilities of the platform, which consists of over 11,000 internal automation functions. Many of these are optimized for speed. Part of the speed of Statistica is that, unlike abstract procedural code, it works more like the user thinks. Some effort has gone into grouping tools that have similar underlying assumptions or that work together (e.g., Define, Measure, Analyze, Improve, and Control are in the same Six Sigma tab).

Statistica's Automation Capabilities

Automation not only increases speed and saves labor, it expands capabilities and sharpens fidelity. Statistica automates redundant tasks such as cleaning and imputing for predictive variables. This becomes invaluable when preparing 300 variables for a prediction model, instead of preparing 30 by hand. Similarly, Statistica can read and write from an electronic data dictionary to monitor and record changes in the data. Statistica facilitates automated and semiautomated reports, which can support dashboards or corporate score cards. A next step in automation can further reduce these score cards or a mound of reports to notable highlights. Finally, these numbers can be further simplified by applying Statistica's quality control tools.

Statistica is nimble in handling the redundant tasks that go into model building, so that Statistica users can mass-produce predictive models and/or build them for large numbers of predictors and observations. Statistica macros are capable of processing a spreadsheet containing data and instructions for analyzing and graphing it—including subtleties like what line colors to use in the plots.

Statistica's Future

With the release of Version 14 in December 2020, Statistica is positioned to continue as a stand-alone option, while playing the statistical heavyweight role for an organization's suite of software. In addition to calling and being called by various software, this release supports Spotfire Data Functions from Statistica's workspaces. This better integration reflects the parent company's vision of incorporating Statistica in providing various end-to-end solutions.

STATISTICAL CONTROL

The control of nuisance variables via an experimental design or statistical technique is rooted in causal inference. To infer causality in a study, a researcher must be able to infer that the results are a result of the treatment and not unchecked nuisance variables. For example, in comparing different drugs to determine which one is most effective in reducing diastolic blood pressure, changes in diastolic blood pressure must be attributable to the drugs. Clearly, if one is not careful in the assignment of individuals to the different drug treatment conditions, then one could end up making the wrong causal inference because of group idiosyncrasies. To make a fair comparison of the drugs, one must have "an equal playing field." The researcher must control those variables that are known to affect diastolic blood pressure like age, health, physical activity, and diet. Because there is also a possibility of unknown variables affecting blood pressure, the researcher must be very careful. In most experimental situations, individuals are assigned at random to the treatment conditions to control for unknown as well as known nuisance variables that could upset the playing field. Ideally, participants in all the treatment conditions should be identical except for the drug being taken. Only under these conditions can one unmistakably infer

causality. Using statistical procedures to adjust the result of a study for nuisance variable differences is the primary purpose of statistical control.

Using statistical procedures to adjust treatment comparisons for individual differences that could bias the comparison is especially important when randomization is not possible. Consider the following example, a researcher studying different methods of teaching math assigns a method to each classroom/teacher. In this situation, for many reasons one cannot assign students to classrooms at random; that is, randomization is not possible. This situation is known as a field study. When randomization is not possible, one must seek other means of control. A way to try to assert control of nuisance variables is to use statistical techniques that equalize the playing field. Statistical techniques equalize the playing field by using the principle of conditionality. Consider age: If age plays a factor in blood pressure, it would be advantageous to use participants of the same age, say 40. Although possible, it is very unlikely to happen because it is very difficult to find only 40-year-old individuals to participate in the study. One can achieve a similar effect, however, with statistical control.

A plethora of statistical techniques can be used to attempt to achieve this "conditionalization" of nuisance variables. This entry discusses only the most fundamental ones: the analysis of variance with a blocked (subdivided) variable, the analysis of covariance, propensity scores, multiple regression, and the statistical control charts.

Blocking

Sometimes, it is possible to equate nonequivalent groups by blocking a relevant variable. To be successful with this procedure, one must be able to identify and reliably measure the variables likely responsible for making the groups different and that are related to the experimental response Y . The variables must be measured before the treatment or they must not be reactive to the treatment. The identification of variables that are likely responsible for group differences is often not only a statistical question but also a theoretical one. Statistically, the primary criterion for selecting the blocking variable is a substantial correlation with the response variable. Go back to the blood pressure example; this time, assume the patients have been treated with drugs a, b, and c and that patients have not been assigned at random to the drugs. This comparison involves preexisting groups. If it is suspected by examining the groups and from a theoretical understanding of variables that can affect blood pressure that age is an

important factor, then age should be incorporated into the analysis. One way of incorporating age into the analysis is by blocking age, that is, subdividing into different age categories. In this situation, the statistical procedure would be the analysis of variance (ANOVA) with a blocked factor to make the comparison. Table 1 illustrates the basic design.

By “equalizing” the rows in terms of age, or blocking, one can examine the relation between age and drug efficacy. The design controls identified individual difference by creating homogenous rows for the drug comparisons. It can be determined whether the drugs work differently across age groups; that is, whether an interaction exists between age and drug. A secondary effect of blocking is that reducing the variability in each cell increases the power of the statistical test. Clearly, a factorial design like this one could involve unequal n s and possibly an empty cell. Thus, one might or might not be able to estimate all of the cell means or test all three hypotheses: drugs, age, and age by drug. The factorial blocked design can be also used when randomization is possible.

Analysis of Covariance

The analysis of covariance (ANCOVA) is similar to the block factorial ANOVA, but it does not group individuals into categories. The ANCOVA can be used with or without randomization. Instead of a blocking factor, ANCOVA relies on the statistical control of the covariate or concomitant variable. To control for age, as in the previous example, the ANCOVA model is given by

$$y_{i,j} = \mu + \alpha_j + \beta * (\text{age}) + e_{i,j}. \quad (1)$$

The observation $y_{i,j}$ is a function of the drug effect α_j plus age and random component e . By including the quantitative covariate age in the model, the drug effect can be estimated without age. The drug effect is statistically adjusted for age differences among the groups.

The coefficient β represents the partial effect of age on response Y . Each mean for the j group is then given by

$$\mu_j = \mu + \alpha_j + \beta * (\overline{\text{age}}).$$

And the adjusted (for age) diastolic blood pressure mean is given by

$$\mu_j - \beta * (\overline{\text{age}}) = \mu + \alpha_j.$$

Next the adjusted means are compared to see the effect of the drugs on blood pressure. Note that the adjusted cell means are not affected by the average age in the group. It does not matter whether one group is older than the other, as long as there is no interaction between age and drug type. Furthermore, as in the blocked factorial design, the inclusion of the covariate in the model generally increases the power of the statistical test. If the relationship between age and Y changes across groups, the model must be modified to include these differences,

$$y_{i,j} = \mu + \alpha_j + \beta_j * (\text{age}) + e_{i,j}. \quad (2)$$

The model in Equation 2 indexes the beta to indicate that there is a beta per group. The model in Equation 2 can be compared against the simpler model in Equation 1 using an F test to evaluate the advantage of adding the interaction. Additional covariates can also be added to the model if other variables are available and theoretically plausible.

As previously mentioned, an ANCOVA can be used in a randomized design or with intact groups. Under randomization, the primary use of ANCOVA is to reduce the noise or random error. With preexisting groups, however, group differences might be caused by real differences between the groups. The ANCOVA adjustment is a hypothetical one and reflects “how the data might have been, but not what they actually were.” It behooves the researcher using ANCOVA with preexisting groups to be careful in the interpretation of the results. Also, one must weigh carefully the ANCOVA assumptions of linearity between x and y , homogeneity of regression, and no measurement error on the covariate to make sure that they are met. Because preexisting (intact) groups have not benefited from randomization, unmeasured variables that are related to the response could pose a special threat to inference. Various researchers suggest that the best way to deal with unmeasured variables is to include numerous covariates in the model that are related to the outcome and that are not likely to be affected by the treatment. Multiple regression is a different version of the ANCOVA model that is used by researchers when the independent variables are all quantitative. Multiple regression will not be discussed here because of space constraints and

because of its similarity to ANCOVA. Regardless of the technique used, theoretical justification should play a big role in the selection of the covariates to avoid artificial situations in statistical control. Albert Bandura, among others, has pointed out that in some cases, controlling a variable can lead to controlling a host of other variables that the researcher is not particularly interested in controlling, hence the importance of considering theory. For instance, controlling for grade point average (GPA) could also control for intelligence and self-esteem because of the correlation among the variables.

Matching Subjects

To equalize two groups, subjects can be matched. In this technique, each subject in the control group is matched with a similar subject in the treatment group. Subjects without reasonable matches are left out of the comparison. The matching usually takes place along an important covariate, and it can take place before or after the experiment. One problem with matching, however, is that it is usually difficult to find good matches. If matching occurs after the experiment takes place, a covariate must be used that was not affected by the treatment. Investigators have cautioned about using matching across two different populations, because of the danger of ending up with matched samples that do not represent either population. For example, Figure 1 depicts two groups where the overlap between the two populations is marginal but the groups have been matched.

Matching these two groups to compare them would not yield a meaningful comparison, because the matched groups would not be representative of their populations.

Propensity Scores

Statisticians have developed procedures for matching based on what has been called propensity scores. Propensity scores provide a way for adjusting for preexisting differences between two intact groups, that is, groups that have not benefited from randomization. Propensity scores work by summarizing all the information about group differences from the covariates into a single variable, the propensity score. This is achieved by building a statistical model to estimate the probability of group membership given the covariates, $P(\text{Group membership} | \text{covariates})$.

Subjects are then matched on their propensity scores across the groups; subjects with similar propensity scores are expected to have similar values on the background variables. Many techniques have been used to

Figure 1 Marginal Match

obtain propensity scores, including logistic regression and predictive discriminant analysis. As with all types of matching, it is important to ensure that a match is reasonably representative of both groups.

The importance of equalizing the groups in field studies can be illustrated with the following study of aspirin. Patricia Gum, Maran Thamilarasan, Junko Watanabe, Eugene Blackstone, and Michael Lauer conducted a study to evaluate the use of aspirin in coronary artery disease. In the study a group of subjects taking aspirin for approximately 3 years was compared with a group of subjects taking no aspirin. This was not a randomized clinical study, and researchers were comparing two intact groups. Of the 6,174 subjects in the study, 2,310 had been taking aspirin. The two groups were different on many covariates including gender, clinical histories, diabetes, and medication use. The simple univariate analysis comparing the two groups without any adjustment showed no association between aspirin use and cardiovascular mortality of 4.5% versus 4.5%. In fact, the two groups showed exactly the same mortality. However, once the groups were adjusted by matching subjects on their propensity scores they found group differences. The difference in mortality between the two matched groups was 4%. Aspirin users had a 4% lower risk of mortality than non-aspirin users (8%).

Process Control Chart

Another important form of statistical control used by manufacturers, hospitals, and other organizations is the process control chart. Many versions of the control chart have been proposed. Many control charts have appeared in the literature including the Schewhart Chart, the Cumulative Sum Chart, and the Exponentially Weighted Moving Average Chart. All of these charts have one thing in common in that the x -axis is always time. In these charts, the researcher generally

plots some sort of average against time. The charts also include upper and lower control limits. The range between the two control limits indicates the bound of “normal” variability. For example, a hospital can plot the mean monthly count of infections during the years to study infection rate across the years. These data are also used to compute the lower and upper control limits. Clearly, in a situation like this one, the upper control limit is more important. A dangerous or abnormal infection rate is one that goes above the upper control limit, signaling a cause for alarm. The basic premise of the control chart is to try to discern between random and not-random causes of variability. Going above the upper limit generally indicates to the staff that the increase in the infection rate is unlikely to be the result of random variation, a special cause. Of course, for control charts to be of value, they must be based on a substantial number of years. The control chart is also used in manufacturing to separate special from common (random) causes in variation. All processes have variability over time. The number of defects in a manufacturing process varies from one instance to the next. Manufacturers have learned that it is important to understand what causes a large spike, a spike that goes outside of the limits, on the number of defects. Going outside the limits indicates that the process is outside of the expected variability and possibly in the range of a special cause. There is no space to discuss here how the upper and lower limits are obtained in a control chart, but it is tantamount of computing a confidence interval. When computing the limits and the process is not stable, it is important to try to determine and eliminate the causes of instability. If a special cause for the variability is found, the data are purged and the upper and lower limits recomputed. Once a stable process is identified, one that contains only random variability, the upper and lower limits are obtained. These limits in turn can be used in the chart to look for future abnormal situations. If a point is found outside the limits, then it is probable that this is an unusual situation that requires special consideration. Figure 2 depicts this situation.

Figure 2 Control Chart

Additional Considerations

In many instances, a researcher can benefit from controlling unwanted sources of variability when making comparisons. Controlling for unwanted sources of variability should always go hand-in-hand with scientific theory. The failure to take into consideration theory when attempting to apply statistical control can lead the researcher to false conclusions. In contrast, especially with intact groups, failing to take preexisting group differences into consideration can also lead to the wrong inference.

STATISTICAL POWER ANALYSIS FOR THE BEHAVIORAL SCIENCES

Motivated by surveys indicating that data analyses published in top behavioral science and psychology journals between 1960 and 1982 were seriously lacking in statistical power, Jacob Cohen wrote the book *Statistical Power Analysis for the Behavioral Sciences* to draw attention to the problem and to provide a handbook of statistical power analysis for behavioral scientists.

The book covers power analysis based on various statistical tests commonly used in behavioral science. These tests include the following: (a) the *t* test for means, (b) significance test of a product-moment correlation coefficient, (c) test of the differences between correlation coefficients, (d) test to determine whether a proportion is 0.5 and the sign test, (e) test of the differences between proportions, (f) chi-square tests for goodness of fit and contingency tables, (g) analysis of variance (ANOVA) and covariance, (h) multiple regression and correlation analysis, and (i) a multivariate version of the multiple regression and correlation analysis.

Each test is discussed in a separate chapter, which starts with a description of the test, continues with a definition of the effect size index, and ends with a power table and a sample size table for the test, along with (for most tests) an explanation of how to use the power table for significance testing. Using the tables provided in the book, one can easily find the power and necessary sample size by locating the specified parameters. For example, given an effect size and a sample size for a *t* test for between-group means, one can find the power by locating the specified effect and sample sizes. Similarly, one can find the required sample size when the effect size and power are specified. In most power tables, a significance criterion in the form of the sample effect size is given to facilitate significance testing if data are available.

The book also discusses issues related to (a) understanding the magnitude of effect sizes, (b) the role of psychometric reliability, and (c) the efficacy of “qualifying” (differencing and partialling) dependent variables in the context of power analysis. A description of the computational procedures associated with each test is provided at the end of the book.

This book is useful in that it not only provides results for power and sample size calculations based on different tests but also describes the tests and the corresponding computational procedures so that interested readers can reproduce the results, presumably

with additional computing aid. This book does have limitations. The first edition of the book was published in 1969. Despite the addition of new material in the revised and second editions (published in 1977 and 1988, respectively), descriptions of power analysis for some important statistical methods currently in common use in behavioral research are missing. These methods include logistic regression analysis, repeated measures ANOVA, and McNemar’s test for the difference between correlated proportions, among others. Thus, researchers might prefer to use one of the various software packages currently available that will conduct power and sample size calculations. Such software is typically user friendly and quickly generates results with complementary tables and/or graphics (e.g., provides power statements with visual demonstrations such as plots of power curves). In addition, current software packages incorporate power analysis for most of the recently developed statistical procedures that are not covered in the book. Individuals interested in understanding power and sample size calculations based on standard and conventional statistical tests might find this book useful. If instead the main goal is to calculate power and/or sample size, especially using modern advanced statistical techniques, then software might prove to be more convenient. Popular software of this sort includes nQuery, Power and Sample Size (PASS), and others.

STEPPED-WEDGE DESIGN

Stepped-wedge designs encompass a broad range of methods, which have gained popularity in recent decades as a means to evaluate interventions that are implemented in a sequential rollout to the target population. The most common approach is for participants to be classified into clusters, which are then randomized (*stepped-wedge cluster randomized trial*) to determine when the cluster receives the intervention.

As all of the eligible participants in the target population ultimately receive the intervention, the design is appealing from a number of perspectives. Due to logistical, practical, or financial constraints, complex interventions can be very challenging, if not impossible, to commence concurrently to all eligible recipients; therefore, there is a need to deliver the intervention in a phased sequence. Furthermore, such designs do not raise the ethical concerns that arise from assigning participants to a nonintervention control group, especially when there are good prior grounds for believing that the intervention will be beneficial. In addition, stepped-wedge designs have the potential advantage that clusters are not randomized to determine *whether* they receive the intervention or control, but to *when* they receive the intervention, which could improve recruitment rates to the study. Intervention evaluation can occur within the context of a routine rollout in real-world settings, and stepped-wedge designs have received increasing attention in pragmatic clinical trials embedded within healthcare systems. The stepped-wedge design offers a means to evaluate such interventions and to fairly (i.e., randomly) allocate the sequencing of the order of who receives the intervention at which stage.

Stepped-wedge cluster designs are predominantly used in health outcomes research, although they are increasingly used to assess a diverse range of interventions in various contexts. The Gambia Hepatitis Study, which examined the effectiveness of the hepatitis B vaccination in the prevention of liver cancer and chronic liver disease, is perhaps the earliest and most widely known stepped-wedge study. In this critical study, the vaccination was delivered routinely in a sequential rollout in different geographical areas (clusters); initially no cluster received the vaccine, and subsequently clusters were randomly assigned to implement the vaccination such that a new cluster was allocated every 10–12 weeks to ensure that national coverage was achieved in roughly 4 years.

Example

In a stepped-wedge cluster design, units receive the intervention at different times; ideally the sequence is randomly allocated. Figure 1 provides a schematic illustration of a standard stepped-wedge design with four clusters allocated to receive the intervention over five time periods.

At Time 1, no cluster is receiving the intervention; this provides baseline data for all units. The intervention is delivered in a step-by-step phased sequence with clusters randomly allocated to when they receive the intervention. At Time 2, Cluster 1 is allocated to start the intervention, with all other clusters remaining in the control condition. At Time 3, Cluster 2 now receives the intervention as Cluster 1 continues to deliver it. Clusters 3 and 4 remain in the control condition. At Time 4, Cluster 3 implements the intervention, while Clusters 1 and 2 continue receiving the intervention. It is only at Time 5 that Cluster 4 commences the intervention.

The figure shows that the design is characterized by a controlled planned transition from no cluster getting the intervention (Time 1) to all clusters receiving it (Time 5). The clusters vary in the timing of when the intervention is implemented and the length of time it is delivered within that cluster. The *steps* in the figure characterize the design. Each cluster will experience a number of stages during the rollout of the intervention: (1) recruitment into the control condition, (2) closing of the control recruitment period, (3) implementation of the intervention, and (4) period of recruitment to the intervention. The closing phase ensures that outcomes of the control condition for participants are not contaminated by the intervention. The implementation phase ensures that participants only receive the intervention when it is delivered as intended.

Conducting a Stepped-Wedge Design

Stepped-wedge designs comprise a broad range of approaches that can vary in terms of exposure to

Cluster 1	Control	Intervention	Intervention	Intervention	Intervention
Cluster 2	Control	Control	Intervention	Intervention	Intervention
Cluster 3	Control	Control	Control	Intervention	Intervention
Cluster 4	Control	Control	Control	Control	Intervention
	Time1	Time 2	Time 3	Time 4	Time 5

Figure 1 Example of Stepped-Wedge Design With Four Clusters Allocated to Receive the Intervention Over Five Time Periods

intervention and length of time participants are involved in the trial. Three main designs have been reported:

Closed cohort: All participants are recruited at the start in their respective clusters, and each participant is exposed to both control and intervention conditions. Repeated measurements are taken from each individual to assess change and its relation to intervention exposure.

Continuous recruitment short exposure: Individuals are recruited as they become eligible and experience either the control or intervention condition, but not both. Participant data can be collected at either one or multiple time points, depending on the research question.

Open cohort: Participants are repeatedly assessed over a series of measurement points and can join and leave the study throughout its duration. The participants comprise a mixture of those who have been exposed to both conditions for the full duration of the trial, and those who have joined the trial at a later time point as they became eligible.

The outcome data in a stepped-wedge design can derive either from measurements taken cross-sectionally (different participants are measured in each time period), longitudinally (same participants are measured in each time period), or a mixture of the two in an open cohort design. Therefore, as well as comparing clusters concurrently under different conditions, the design allows comparison of participants in the same cluster before and after the introduction of the intervention. However, given the longitudinal nature of the stepped phases, the analysis of intervention effects requires mathematical modeling to partition the effect of changes over time (*secular trends*) from the effect of the intervention on the outcomes. As clusters cross over from a control phase to the active intervention phase, the data from the intervention phase are provided at a later calendar time. The potential confounding effect of time needs careful estimation and should be controlled for.

As multiple observations from the same cluster may be correlated, the intraclass correlation coefficient between observations within a cluster should be factored into both the sample size calculation and analyses to obtain valid inferences. As it is not feasible to blind the status of those delivering and receiving the intervention, it is desirable to ensure that those assessing the outcomes are blind to the participant's intervention or control status during data collection. A CONSORT reporting guideline for stepped-wedge cluster randomized trials was

developed to promote high standards in the methodological conduct and reporting of such trials.

STEPWISE MODEL SELECTION

Stepwise model selection refers broadly to the use of an iterative procedure for the identification of predictors for inclusion in a model, whereby the utility of predictors is evaluated at each step and the results of this evaluation are used to inform the inclusion of predictors at subsequent steps of the process. Predictive modeling can encompass a number of research goals, such as maximizing accuracy, whittling down predictors to minimize redundancy, testing specific predictive hypotheses, or comparing competing predictive models. In well-researched areas with strong theoretical guidance, the choice of predictors to test in a model may be relatively clear. The focus of such research may be on testing the incremental value of specific predictors or testing competing predictive models. However, in domains lacking strong theoretical or empirical bases, researchers may lack sufficient guidance to choose from myriad candidate predictors relevant to an outcome. Often, this indicates further exploratory research is needed to refine the topic; in other situations, it may still be valuable to develop predictive models on theoretical grounds. For instance, the prediction of suicide completion is an area with limited empirical or theoretical foundation, yet with substantial value in identifying risk factors via predictive modeling.

Stepwise model selection is a procedure for identifying a subset of predictors that maximize explanatory power while culling redundancy in candidate variables. While the specific applications vary, the general

procedure of stepwise model selection is to run a recursive algorithm with an evaluative stage between each repetition of a model to determine the inclusion or exclusion of candidate predictors. This algorithm is run until a prespecified stopping point, resulting in a reduced subset of predictors that are selected into the final model. Stepwise model selection has been criticized for potential bias, misapplications, and its role as a potential *data dredging* technique, yet proper interpretive guidelines and cross-validation methods can address some of the limitations and applications that have raised such concerns. This entry emphasizes how and under what conditions stepwise techniques can be applied, along with their limitations as stand-alone methods.

Application

The earliest forms of stepwise procedures determined whether predictors would be included in a regression model by evaluating the statistical consequences of predictors added or subtracted one-by-one to a model. In this context, *forward selection* refers to a stepwise procedure starting with no predictors and sequentially adding them one-by-one to the model, assessing the incremental predictive performance of the model at each step. *Backward elimination* refers to the stepwise removal of predictors, assessing the extent to which predictive accuracy is diminished with each removal. Predictors that substantially improve (in a forward selection procedure) or diminish (in backward elimination) the predictive ability of the model are retained, while those offering little incremental benefit are dropped. The statistical significance of predictors included, the R^2 change from one step to the next, or likelihood ratio test comparing models with and without a predictor can be used as the criterion at each step of forward or backward selection to determine whether the predictor is retained. Beyond forward selection and backward elimination, *bidirectional* methods combine these approaches by adding predictors one-by-one (as in forward selection) but at each step removing previously added predictors if they do not meet a prespecified criterion for incremental predictive ability (like backward elimination).

The order with which predictors are tested in stepwise procedures can be predefined by the researcher yet are more commonly selected or removed in order of incremental predictive ability. That is, the procedure will select what predictors to include or remove at each step relative to how they perform in the context of variables retained in the previous step. This approach is far more efficient than testing all possible combinations of predictors yet comes with ample drawbacks that

become more severe with larger sets of candidate predictor measures. The unfortunate consequence of this approach is that the solution can become locally optimized given a set of predictors included (or excluded) in earlier steps of the procedure and yet can fail to achieve global optimization that would result in the *best* combination of predictors out of all possible combinations. More specifically, due to overlap in the variance explained in the outcome by predictors included at earlier steps with variance explained by predictors tested at later steps, important predictors risk being passed over by this algorithm that could improve the predictive ability of the final model. If such predictors were included or retained in earlier steps, the configuration of variables included at later stages may look very different yet result in a better final model.

Other critiques of this procedure are noteworthy as well. The initial stepwise implementations described in the late 1970s (yet still implemented) rely on significance tests for the inclusion of predictors, which assume no contingency with prior tests and assume a single hypothesis test rather than repeated, stepwise evaluation. The result is that the significance criteria used for evaluation at each step of this procedure are interpreted under conditions that deviate from such tests' intended purposes. Even if the researcher adjusts the significance criteria to be more stringent, several authors have noted exaggeration in the certainty of estimates (resulting in overly narrow confidence intervals) and size of the inferential statistics (resulting in deflated p values) computed for the predictors in the final stepwise-selected model. A third noteworthy criticism has to do with the number of candidate predictors inputted into stepwise procedures. With an increasing number of predictors, the chances that spurious associations are retained in stepwise procedures grow; with more variables, the more likely that patterns of association emerge that are unique but meaningless, resulting in solutions that fail to replicate. The stronger the correlations among candidate predictors, the less reliably stepwise procedures will perform, as predictors become increasingly interchangeable on the basis of spurious incremental gains in model performance under conditions of collinearity. In other words, the more interrelated one's variables are, the more interchangeable they will be as predictors given the criteria of stepwise algorithms.

Given these criticisms, several authors advise against a stand-alone implementation of stepwise procedures for culling variables in a predictive model. Alternate procedures such as least absolute shrinkage and selection operator (LASSO) and especially adaptive LASSO can achieve similar goals without the substantial caveats of stepwise methods—particularly when selecting

from a large set of interrelated candidate predictors. However, the use of stepwise procedures based on criteria other than statistical significance (e.g., minimizing residuals or the Bayesian information criterion [BIC]) for predictor selection, followed by cross-validation using confirmatory methods, overcomes a good number of such criticisms. In particular, when the selection of predictors does not also imply significance testing, the framework of the analysis is exploratory by nature. On the basis of this exploratory predictor selection, the researcher can then cross-validate the identified predictors on a replication data set using regression modeling. An even more robust approach is to employ multiple predictor-selection algorithms to determine whether they converge at the exploratory stage and then cross-validate only those predictors selected across algorithms.

To implement stepwise selection as an exploratory procedure followed by confirmatory methods, the following general steps can be used:

- (1) Examine the correlation matrix among candidate predictors. Determine whether all predictors should be included as candidate variables or whether redundancies can be eliminated on the basis of statistical (e.g., large correlations) or conceptual criteria.
- (2) Split the data set into training and replication data sets by randomly assigning observations to either training or replication groups.
- (3) Identify the stopping rule, that is, the criterion at which the stepwise procedure will be terminated, based on minimizing residuals or information criteria (e.g., the BIC). Avoid statistical significance tests as a criterion.
- (4) Run the stepwise model selection procedure in the training data set. Interpret the change in the criterion selected in Step 3 at each step to determine whether it was too stringent or weak. Do not interpret the significances or confidence intervals associated with coefficients selected on the basis of this criterion.
- (5) Test the predictors in the replication data set using, for example, regression modeling. Interpret the significance and confidence intervals associated with the resulting coefficients. Determine whether the magnitude of coefficient estimates varies across the training and replication data sets.

The aforementioned steps will help select an optimal subset of predictors from a large set of candidate variables that are internally cross-validated within one's data. Consequently, the resulting set of predictors will be cross-validated only within one's data set and ideally would be validated against an external data set as well.

While these steps do not entirely mitigate the risk that one's solution is locally optimized, they correctly apply stepwise model selection as an exploratory tool and help to mitigate problems associated with relying on significance criteria to both select and test predictors.

Advantages

The primary advantage of stepwise approaches to model selection is that they help cull from a larger set of variables a more optimized subset of predictors. If the candidate variables are selected thoughtfully, and the resulting subset of predictors is adequately cross-validated, stepwise model selection can yield important data-driven insights into the explanatory factors contributing to an outcome. This may be especially fruitful when the outcome is difficult to predict on the basis of extant theory or empirical literature.

Limitations

Limitations of stepwise model selection include bias in the resulting inferences, the risk of locally optimized solutions, and poor performance with intercorrelated predictors. Inferential test statistics and confidence intervals resulting from stepwise procedures alone should not be interpreted. Local optimization is a risk against which stepwise procedures have little safeguard; therefore, the results of stepwise methods should be cross-validated or evaluated for their convergence with other techniques. The problem of handling intercorrelated predictors is endemic to procedures designed to cull predictor variables from a larger set. However, methods such as adaptive LASSO have far more sophisticated ways to address this problem than the majority of stepwise procedures.

Alternatives

Several alternatives to stepwise modeling are available for exploratory predictor selection. As mentioned, LASSO implementations have certain advantages over stepwise model selection, including the use of shrinkage penalties that aim to reduce redundant coefficients to zero or near-zero, which can be especially useful given intercorrelated predictors. While this introduces bias into the model, the bias trends toward the notion that many regression coefficients will be more plausibly zero than nonzero and can importantly mitigate problems of overfitting (i.e., nonreplication of the selected predictors on external data). Moreover, since most LASSO procedures are performed in a single run, test statistics associated with the resulting coefficients can

be interpreted. *Tree*-based algorithms such as random forest classifiers and regression trees can achieve similar exploratory aims; however, the researcher must be careful in selecting the appropriate method and parameters so that these procedures are appropriately optimized and fitted. Bayesian model averaging is another technique that can be especially useful when correlations between redundant variables and the outcome are expected but not informative.

Final Thoughts

Stepwise procedures represent one among several methodological approaches that can be applied to whittle down predictors from a larger candidate pool of variables. Whatever procedure is implemented for predictor selection, it is crucial that the researcher interprets the results as exploratory in nature. An optimal strategy may be to use two or more model selection approaches, determine whether these approaches converge in the selection of predictors and then assess the performance of the selected model on a replication data set. This method can yield data-driven insights into potentially important predictors when little is known about a domain or when theoretical guidance is ambiguous.

STEPWISE REGRESSION

Stepwise, also called stagewise, methods in fitting regression models have been extensively studied and applied in the past 50 years, and they still remain an active area of research. In many study designs, one has a large number K of input variables and the number n of input-output observations $(x_{i1}, \dots, x_{iK}, y_i)$, $1 \leq i \leq n$, is often of the same or smaller order of magnitude than K . Examples include gene expression studies, where the number K of genomic locations is typically larger than the number n of subjects, and signal or image reconstruction, where the number K of basis functions to be considered exceeds the number n of measurements or pixels. Stepwise methods are perhaps the only computationally feasible ways to tackle these problems, and certain versions of these methods have recently been shown to have many desirable statistical properties as well.

Stepwise regression basically carries out two tasks sequentially to fit a regression model

$$y_i = \beta^T x_i + \varepsilon_i, 1 \leq i \leq n, \quad (1)$$

where $\beta = (\beta_1, \dots, \beta_K)^T$ is a vector of regression parameters, $x_i = (x_{i1}, \dots, x_{iK})^T$ is a vector of regressors (input variables), ε_i represents unobservable noise, and y_i is the observed output. The first task is to choose regressors sequentially and the second task is to refit the regression model by least squares after a regressor has been added to the model. For notational simplicity, assume that the y_i and x_{ij} in Equation 1 have been centered at their sample means so that Equation 1 does not have an intercept term.

To begin, stepwise regression chooses the regressor that is most correlated to the output variable (i.e., such that the [sample] correlation coefficient between y_i and x_{ij} is the largest among the K regressors). One then performs least squares regression of y_i on the selected regressor x_{ij} , yielding the least squares fit $\hat{y}_i = \hat{b}_j x_{ij}$ and the residuals $y_i - \hat{y}_i$. A variable selection criterion is then applied to determine whether the chosen regressor should indeed be included. If the criterion accepts the chosen regressor, then the researcher repeats the stepwise procedure to the remaining regressors but with $y_i - \hat{y}_i$ in place of y_i . More generally, after the regressors labeled $j_1, \dots, j_k$ have been included in the model and the residuals $e_i = y_i - (\hat{b}_{j_1} x_{i,j_1} + \dots + \hat{b}_{j_k} x_{i,j_k})$ have been computed, the researcher chooses $\tilde{j} \notin \{j_1, \dots, j_k\}$ such that the correlation coefficient between e_i and $x_{i,\tilde{j}}$ is the largest among the remaining $K - k$ input variables, and it performs least squares regression of e_i on $x_{i,\tilde{j}}$, yielding a

new set of residuals e_i , which are used in the criterion to determine whether the regressor labeled $\tilde{j}$ should be included. If the criterion rejects the regressor, then it is not included in the model, and the stepwise regression procedure terminates with the set of input variables $x_{i,j_1}, \dots, x_{i,j_k}$.

A traditional variable selection criterion is based on the F test of $H_0: \beta_j = 0$ in the regression model $y_i = \beta_{j_1}x_{i,j_1} + \dots + \beta_{j_k}x_{i,j_k} + \beta_{\tilde{j}}x_{i,\tilde{j}} + \varepsilon_i$ to determine whether the regressor labeled $\tilde{j}$ should be added to the model that already contains the regressors labeled $j_1, \dots, j_k$. If the F test rejects H_0 at significance level α , which is often chosen to be 5%, then the regressor labeled j is included in the model. Otherwise, β_j is deemed to be not significantly different from 0, and therefore the corresponding regressor is excluded from the model. Note that because this test-based procedure carries out a sequence of F tests, the overall significance level can differ substantially from α . Such an F test of whether a particular regressor in a larger set of input variables has regression coefficient 0 is called a *partial F test*, and the corresponding test statistic is called a *partial F statistic*.

The forward selection of variables presented previously, until the latest entered variable is not significantly different from 0, is often combined with a backward elimination procedure that begins by computing the partial F statistic for each included regressor. The smallest partial F statistic F_L is compared with a prespecified cutoff value F^* associated with the partial F test of $H_0: \beta_L = 0$. If $F_L > F^*$, the researcher terminates the elimination procedure and includes all the entered variables. If $F_L < F^*$, then the researcher concludes that β_L is not significantly different from 0 and removes its associated input variable from the regressor set. This backward elimination procedure is then applied inductively to the set of remaining input variables at every stage.

Although this test-based method using partial F tests was the earliest variable selection method and is still widely used in software packages, a better approach is to choose models based on their performance assessment, which relates to how well a model can predict the outputs of future test data generated from the actual regression model. Without actually generating future test data, in-sample estimates of out-of-sample performance have been developed for the linear regression model in Equation 1. These include Mallows' C_p statistic, Akaike's information criterion $AIC(p)$, and Schwarz's Bayesian information criterion $BIC(p)$, for a set of p input variables included in the regression model. Let $RSS_p = \sum_{i=1}^n (y_i - \hat{y}_i)^2$ denote the residual sum of squares after performing least squares

regression of y_i on these p regressors, and let $\sigma_p^2 = RSS_p / n, s_K^2 = RSS_K / n$, recalling that $K(\geq p)$ is the number of available regressors. Then C_p , $AIC(p)$, and $BIC(p)$ are defined by

$$C_p = (RSS_p / s_K^2) + 2p - n, \quad (2)$$

$$AIC(p) = \log(\hat{\sigma}_p^2) + 2p / n, \quad (3)$$

$$BIC(p) = \log(\hat{\sigma}_p^2) + (p \log n) / n. \quad (4)$$

Because each quantity in the previous example is an in-sample estimate of some expected prediction loss, the criterion-based approach is to select the model with the smallest value of Equations 2, 3, or 4.

The direct application of a variable selection criterion to the set of all possible subsets of K variables leads to a large combinational optimization problem that is computationally expensive for large K . To circumvent these difficulties, one can use stepwise methods consisting of forward addition of variables followed by backward elimination of the type described previously but with the partial F statistics replaced by changes in the criterion between the models with p and with $p+1$ regressors. Although the theory underlying the selection criteria in Equation 2 through Equation 4 assumes K to be substantially smaller than n , recent advances in the literature have shown how Equations 3 and 4 can be modified for the case where K is larger than n , and have also developed efficient computational methods to perform stagewise regression in this case.

STOCHASTIC PROCESSES

If one follows the usual definition of a process as a chain of events and events being changes of the state of some entity, one can distinguish between processes whose events are deterministic changes of the state of an entity and those in which the state of an entity changes with a certain probability. These latter processes are called *stochastic processes*. Another distinction that can be made is between continuous and discrete processes: In continuous processes, the state of an entity changes smoothly; in discrete processes, it changes only at certain points of time, either equidistant or not. Moreover, the states that an entity can acquire can be continuous or discrete. Whether processes in the real world are deterministic or stochastic, continuous or discrete is not often clear; the distinction rather refers to the models of these processes and the way an observer observes them.

Processes Discrete in Time and State Space

The simplest model of a stochastic process is discrete in time and state space, that is, the state space is countable, events happen at equidistant points of time, and for each pair of subsequent states $X_s = i$ and $X_t = j$, a certain probability $p_{ij}(s, t)$ holds (Markov chain in the strict sense). It is defined by its matrix of transition probabilities:

$$\mathbf{M}_{(s,t)} = \begin{pmatrix} p_{11}(s,t) & \cdots & p_{1n}(s,t) \\ \vdots & p_{ij}(s,t) & \vdots \\ p_{n1}(s,t) & \cdots & p_{nn}(s,t) \end{pmatrix}, \quad \sum_{j=1}^n p_{ij} = 1.$$

The state of the process is described as a vector containing the probabilities of the entities being in each possible state such that for two times $s < t$ the probabilities of finding the entity in any of its possible states is

$$\begin{aligned} & (p_1(t) \quad \cdots \quad p_i(t) \quad \cdots \quad p_n(t)) \\ &= (p_1(s) \quad \cdots \quad p_i(s) \quad \cdots \quad p_n(s)) \\ & \begin{pmatrix} p_{11}(s,t) & \cdots & p_{1n}(s,t) \\ \vdots & p_{ij}(s,t) & \vdots \\ p_{n1}(s,t) & \cdots & p_{nn}(s,t) \end{pmatrix}. \end{aligned}$$

Markov chains are called homogeneous if $M_{(s,t)} = M_{(s+u,t+u)}$, that is, if $\mathbf{M}$ is always the same for $t - s = \Delta$. The standard case of a homogeneous Markov chain is the so-called random walk between cumulative gains and losses of a simple game tossing coins whereby head wins one unit and tail loses one unit. The states of this process are all positive and negative integer numbers with a transition matrix that contains only zeros in the main diagonal, q in the diagonal below the main diagonal, p in the diagonal above the main diagonal, and zeros elsewhere such that the cumulative gains and losses change only between neighboring states but can reach every positive and negative numbers (with a fair coin, $p = q = 0.5$ holds).

Stochastic Processes in Continuous Time and State Space

Random walk can be generalized to the so-called Brownian motion in continuous time and space: If the difference between neighboring states is called η , and the time span between subsequent observations Δ and the limit $\Delta \rightarrow 0$, $\eta \rightarrow 0$ is taken one can show that the probability density function (PDF) of the current state of Brownian motion is the PDF of the normal distribution whose mean is the state at the beginning of the process and whose variance is proportional to the time elapsed since the process started. Moreover, the PDF of the state change in a constant time interval is the PDF of the normal distribution with mean zero and constant variance.

As this stochastic process can also be written as a superposition of all harmonic (sine) waves of constant amplitude and all conceivable frequencies, this process is also called *white noise* (like what one can hear and see on an analogous TV set not connected to an aerial). This white noise as a process, which is stationary with respect to both mean and variance (and also all higher moments), is an important building block for modeling processes in continuous time (and also in equidistant discrete time), with applications in demography, economics, and other social sciences where time series can be analyzed with the help of ARIMA and related algorithms. ARIMA stands for an autoregressive (AR) integrated (I) moving-average (MA) process. Processes in the real world cannot be continuously observed—any observation technique yields only data at discrete points of time; hence, tools for analyzing observed process data that use the theory of stochastic processes in continuous time and state space have to be adapted to the discrete data at hand.

To identify the parameters of an appropriate model of the data delivered by an observed process (say, Y_t), it is first necessary to modify (*filter*) the data in order to

derive a new time series $X_t = f(Y_t)$, which is stationary both with respect to mean and variance (this is typically done by taking first or higher order differences and by taking logarithms, respectively). This derived process X_t can be written as:

$$X_t = \alpha_1 X_{t-1} + \alpha_2 X_{t-2} + \cdots + \alpha_p X_{t-p} + \varepsilon_t - \beta_1 \varepsilon_{t-1} - \beta_2 \varepsilon_{t-2} - \cdots + \beta_q \varepsilon_{t-q}$$

and is called an ARIMA($p, 0, q$) process. The first part is the autoregressive part of the process as the state of the process depends on several of its past states with regression coefficients $\alpha_i, i = 1 \dots p$, whereas the second part is the moving average part of the process with weighting coefficients $\beta_i, i = 1 \dots q$, determining the impact of the past of a white noise process ε_t . Discussing algorithms to determine the filter function f and the coefficients $\alpha_i, i = 1 \dots p$, and $\beta_i, i = 1 \dots q$, is beyond the scope of this entry. Most statistical packages provide these algorithms.

Stochastic Processes on Micro- and Macrolevels

In all social sciences, it is of interest what happens between the microlevel of individuals and the macrolevel of a group or a whole society. The theory of stochastic processes offers tools for this central problem, too. As a simple example, consider a small population whose members can switch between two alternatives, just as in a town hall meeting where community members can decide whether to accept or reject a motion to establish a nature conservation area. During the debate, community members change their opinion between the two alternatives according to what they perceive as the majority opinion. This opinion change is certainly not random but can be modeled as a stochastic process in discrete time and state space where the switching

probability depends on the current state of the majority building process, for instance, as follows:

State of the Population	State Changes of the Individuals
$x = \frac{n_{\text{yes}} - n_{\text{no}}}{n_{\text{yes}} + n_{\text{no}}}$	$p_{\text{yes} \leftarrow \text{no}} = v \exp(\pi + \kappa x)$
	$p_{\text{no} \leftarrow \text{yes}} = v \exp[-(\pi + \kappa x)]$

In this model, v is a parameter determining the speed of the individual opinion change, π is a preference parameter common to all individuals, and κ is a coupling parameter determining how closely the individual decision is influenced by the community as a whole. Given these simple assumptions, the process on the macrolevel will have a time-dependent PDF as shown in Figure 1.

The derivation of the time-dependent PDF uses the master equation (beyond the scope of this entry). But the example shows that the theory of stochastic processes is a powerful tool not only for analyzing time series but also for a better understanding of the micro-macro link.

STRATIFIED SAMPLING

Stratified random sampling (usually referred to simply as *stratified sampling*) is a type of probability sampling that allows researchers to improve precision (reduce error) relative to simple random sampling (SRS). The population is divided into non-overlapping groups, or *strata*, along a relevant dimension such as gender, ethnicity, political affiliation, and so on. The researcher then collects a random sample of population members from within each stratum. This technique ensures that observations from all relevant strata are included in the sample.

Types of Stratified Sampling

Proportionate Stratification

A sample with proportionate stratification is chosen such that the distribution of observations in each stratum of the sample is the same as the distribution of observations in each stratum within the population. The *sampling fraction*, which refers to the size of the sample stratum divided by the size of the population stratum (n_h/N_h), is equivalent for all strata. Proportionate stratification is primarily useful when a researcher wishes to estimate values in a population and believes that different groups within the population differ on the variable of interest. For example, suppose a university administrator wants to measure attitudes about imposing a new student fee among students at a university with 10,000 students, including 4,500 in the humanities, 3,000 in the sciences, and 2,500 in business. If the administrator wanted a sample of 200 (2% of the students), she would randomly sample 90 humanities majors (2% of 4,500), 60 science majors (2% of 3,000), and 50 business majors (2% of 2,500). It is essential that the stratification factor be related to the variable of interest. Stratification by major will improve the precision of the estimate of attitude in the population to the extent that students in different majors have different attitudes about the fee increase and relatively similar attitudes to other students within their major.

Disproportionate Stratification

In disproportionate stratification, the sampling fraction is not the same across all strata, and some strata will be oversampled relative to others. Disproportionate stratification is primarily useful when a researcher wants to make comparisons among different strata that are not equally represented in the population. For

example, a researcher in the United States who is interested in comparing learning outcomes among children of different ethnic backgrounds might use disproportionate stratification to ensure that the sample includes an equal (or at least sufficient) number of children from minority groups. Suppose that a school district of 10,000 children is 80% Caucasian (8,000 children), 15% African American (1,500 children), and 5% Asian American (500 children). If a researcher draws a simple random sample of 100 children (1% of the population), the sample is likely to contain about 15 African American and 5 Asian American children, but by random chance those groups could be considerably smaller. To ensure adequate samples of African American and Asian American children, the researcher can increase the sampling fraction of these subgroups. Say the researcher decides to include 40 students from each group in the sample. In this case, the sampling fraction for Caucasians is $40/8,000 = .005$, for African Americans, it is $40/1,500 = .03$, and for Asian Americans it is $40/500 = .08$.

Although a disproportionate stratified sample is optimal for making comparisons among strata, it is not ideal for making estimates regarding the total population, because the sample does not evenly represent the population. If the researcher wishes to draw conclusions about the population as a whole based on a disproportionate stratified sample, then results must be weighted to reflect the different sampling fraction of each stratum.

Benefits of Stratified Sampling

Increasing Representativeness of the Sample

In a simple random sample, every member of the population has an equal chance to be selected as a member of the sample. In theory, this should produce samples that are perfectly representative of the population. In practice, this is often not the case, particularly when the sample size is small or when the population contains small subgroups that might be underrepresented or missed entirely in a randomly drawn sample. Stratified sampling helps ensure that all relevant groups are represented in the final sample.

Improving Precision of Estimation

Proportionate stratified sampling can provide an increase in precision (meaning a reduction in error) relative to simple random sampling, if variability within each stratum is smaller than variability across the entire population. Variance between strata is

removed from the total variance, thus reducing the standard error and improving precision of the estimate. Error variance will be reduced to the extent that groups are homogeneous within strata and heterogeneous between strata. Thus, it is important to choose stratification variables that divide the population into groups that are distinct from each other and consistent within each group.

If the strata do not differ (the between-strata variance is zero), then the total variance will not be reduced; however, the total variance will never be increased by using proportionate stratification.

Economy

When used properly, stratified sampling can substantially reduce the number of data points necessary to achieve precise population estimates and statistically significant comparisons. A researcher can achieve the same degree of power using a smaller sample if the within-strata variability is smaller than the total population variability. In addition, stratified sampling can be used to reduce overall costs of data collection through effective allocation of resources. For example, when predicting the outcome of a presidential election, it is necessary to stratify by state because the general election is decided by the popular vote within each state rather than by the overall popular vote in the nation. In states where the voting trends are very strong, such as Oklahoma, which voted 66% for McCain versus 34% for Obama in the 2008 Presidential election, accuracy in predicting the election outcome can be achieved with a relatively smaller sample compared with states where the election is very close. Small fluctuations in sampling are unlikely to lead to an incorrect prediction in a population with such high internal consistency. In contrast, accurate prediction requires a larger sample in states with close contests, such as North Carolina, which elected Obama with a final advantage of fewer than 14,000 votes out of more than 4 million votes cast. Knowing which states can be predicted with smaller samples can allow pollsters to distribute their resources more efficiently.

Reducing Bias Caused by Nonresponse

Biases caused by nonresponse might be reduced, although not eliminated, using stratification. When individuals who are initially selected for a study choose not to participate, this leads to a biased sample, particularly if certain groups of people are more likely than others to eschew participation. Using stratified sampling during the data-collection phase, nonresponders can be replaced by participants from the

same stratum, thus reducing the bias. After data collection, it is possible to use stratification weights to correct for minor sample biases resulting from nonresponding; this procedure is known as *poststratification*.

Concerns About Stratified Sampling

Not Knowing Distribution of Strata in the Population Leads to Inaccurate Estimates

A properly stratified sample can be difficult to achieve. It is essential to have up-to-date and accurate information about the strata in the population. If the distribution of strata in the population is measured or estimated inaccurately, then the stratified sample will mimic this inaccuracy and will not be representative of the population. For example, using census data to determine strata might lead to inaccurate stratification if the distribution of population characteristics has changed during the time since the census was conducted. When disproportionate stratification is used, inaccurate knowledge about population strata will lead to incorrect weighting, which leads to inaccurate population estimates based on the sample.

In some cases, it is not possible to have complete knowledge about population strata prior to data collection. For example, election pollsters cannot know in advance which people will actually vote in the election and must do their best to estimate the voter turnout among different groups. Stratifying by gender and ethnicity according to their overall population distributions will lead to inaccurate election predictions if voter turnout is different among men and women from different ethnic groups.

Stratifying on an Irrelevant Factor Does Not Improve Precision

Stratified sampling will confer no benefit if the characteristics used to divide strata are not relevant to the research question(s). For example, if student attitudes about a university fee increase do not vary across different majors, then stratifying the sample by major will be a wasted effort. In studies that measure multiple variables, relevant stratification factors might not be the same for all variables. When using a complex survey, it might not be practical or even possible to stratify along all dimensions that are relevant to the variables. Researchers must balance the cost of creating a stratified sample against the measurement precision gained by stratification.

Disproportionate Stratification Can Lead to Reduced Precision

Population estimates made using a proportionate stratified sample will never be less precise compared with estimates made using an SRS of the same size. However, a disproportionate stratified sample might be less precise compared with SRS. This problem occurs when strata that are oversampled relative to their population distribution have higher variance compared with strata that are undersampled. Disproportionate stratified sampling can lead to reduced overall precision, if the variance in oversampled strata is greater than the variance in the overall population.

Stratification Does Not Eliminate the Need for Probability Sampling Techniques

Stratified sampling requires that samples be drawn randomly within each stratum. Using nonprobability techniques (e.g., volunteers) to sample within strata is called *quota sampling*. Quota sampling helps ensure that members of relevant groups are included in the sample, but it does not ensure that the sample is representative. A convenience sample is still a convenience sample, even if the researcher has taken care to recruit volunteers from different genders, education levels, and so on.

Analytic Strategies With Stratified Samples

Estimating population values using a stratified sample is more complicated compared with using SRS. The analysis effectively involves two steps. First, sample statistics are calculated for each stratum, and then these estimates are combined using weights that reflect the relative distributions of the strata in the population. As shown in the following formula (from Richard Scheaffer, William Mendenhall, and Lyman Ott) for sample mean based on a stratified sample ($\bar{y}_{st}$) with L strata, the sample mean is computed for each stratum ($\bar{y}_i$), multiplied by the population size of that stratum (N_i), and summed across all L strata before dividing by the total population size (N).

$$\bar{y}_{st} = \frac{1}{N} \sum_{i=1}^L N_i \bar{y}_i.$$

The error variance ($s_{\bar{y}_{st}}^2$) is computed as follows, where s_i^2 is the variance of a given stratum and n_i is the sample size for a given stratum:

$$s_{\bar{y}_{st}}^2 = \frac{1}{N^2} \sum_{i=1}^L N_i^2 \left(\frac{N_i - n_i}{N_i} \right) \left(\frac{s_i^2}{n_i} \right).$$

Statistical analysis programs such as SPSS, an IBM company, formerly called PASW® Statistics, provide commands to specify variables used for stratification and compute parameter estimates based on the stratified sample.

“STRENGTH OF WEAK TIES, THE”

Mark Granovetter’s 1973 article “The Strength of Weak Ties,” published in the *American Journal of Sociology*, is an influential work in sociology and beyond. Its main role lies in establishing an association between microlevel research (e.g., looking at interactions of actors) and macrolevel research (e.g., studying themes social structures and social mobility) empirically. For this, Granovetter focuses on the *strength of ties*, which he defines based on a combination of three factors: the frequency and duration of contact, emotional intensity, and the reciprocal nature of the dyad.

In this entry, the basic information about the concept of the strength of ties as published by Granovetter is given. Also discussed is the reception of this article, including important criticism that has been voiced.

Weak Ties as Bridges

How is the strength of ties important? Granovetter points to prior research on transitivity, which is an important concept in social network research. The basic idea is that if Node X is positively connected to Nodes Y and Z, it becomes more likely that Node Y is

also positively connected to Node Z. This then would form a so-called *transitive triad*. Often, based on the definition provided, these links are also quite strong. The nodes know each other very well—not only because they are direct contacts but also because they share acquaintances.

Weak ties can be conceptualized as ties outside these transitive triadic structures. Instead, weak ties often form bridges *between* such triads; they connect two nodes (and group of nodes) that otherwise would not be connected. Hence, this plays an essential role for, for instance, the diffusion of innovations or individuals' learning of new information. This is also reflected by the fundamental empirical finding of this article. Granovetter found that in his sample of Boston engineers, people found such weak ties to be more helpful in finding a new job because ego's weak acquaintances have access to different pools of information.

Reception

The 1973 article "The Strength of Weak Ties" is based on Granovetter's dissertation, which was submitted 3 years prior. The article was well-received, given that it narrowed the gap in research about the micro–macro link of social science research. Today, it is one of the most cited texts on social network analysis.

Ten years after this article, Granovetter published a direct follow-up article with the title "The Strength of Weak Ties: A Network Theory Revisited," wherein he reviewed work that tested and further developed his arguments from 1973. The discussion of weak ties also provided a fruitful basis for Ronald Burt's concept of structural holes, which became another foundational concept in network theory.

Importantly, the argument has not been without its critics. It is especially the operationalization of the (very central) strength of ties that was not addressed in detail by Granovetter and that impeded research on the topic. Firstly, there is the question of how to adequately measure the strength of ties. How can one collect data about the three elements of the strength of ties—the frequency and duration of contact, emotional intensity, and the reciprocal nature of the dyad? And, how does one integrate these data to form a final verdict about the strength of a tie? Even ignoring practical problems of conducting this measurement, the very definition seems problematic. For example, Granovetter emphasizes the frequency and duration of contact—arguably because it is easier to measure than the other two. However, empirical research shows that two persons can be close without a high frequency of interactions, or vice versa, two people can remain rather distant from each other despite a high frequency of interaction.

Going further, the strength of ties could be perceived as a multidimensional phenomenon, which is not captured by Granovetter's initial definition. Some aspects of a relationship may be strong (e.g., colleagues who work together intensively and who trust each other), whereas others are underdeveloped (e.g., the colleagues may still be emotionally disconnected). Granovetter's definition offers little guidance on how to deal with such cases.

Secondly, it is doubtful that the binary classification as a weak or strong tie is able to capture the social reality at the level that would be appropriate for many research questions. Put differently, the strength of ties could be conceptualized as a continuous phenomenon. Shades exist between the extreme end points of *weak tie* and *strong tie*.

Nevertheless, Granovetter's work inspired further development of the concept of weak ties and adjacent concepts. As mentioned earlier, it has inspired an ongoing debate about how microlevel interactions lead to macrolevel outcomes. Both the 1973 article presented in this entry and the concept of the strength of ties that it develops became and still are core knowledge within the field of social network analysis.

STRUCTURAL EQUATION MODELING

Structural equation modeling (SEM) belongs to the class of statistical analyses that examine the relations among multiple variables (both exogenous and

endogenous). The methodology can be viewed as a combination of three statistical techniques: multiple regression, path analysis, and factor analysis. Its purpose is to determine the extent to which a proposed theoretical model, often expressed by a set of relations among different constructs, is supported by the collected data. Therefore, SEM is a technique for confirmatory instead of exploratory analysis. This entry represents a nonmathematical overview of SEM, with an emphasis on its benefits, usage, and basic underlying assumptions. Principal concepts related to the methodology and summarized comparisons with other multivariate analyses are also presented. Then, the entry outlines and discusses a pragmatic six-step framework to carry out the SEM statistical analysis. Advances in SEM with respect to the relaxation of its fundamental assumptions conclude the entry.

Overview

Essentially, SEM statistically tests hypotheses of multiple relations among measured variables. As depicted in Figure 1, the conceptual variables or constructs are denominated “latent variables.” Hence, SEM models these qualitative relations among the latent variables and then tests the extent to which these relations explain the data according to a fit criterion. In many cases, the latent variables cannot be directly observed and are further specified and estimated through the measurements of underlying variables (the Xs and Ys in Figure 1). Besides, through the

model’s latent variables and their underlying measured variables, SEM can explicitly account for measurement errors.

In general, two distinct but interconnected models lie within a single SEM analysis: a measurement model, aimed to evaluate the extent to which the measured (underlying) variables effectively capture the concepts (or constructs) in the model, and a structural model, aimed to simultaneously test all the causal relations (i.e., the links among the constructs) found in the overall SEM model. The consistency of the causal relations among the latent variables does not rely on the confirmatory testing but on the theoretical support of the model proposed.

SEM has its origins from several different multivariate methods. On one side, the measurement model originates from a much broader category of *factor analysis*. This statistical technique is often used to study patterns within a set of variables, with the objective to identify their underlying structure. These groupings of variables are known as *factors*. Initial development of factor analysis came from Charles Spearman (1904) by his work on the identification of underlying structure of mental abilities.

Factor analysis is generally considered an exploratory technique. On the contrary, confirmatory factor analysis requires from a priori assumptions about the structure of the variables and serves the same purpose similar to that of the measurement model in SEM framework.

Figure 1 An Example of SEM Involving Measurement and Structural Models

The second constituent, *path analysis*, corresponds to the structural model within SEM analysis. It allows a researcher to model complex relationships among various variables and visually represents them in a path diagram. Path analysis compares the regression weights obtained from a proposed causal model to the correlations obtained from the data and estimates the fit of the data to the proposed model. In contrast to SEM, path analysis does not perform the simultaneous estimation of all causal relations specified in the model.

Third, SEM relates to *multiple regression*. This technique is used to learn about the relation between several independent variables and a dependent variable. Instead of dependent and independent variables, SEM identifies and utilizes exogenous and endogenous latent variables. Exogenous latent variables are mostly equivalent to the independent variables in multiple regression because they are not determined by other latent variables in the model. Endogenous latent variables, however, are dependent on other latent variables within the SEM structural model. In contrast to multivariate regression analysis, SEM allows an endogenous variable to serve as both dependent and independent constructs at the same time along with simultaneous estimation of all model equations (i.e., relations in the model). In Figure 1, the latent variables one, two, and four are exogenous, and the latent variables three and five are endogenous.

Multiple regression establishes correlational links between independent variables and a dependent variable. SEM attends to three different types of links between the variables: (1) the relation between the latent variable and the measured variables, (2) dependent relations between latent variables, one exogenous or endogenous latent variable (the cause) and one endogenous latent variable (the effect), and (3) correlational relations among exogenous latent variables, in which no causality is presumed. The three types of links are represented in Figure 1.

SEM is widely used in scientific research because it offers clear advantages over other multivariate techniques. SEM is also the analytical technique of preference in nonexperimental research designs (where randomization and manipulation are not possible). Many researchers realize its great advantage of being able to test multiple relations and to account for multiple variables without compromising statistical power. At the same time, SEM integrates the test of the proposed theoretical model and the study of the errors of measurement in a comprehensive approach.

Although the versatility of SEM and its possible analysis of latent variables (constructs) without measurement errors open the door to enormous

opportunities, there exist a variety of limitations and weaknesses through its adoption. Common limitations of SEM include that it cannot overcome problems inherent to study, model design, and method; the impact of study design on power and sensitive of measures; the potential omission of variables; and failure to consider equivalent and alternative models. SEM is also subject to estimation problems, particularly for models with many free parameters. As pointed out by Christof Nachtigall and colleagues (2003), SEM estimation typically requires a significant sample size. This may represent an issue if the availability of the pool of subjects is bounded. Consequently, simpler or more straightforward statistical models may be of greater advantage when the sample size is small. Jihye Jeon (2015) stated that generalization of SEM results can be problematic since they are subject to sampling or selection effects with respect to at least three aspects—individuals, measures, and occasions. The article also offers a structured review of the weaknesses associated with SEM.

Current commercial packages for conducting SEM have simple interfaces and are easy to use. Among them are LISREL, AMOS (SPSS interface), *Mplus*, and EQS. The statistical programming language R and Python also provide a variety of packages to perform SEM analyses.

Six-Step Framework

SEM practice requires attention to both the theoretical support of the model and the experimental design. There are a number of basic steps, as summarized in

Figure 2 Six Steps in a Typical SEM Framework

Figure 2, to perform a typical SEM analysis. Initially, the constructs are defined and the models involving the underlying variables are specified, paying special attention to the measurement model and the inherent experimental design. After the estimation of the path coefficients in the model, the collected data are used to determine the fit of the model. Once validity of the latent variables has been confirmed, the researcher then focuses on the structural model. In an iterative process, the researcher can test structural variations of the model to assess their fit to the data. Final interpretation of the results should be based on the fit of model, the design of study, and the extent of how closely the gathered data conform to the basic SEM assumptions.

Step 1: Model Specification

The initial step in the development and testing of a SEM model focuses on identifying the definitions and operationalization of latent variables and forming the basis for the measurement model. Appropriate measurement of each latent variable through the use of indicators (i.e., underlying variables X s and Y s in Figure 1) that properly represent the true subdimensions of the construct is essential not only to drawing valid and meaningful conclusions but also to maintain integrity of the overall SEM analysis.

Likewise, a solid theoretical support is required to generate the initial structural model, which connects latent variables (constructs) through both causal and correlational links. Causality implies a directional relation between a construct identified as the cause and another construct identified as the effect. John Stuart Mill proposed three requirements to demonstrate the existence of a causal relation: (1) the cause must precede the effect, (2) the cause is nonspuriously related to the effect, and (3) there is no plausible explanation for the effect other than the cause. To the greatest extent possible, and in order to justify the validity of the conclusions drawn from the SEM analysis, a researcher has to attend to previous findings. The formal process of specifying the structural model consists of deciding which path parameters are fixed to zero (for those constructs without any assumed causality) and which parameters are free and can thus be estimated and tested by the data. The number of free parameters used in the structural model also has implications to the design of the study. More details are discussed in the next section.

There exist different approaches to model development and testing, depending on the stage in the scientific discovery process the researcher is at, and the previous or existing knowledge on the links found in

the model. With the primary purpose of conducting confirmatory analysis, a single model can be proposed and tested against the data. Otherwise, alternative models can be generated by the existing theories and compared using their goodness of fit to the data. To refine a model, one can adopt a third strategy that progressively modifies the experimental model by accounting for the improvement in its ability to fit the data.

Despite the strategy followed and the final level of fit achieved, a researcher must keep in mind that the tested model holds only for the sample included in the study. Any further causal generalizations with respect to persons, settings, treatments, and outcomes must be carefully considered and evaluated based on existing conceptual frameworks and theories.

SEM allows a researcher to test theoretical propositions using nonexperimental data, resulting in valid conclusions only when theoretical rationale is consistent. Furthermore, it is possible that a large number of latent variables can lead to multiple alternative models with similar levels of fit to the empirical data. A researcher must use his or her own knowledge and judgment to develop and obtain a valid and meaningful model. In summary, a priori specifications are essential to SEM analysis. This precursory requirement characterizes SEM as a confirmatory (rather than an exploratory) statistical technique.

Step 2: Study Design

After the theoretically constructed model has been specified, several considerations affecting the design of the study must be made. Each latent variable should be specified through the measurement of multiple

Figure 3 Measurement Model of SEM

indicator variables (denoted by X1 to X4 in Figure 3). These indicator variables would be operationalized as scale items in modeling. Although it is recommended to utilize multiple indicator variables per latent construct and to adopt previously tested items for better theoretical support, it is up to the researcher to decide how many indicators are to be included in a given latent construct. At the same time, the researcher should also be aware that the type of scale selected for each item (nominal, ordinal, interval, or ratio) and the range allowed for the measured values (e.g., 3-point Likert-type scale vs. 7-point Likert-type scale) exert an influence on the covariances among the latent variables, which in turn affect the final outcomes and the goodness of model fit.

In addition, there are two other important factors for design of study: the sampling method and the sample size. The sample used in SEM should be representative of the population in order to derive useful causal generalizations. The sampling procedure should also allow room for flexibility regarding missing data points. Generally speaking, the minimum sample size required is 200. Very large samples, especially the ones with more than 400 records, may result in data overfitting and poor performance and generalizability of the SEM model. The number of free parameters in the model, which increases with the number of indicator variables and the number of latent variables, should be adjusted for larger sample sizes. Other factors affecting the required sample size are associated with the statistical assumptions of SEM, namely, deviations from multivariate normality (critical when maximum likelihood estimator [MLE] is used to estimate the path coefficients), missing data, and specification errors (omitted variables), which may distort the correlations between the error terms and the exogenous variables.

Finally, although it is not desirable to have missing data points, the situation may inevitably occur due to uncontrollable factors. In such case, a researcher should examine the missing samples in the data set as a precautionary step. The general rule of thumb is that the samples should be missing completely at random, that the missing data do not depend on another variables, or that samples are missing at random when the missing data for a variable are related to another variable. Missing data should not represent more than 10% of the total data and constitute any explicit patterns.

Step 3: Model Estimation

The model estimation step follows the assessment of the free parameters identified in Step 1. Unless they are fixed, links in the SEM model, including the ones between the error terms and the indicator variables and the causalities in structural model (see Figure 1), need to be estimated. Simply put, after compiling the data with respect to the model specifications determined in Step 2, sample covariance (or correlation) matrix for various entities can be calculated. Then, in the model estimation process, each parameter is estimated in a way that reassembles the sample covariance (or correlation) matrix to the maximum extent. Mathematically, a fitting function is used to minimize the difference between the observed and the estimated matrices. The most common fitting function is based on MLE, although other methods such as generalized least squares, weighted least squares (WLS), and asymptotically distribution free (ADF) estimation are frequently available in the software packages. In situations where MLE shows great sensitivity to nonnormality or the multivariate normality assumption is not met, the other fitting functions, especially ADF estimation, are of preference.

Although it is recommended to compare covariance matrices in SEM analysis, the fit may also be assessed using correlation matrices. A correlation matrix is standardized, dimensionless, and easier to understand; however, it offers less information than the covariance matrix. A researcher should use his or her best judgment to determine which option better accomplishes the goals of the study.

Some researchers have suggested using multistep approaches in which the estimation of the parameters of the measurement model and the estimation of the parameters of the structural model are performed in different steps (see Schumacker & Lomax, 1996).

Step 4: Measurement Model Validation

Validity refers to the extent in which an inference is truthful and consistent with previous empirical findings and existing knowledge (Shadish, Cook, & Campbell, 2002). The measurement model validation step explores and verifies the validity of the tested model through an examination of the validity of the measurement model's latent variables, that is, an assessment of the goodness of fit of the specified model.

Validity of the latent variables (or constructs) should be examined from both statistical and conceptual perspectives. Their assessment is a process covering the context of appropriateness of construct definitions,

correct identification of internal structure (content validity, face validity), adequate operationalization (or implementation) through multiple items—indicator variables (predictive, concurrent, convergent, and discriminant validities should be evaluated), and estimation of reliability of the measures.

The estimation of a goodness of fit is based on a statistical evaluation of the similarity between the actual covariance matrix and the estimated covariance matrix. A larger degree of similarity between the two matrices usually implies a better fit of the model to the data. Nevertheless, researchers should be cautious of the problem of overfitting in SEM analysis.

In order to assess the fit, several measures of fit can be considered. The most common measure of fit, chi-square (χ^2), statistically assesses the significance of the difference between the observed sample covariance matrix and the estimated covariance matrix. Alternative measures of fit, along with some brief comments, are compared with χ^2 in Table 1. The number of parameters and parameters to be estimated (calculated and referred as *degrees of freedom*) is frequently used to account and compensate for model complexity. The final adoption of a given model should be considered on a case-by-case basis and special attention paid to the characteristics of the sample data, the proposed model, and the overall design of the study. Researchers can use several fit measures when assessing the goodness of fit of the measurement model.

Validity issues in the measurement model should be corrected before advancing to the estimation of the structural model.

Step 5: Structural Model Fit

The estimation of the structural model relies on the previous specification of the relations in the model

(Step 1). Figure 4 presents an example of a structural model with four hypotheses.

To assess the validity of the structural model, a structural goodness of fit is calculated. Similar to Step 4, the estimated covariance (or correlation) matrix is compared to the covariance (or correlation) matrix calculated from the observed data. The χ^2 statistic is a general guideline to establish the fit of the model. Specific hypothesis relating two of the latent variables in the model can be evaluated by looking at the significance and value (to assess the directionality) of the path parameters. Corresponding to the model selection and refinement strategies described in Step 1, competing models can be compared using the adjusted goodness-of-fit index or the comparative fit index (see Table 1) or their χ^2 values tested for significance using the chi-square difference test statistic ($\Delta\chi^2$).

Estimation of the structural model is generally conducted in an iterative manner, in which the researcher modifies the structure of the model and reestimates until a satisfactory goodness of fit is achieved.

Figure 4 An Example of a Structural Model in SEM

Table 1 Goodness-of-Fit Measures

Goodness-of-fit measures	Statistical test	Advantages
Chi-square (χ^2)	Yes	Sensitive to sample size and the number of parameters
Adjusted goodness-of-fit index (AGFI)	No	Adjusted for the complexity of the model and has lower sensitivity to sample size than χ^2
Root mean square error (RMSE)	No (confidence interval can be reported)	Corrects for sample size and model complexity
Comparative fit index (CFI)	No	Partly insensitive to sample size. Allows incremental verification of fit
Wald test	Yes	Can evaluate difference in χ^2 when a parameter is added or dropped

**Figure 5** SEM Process in Schematic Flowchart

Step 6: Interpretation and Discussion

Virtually essential in any scientific endeavor, the final step in the SEM analytical framework is to efficiently communicate and interpret the results of the study. At this point, the researcher should recapitulate the characteristics and consistency of the model, design factors, and possible violations of the assumptions of SEM. Also, design considerations should impact the validity and the generalizability of the findings.

To facilitate the verification of the proposed theory, interpretive discussion should include study setting, samples, measurements, or estimation decisions that may have any underlying effects on drawing the conclusions from the SEM analysis.

As a summary of the entire SEM process, a schematic flowchart depicting Steps 1 through 6 can be seen in Figure 5.

Developments

This entry has briefly introduced SEM. Methodological advances capable of extending the basic statistical qualities and relaxing some of the fundamental assumptions of SEM exist. For instance, nonnormality can be addressed using WLS estimators. Besides, developments in SEM allow nonlinearity of the observed variables and existence of interactions among latent variables (e.g., Kelava & Brandt, 2019; Schumacker, 2017). Simultaneously, nonlinear structural equation mixture modeling has been proposed and developed (e.g., Mayer, 2017). Two-stage least square estimation is a solid alternative to MLE to account for interactions. It is also useful when the model contains feedback loops. Longitudinal analysis of data can be performed in SEM using the latent growth curve model (see Kaplan, 2000) or the Bayesian approach (see Liang et al., 2017). Furthermore, there exist a growing number of studies empirically examining SEM used in conjunction of bootstrapping in order to improve performance (e.g., Kock, 2018; Streukens & Leroi-Werelds, 2016).

STRUCTURAL EQUIVALENCE

Structural equivalence refers to the similarity of relationships between given network elements. In the literal sense, “structure” means the arrangement and mutual relationship of the elements which form the whole, that is, the construction of that whole. Structural research may include the structure of a phenomenon, such as network relationships or correlations of variables, or comparing the constructions of two or more objects over time, whereby they are studied over two or more periods. However, understanding the structure of relationships, especially long-term ones, has become an elementary research category. Modern research in the social and natural sciences, in which networks play a pivotal role, focuses on the structure of relations between elements. Structural equivalence is operationalized slightly differently in various analytical systems, but this entry focuses on its meaning in social network analysis. The principles and techniques discussed here apply in similar ways to other methodologies.

Principles

An important category in network analysis is the equivalent structure in relation, where the examination of the internal structure is a crucial element in the validation process. It is particularly important due to the realities of the Covid-19 pandemic in 2020, which prompted researchers to focus on understanding validation as a kind of declaration of the validity of a research method, ensuring that all the requirements set before the trial were met, and the obtained result is credible and dependable.

Structural equivalence means that a node is identically related to another node; thus, these nodes are considered equivalent. An essential choice of the researcher is to set up the network mechanism (i.e., network architecture). This involves focusing on the pattern of relationships rather than on the content of the bond. This approach, also known as topological, can be referred to as structural embedding. The topological perspective states that two nodes achieve comparable results because they have a structurally similar position, even if they are not related to each other. Actors in a network are structurally equivalent as far as they are related to a third node. The type of behavior in which nodes behave similarly means relationships that influence each other and adapt specific features. One feature of structural equivalence is its substitutability concerning relational bonds. Network architecture also involves a set of actors clustered together whereby researchers treat their roles as data. Because of

their structural equivalence, two persons performing the same role can be replaced. Thus, their reflexive, symmetric, and transitive binary relation defined in a set identifies its elements with each other in some way, which establishes the division of the set into disjoint subsets according to this relation.

Techniques

The first step in studying equivalent structure is constructing a matrix that represents for each pair of actors the similarities and differences to the structure of relationships with others. There are many ways to measure similarity and difference, but two common metrics are the Pearson's correlation coefficient and the Euclidean distance. The value of the Pearson coefficient indicates the strength and direction of the linear relationship between two variables. The value of the correlation coefficient is in the closed range $[-1, 1]$. The greater its absolute value, the stronger the linear relationship between the variables—that is, two actors are always closely related to each other, thus, they occupy a structural equivalence: 0 means there is no linear relation, 1 means there is a positive relation, and -1 means there is a negative relation between features. The Euclidean distance allows the measurement of diversity. In most cases, the analysis of structural equivalence based on the Euclidean distance and the Pearson correlation coefficient gives complete information about the equivalence between items in the network. Therefore, a structural equivalence is related to the similarity of the relationship patterns between network elements. Hence, two items are mutually equivalent if they have the same relationship with all other items.

In social sciences, studies of structural equivalence are predicated on the basis of predetermined characteristics of “actors,” the identification of unobservable features, or probabilities of certain chain elements belonging to a given hidden class (e.g., available from previous statistical analyses).

The analysis of the balanced structure in the a priori approach consists of identifying similar items from the point of view of their relations with other elements of the system. The degree of similarity is often measured based on certain positive matches and presented using hierarchical cluster analysis methods. The items with identical relations with other elements in the chain structure are considered the most balanced. In the assessment of structural equivalence, not only are individual elements distinguished, but also certain blocks of features, consequences, and values that are mutually replaceable. This property in the a priori approach can be more strongly distinguished using the convergence of iterated correlations (CONCOR) model. It is a

model of iterative correlations that allows assessing the degree of similarity of the vectors of similarities of X positions to the vector of similarities of Y positions.

The a posteriori approach—that is, the identification of hidden relational segments—can be estimated on the basis of the maximum likelihood method based on the expectation maximization (EM) algorithm or Bayesian estimation (Gibbs randomization). Thus, stochastic block models of relational data are applicable here, allowing the isolation of hidden classes of structural relationships between the positions taken by the interaction partners. This is a completely different approach to using combinatorial optimization algorithms such as taboo searches to find partitions that minimize errors. Once the nodes are broken down into structurally equivalent nodes, they are typically used as a qualitative factor in predicting results at the node level. The significant relationship between the structural division of equivalence and attitude suggests that attitude is, at least in part, determined by the position in the network. Blockmodeling makes it possible to extract this structure from the observed social relations. A pragmatic justification is to reduce a large, potentially incoherent web to a smaller, intelligible structure that is easier to interpret. Blockmodeling also makes this easier. In both cases, blockmodeling is an empirical partitioning (clustering) procedure.

The adequacy of such a procedure can be claimed on two levels. One level can be found in ideal structures where nontrivial structural equivalences exist. In such ideal structures, it is possible to decide whether known equivalences in the network are located using a specific blockmodeling procedure. The second tier is found in empirical (nonideal) networks with few exact matches. An alternative approach is to use the initial correlation (or distance) matrix directly, instead of first finding the discrete clusters of equivalent nodes and using cluster membership as a variable. In this approach, the correlation between two nodes gives a degree of equivalence between them, and this is used to predict the degree of similarity in their behavior, attitudes, or other effects. In addition to using continuous degrees of equivalence, this approach has the advantage of being less “massaged” than the cluster membership variable. The clustering algorithms are numerous and can give quite different responses, leaving open the question of whether the relationship found between structural equivalence and the result variable would still be found if a different clustering algorithm were used.

There are good reasons to pursue the idea of structural equivalence. One is the idea that there are fundamental role structures with observed network behavior, especially interaction, providing indicators of the basic structure. Another is that structural equivalence is

associated with obtaining a lower level of risk related to difficulties in distinguishing the factors influencing that individual relationships in the network analysis are understood as relationships between units.

“STRUCTURAL EQUIVALENCE OF INDIVIDUALS IN SOCIAL NETWORKS”

The 1971 article by François Lorrain and Harrison C. White titled “Structural Equivalence of Individuals in Social Networks” and published in the *Journal of Mathematical Sociology* intends to further our understanding of the interrelations among in the connections in social groups. The authors introduced an approach to social network analysis that pays special attention to identifying social positions and roles. The algebraic procedure of aggregating relationships and individuals concurrently presented in this article allows for distilling “global patterns” of social positions and roles.

The original article is structured as follows: Lorrain and White start by presenting the general aim of the article besides arguing for the significance of global patterns to be explored. They then present fundamental network analytic terms and models and introduce their own set of concepts, such as compounds, morphisms, or categories. Afterward, Lorrain and White construct an example to illustrate diverse concepts and subsequently dive into what is arguably the core of the article: structural equivalence and the necessary operations of aggregation and reduction to make it visible. They

revisit the constructed example with an intent to show these processes in a relatable manner. The authors conclude their article after providing two further illustrations. Throughout the article, Lorrain and White attempt to link algebraic operations to sociological argumentation, which makes the article accessible also to audiences that are less informed about mathematical sociology.

In the following, the core construct of this article, structural equivalence, is further explained. Then, the significance of the text is discussed in relation to social network analysis and research design.

The Objectives of the Article and the Concept of Structural Equivalence

Lorrain and White define two objects (nodes, actors, individuals) to be structurally equivalent, when both objects relate to all other objects in the same ways. As such, structural equivalence can be perceived as an operationalization of both social positions (the collection of individuals associated to others through similar ties) and social roles (the pattern of ties between positions). In terms of the purpose of research and research design, a research necessitating the perspective of structural equivalence would be less interested in the relationship of individual actors and the rest of the network (e.g., through centrality metrics) but more focused on identifying individuals who take similar positions (e.g., two employees being subordinate to the same supervisors and having access to the same peers for information). To illustrate this point, it is beneficial to contemplate a reference to kinship; Lorrain and White have also included kinship research at multiple points of their article. Kinship offers an interesting example, as we can label relatively complex relationships based on heritage and marriage even in everyday language. For example, “silent-brother-in-law” describes a relatively complex social position from the point of view of one individual that draws from multiple types of ties. While actors may share a specified social role, they do not (necessarily) form cohesive subgroups (a group of silent-brothers-in-law that relate to each other), which would be the focus of graph theory-based social network analysis. Importantly, this also suggests that structural equivalence is to be determined based on a multitude of types of ties (marriage and heritage in the kinship example, hierarchical relationships and information access in the employee example). Bearing this in mind, we could think of this approach of finding structural equivalence by applying functions of aggregation and reduction as a means of thinking about social positions that we cannot label easily.

Impact and Reception of the Article

Lorrain and White’s article was very influential in opening a field of research within social network analysis not based on graph theory, consequently opening opportunities for more varied research designs. (Note: In the article, Lorrain and White often refer to graph theory-based studies in order to provide a contrast to their own approach.) It is especially their concept of structural equivalence that first appeared in this article and was picked up by other scholars. It was also further developed and generalized (e.g., toward concepts such as regular equivalence, generalized equivalence, or the domain of procedures of blockmodeling). The essence of this approach is the focus on more aggregated, global structures encompassing different roles and positions, which until then had not been considered by graph theory-based network analysis.

From the perspective of research design, in general, Lorrain and White’s text opened up an entirely new set of research questions based on structural equivalence to be tackled and established the methodological foundation (as discussed earlier in this entry). That said, the text does not discuss other aspects of research design, such as how data are being procured, which leaves it to researchers to determine how the concept of structural equivalence may be fit into an overall research design.

STRUCTURAL HOLES

Structural holes have been examined in a variety of contexts, most notably organizational and health ones, by scholars representing a number of

disciplines. The original conception was developed by sociologist Ronald Burt. In his 1992 book *Structural Holes: The Social Structure of Competition*, he describes how individuals who developed relationships that brokered gaps in social structures were more likely to be promoted faster at an earlier age. He argued that much of market-oriented competitive behavior could be explained by access of individuals to “holes” in social structure. In subsequent research, he found that such managers were more likely to be exposed to new ideas.

Structural holes reflect a paradox, the natural tendency of human systems to differentiate, to specialize effort, while at the same time these separate efforts need to be integrated into a large whole, often by a human agent, either a broker or bridge. Brokers are individuals (e.g., senior level managers, deans) who stand between two groups (e.g., marketing and engineering divisions) that are not naturally likely to have relationships with each other, while another set of individuals bridge different groups while maintaining membership in one (e.g., lower level managers, department chairpersons, opinion leaders). While it is possible to identify such individuals crudely by their formal roles or even their demographic characteristics, more sophisticated approaches use network analysis as a means to precisely identify individual positions in social structures. For example, betweenness centrality refers to the shortest distance between two points in the network; brokers have betweenness centrality since they are the go-betweens for transmission of messages from one grouping in a network to another and therefore can facilitate, impede, or bias the transmission of messages from different groups. This bridging, characterized by network linkages between cliques, indicates access to new resources and opportunities for innovation and profit. But the maintenance of such linkages may come at some cost to both the broker and to the social system (brokers jealously guard these relationships) revealing the dark side of networks. While in many instances people in brokerage positions have an information advantage, reflected in the associated concept of the strength of weak ties, in other cases, such as disease contagion, these people are particularly vulnerable.

Making Decisions and Evaluating Research Design

For network analysis in institutions, access is a key impediment; one needs willing partners who provide access. The major weaknesses of network analysis lie at the level of methods, particularly measurement. In practice, there are a variety of methodological

difficulties associated with the collection of the data, which in effect places ceilings on the use of particular methods for particular networks (e.g., only very small n 's are feasible in observational studies). These problems are exacerbated by the difficulties associated with sampling from populations to obtain network data. So in practice, early network analysis research was done on a census of the members of relatively small social systems.

Given these measurement issues, a number of studies focus on radial networks. Essentially radial, or ego-centric, network data are a focal network composed of an individual's overall pattern of relationships with others. This type of network is amenable to analysis by more traditional surveys and associated statistical analysis procedures focusing on issues such as the size of someone's immediate network and its heterogeneity, a key indicator of structural holes. Since by definition brokers and bridges operate at the boundary of social systems, research related to them exacerbates the problem of where to draw boundaries around networks.

Missing data, which can seriously distort measures such as nonredundant relationships used to determine structural holes, and reciprocity interact to create grave problems in determining which relationships should be analyzed. The accuracy of self-report network data has been questioned on many grounds, but, for pragmatic reasons, it has been the predominant method used for network analysis.

Since network analysts often deal with concrete, objective entities (e.g., people, organizations) and surface manifestations of relationships (e.g., an email message), they have not been as concerned as other social scientists with issues of measurement, reliability, and validity (which has been seldom tackled systematically).

Interpreting Data, Results, and Drawing Valid Inferences

When census-based approaches are used, a large number of indices (e.g., nonredundant ties, structurally autonomous linkages, constraint, density) are available to evaluate structural holes. To some extent, they allow one to triangulate, to get at different nuances, since, just as with social capital, there are multiple conceptualizations of this concept.

Most modern statistical techniques often rest on the assumption of independence between observations, but fundamentally, network analysis rests on the relationship between parties with parties influencing each other. This requires different approaches to inference (e.g., jackknifing, quadratic assignment procedures).

Undertaking Research Projects in an Ethical Manner

True experiments in the real world pose ethical problems and difficulties. In an organization, do you raise the incentives for one group, while withholding them for another?

Human subjects review committees have begun to raise fundamental objections to collecting censuses of respondents who are asked to report on their behavior involving others who may not have given their consent. However, due to the nature of network analysis research, respondents must be identified. It is a basic requirement that researchers know with whom respondents are interacting. Thus, complete anonymity and confidentiality are not possible in network analysis research, raising concerns about truly informed consent and privacy.

STRUCTURAL HOLES: THE SOCIAL STRUCTURE OF COMPETITION

The theory of structural holes emerged from the work of Ronald Burt. A major breakthrough in social network analysis and social capital research, Burt's 1992 book *Structural Holes: The Social Structure of Competition*, along with his subsequent publications, has been one of the most influential works in structural sociology and strategic management, generating more than 80,000 Google citations. *Structural hole* is a metaphor for and the signature of a theory on the social structure of competition. The metaphor refers to the absence of a connection between nonredundant contacts in a

sparse network. The theory of structural holes explains the network structure of and competitive advantages generated by structural holes. This entry describes Ronald Burt and the theory of structural holes, Burt's initial research design to test the theory, and his subsequent research efforts to examine broader implications of the theory.

Ronald Burt and the Theory of Structural Holes

In the 1970s and 1980s, Ronald Burt, under the influence of James Coleman, Mark Granovetter, Nan Lin, and Harrison White, began to develop his ideas and models on network contagion and network brokerage. His basic question was whether dense or sparse networks are the source of social capital. This question generated more than a decade of creative scholarship to discover the social structure of competition, leading to the publication of *Structural Holes*.

The theory of structural holes is elegantly simple. As Burt explained, an egocentric network can be dense or sparse. A dense network is full of redundant alters who are interconnected with one another through strong ties. Ego is constrained by emergent network closure and thus lacking structural autonomy. A sparse network, in contrast, contains nonredundant alters, some of whom are either directly or indirectly disconnected from each other. The disconnections between them are structural holes generating two sets of benefits for Ego. One is the directed flow of information about rewarding opportunities from otherwise disconnected contacts to Ego, giving Ego the information benefits of access, timing, and referrals. The other is the rational utilization of gained information to secure favorable terms in the opportunities Ego chooses to pursue, giving Ego the control benefits of negotiating social relationships under imperfect market competition. Because networks of structural holes are the social structure generating competitive advantages, it follows that the career success of strategic players is to build structural hole networks from which to maximize the embedded and emergent information and control benefits.

Initial Research Designs

An adequate research design to test the theory of structural holes has these basic requirements: network data, competitive behaviors, and measures of structural autonomy and outcome variables. In *Structural Holes*, Burt presented two research designs: an aggregate analysis of product markets and an individual-level analysis of corporate managers.

Burt's aggregate analysis was designed to answer this question: Can producers with networks richer in structural holes negotiate favorable terms in their transactions with suppliers and customers and therefore enjoy higher profit margins? Data for this analysis were input-output transactions among 77 U.S. product markets from 1963 to 1977. Concentration ratios were used as a proxy to structural autonomy defined by a market rich in structural holes. The four-firm concentration ratio is the proportion of total market output produced by establishments owned by the four largest firms. Thus, a ratio close to one means there are few structural holes within the market, and a ratio close to zero means there are many. A regression analysis showed two significant hole effects: lower profit margins were gained by markets with higher concentration ratios within producer market and by markets with higher concentration ratios among their suppliers and customers.

Burt's individual-level analysis used a direct measure of structural autonomy. This analysis was designed to assess the effect of structural holes on corporate managers' promotion. Data came from a survey of 284 managers in a top high-tech U.S. company with 120,000 employees and 3,500 managers. In addition to promotion data, respondent managers were asked to provide data on their work and social contacts and the relations among cited contacts. A structural autonomy variable was constructed with high values indicating many structural holes among the cited contacts and low values indicating few structural holes. A regression analysis showed significant hole effects on promotion: Compared to peers, managers with networks rich in structural holes got promoted earlier and faster, by a higher pace, and placed in higher ranks.

Later Research Designs

Burt had later publications that were also important in advancing these concepts. His later studies were aimed at testing broader implications of the theory of structural holes presented in *Structural Holes*. Two are described here. One is about hole effect on good ideas. The other is about hole effect in China.

Competitive managers are thirsty for good ideas. This makes generating good ideas a competitive context adequate for testing the structural hole theory. The argument is that new ideas are generated not just by creative minds, but they emerge from selection and synthesis across structural holes between groups and are broadly evaluated by people to be good ideas. To test this argument, a web-based survey was conducted among supply-chain managers, who were asked for an idea to improve the supply chain. Then, they were

asked with whom they had discussed the idea, their relations with cited contacts, and connections among the cited contacts. Of the 673 respondents, 455 discussed supply-chain ideas with others, resulting in 5,010 cited contacts and 4,139 dyadic relations. Summary results are as follows: The between-group brokers are more likely to express ideas, less likely to have ideas dismissed, and more likely to have ideas evaluated as valuable.

Competition is the signature for rational actors maximizing their own interests in an individualist culture. Would structural hole networks generate the same competitive advantages in a collective culture such as China? Burt's analysis of a random sample of 700 Chinese private entrepreneurs provides a positive answer. Data collection was based on a network module containing name and interpretative generators, similar to those used in American studies. It asked Chinese entrepreneurs about *important contacts* who provided assistance at business founding and subsequent events of the company's development. Despite a resilient collective culture in which *guanxi* networks of strong ties dominate Chinese entrepreneurial networks, structural holes matter at business founding, business takeoff, and later success.

Impact on Research Design

Burt's work led to improvements in research design as applied to social network analysis and other areas where visualizing relationships as networks is useful. New designs influenced by Burt allow for data on network structure to be accounted for and included in modeling. This allows for stronger analyses. In a survey project, for example, in addition to information about ego-alter relationships, it is also necessary to collect information about alter-alter relationships. Among Ego's primary-contact alters, when all of them are connected to each other, Ego does not have a structural hole. When a small number of Ego's primary-contact alters are disconnected with one another, Ego has a few structural holes. When many of Ego's primary-contact alters are disconnected with one another, Ego occupies many structural holes. If information about secondary contacts (i.e., friends' friends) is considered to be important, then it requires substantial effort to both design the research project and collect the accurate information from survey respondents.

STRUCTURAL PARADIGM

“Structural” and “structuralism” in the context of this entry do not refer to Talcott Parsons’s structural functionalism as a framework for building social theories that see society as a structured system of high complexity. Rather, these terms refer to a framework developed in modern philosophy of science for formally reconstructing theories with a set-theoretic approach, reflecting a longish discussion in the community about the translatability between observational and theoretical terms and statements.

Observational and Theoretical Statements

In the 1960s, Rudolf Carnap, in his *Philosophical Foundations of Physics*, published in 1966, found “the distinction between what may be called . . . empirical laws and theoretical laws . . . one of the most important distinctions between two types of laws in science” (p. 256). In his definition, empirical laws refer to “properties directly perceived by the senses” such as “blue,” “hard,” and “hot” from the point of view of the philosopher, or properties “that can be measured in a relatively simple way” from the point of view of practicing scientists in their disciplines (p. 225). But what the senses deliver is not precise. For example, “hardness” is not a binary category opposing hard and soft. Rather, the senses allow for gradual distinctions, sensing one thing “harder” than another thing and even sensing that Thing A is harder than Thing B and this in turn is harder than Thing C. Such an experience can similarly be made with concepts like color or temperature, attitude (uttered in everyday language), or even gender (as most languages have words like “effeminate” making clear that sex and gender are not simply binary). Moreover, a property measured in a “relatively” simple way is not really clear-cut, and whether a measurement is “simple” depends on the experience and the disciplinary background of the researcher. For

example, a physician needs to have a thermometer at hand to measure a temperature, or a political scientist needs a questionnaire to measure a political attitude such as party identification. To measure these concepts, one already has used some theory about the linear function between a temperature and the expansion of mercury or about the complicated connection between the answers to questions in a survey and the behavior when casting a ballot, respectively. Perhaps the laws mentioned in these two examples are “observational” and not “theoretical” laws, as the linear function assumed in a clinical thermometer is just arbitrary before the underlying mechanism that makes mercury expand is clarified. The same applies to the relation between the communication between interviewer and interviewee and the ballot finally cast by the interviewee (or the answer given when asked for the prospective ballot). In the case of the political scientist, the assumption that there is some function between the two “measurements” is even more arbitrary when the underlying mechanism that makes this interviewee—and many other interviewees—give the two answers is not yet analyzed in more depth.

The problem persists that theoretical laws were formulated in theoretical terms, whereas empirical laws were formulated in observable terms. Moreover, it is not always clear (as in the two examples) whether assumptions such as “the hotter the longer” or “mercury expands by 18×10^5 per Kelvin” are observational or theoretical laws. The former seems to be observational, as “hotter” and “longer” are accessible to the senses; whereas the latter rests on the assumption that the expansion coefficient is equal for all temperatures at which mercury is liquid and thus seems to be a theoretical law. The law determining that interviewees who say that they like a candidate best among a selection of candidates are frequently those who say they will vote for a particular candidate is an observational law; whereas a law stating that there is a positive correlation between the value on a sympathy scale given to a candidate and the propensity to vote for that candidate is likely to be a theoretical law, mainly because “propensity” is not available to the senses.

Hence, so-called correspondence rules were suggested by the so-called syntactic view of theory structure to bridge the gap between the two kinds of terms.

Frank Ramsey’s approach and his “Ramsey sentence of a theory” (1931) could eliminate the theoretical terms from a theoretical law but still use the correspondence rules for the elimination. The problem was only solved with the so-called semantic view on theory structure, which gave up the idea of *absolutely observational* and *absolutely theoretical* terms, perhaps because even a term such as *hot* has first to be learned

in some very elementary theory coupling the word *hot* to the sensory impression. Set-theoretical entities instead of linguistic ones were introduced in John D. Sneed's 1979 attempt to define the logical structure of a theory.

Theory Elements and Its Models

The structuralist program defines theory elements to describe mathematical structure. This description consists of a theory core and a set of intended applications whereby the theory core describes what can be said about the intended applications of the theory core. Theory elements are usually about a few laws within a scientific discipline, for instance, the laws behind Thomas Schelling's model of segregation along the lines of an important trait—the language—of people in a blockwise-structured city. These laws postulate that persons move to another part of the city when the percentage of their neighbors using a language other than their own exceeds a certain threshold. This results in a segregation of people into several regions homogeneous with respect to language, even though initially the areas comprised people using various languages and even when persons move away when their language is the majority language.

The theory core is a set-theoretic predicate which is typically defined as follows:

T is a theory element if and only if there exist sets of partial potential models M_{pp} , of potential models M_p , of models M , of constraints GC , of links GL , and of intended applications I such that

$K = \langle M_{pp}, M_p, M, GC, GL \rangle$ is a theory core,

$T = \langle K, I \rangle$ is the theory element and

$$I \subseteq M_{pp}$$

The set of potential models M_p of Schelling's segregation theory (SST) is defined, with its elements y defined as another mathematical structure listing all terms that are necessary to speak about the theory in question. In the case of Schelling's laws, this list contains a finite set of city blocks W , a finite set of persons P , a function $l(w, p)$ assigning each person their language, two constants— θ , the threshold for moving, and ρ , the radius of neighborhoods which people use for their decisions—, a function $\phi(w, p)$ yielding the percentage of persons using the same language as p in the neighborhood of their current block w , and another function $\delta(p)$ yielding the nearest city block where the percentage of people speaking p 's language in their neighborhood is higher than in their original neighborhood. The result of all these movements (which come to an end when nobody finds a city block that fits their

linguistic preferences better) is a segregated city, which can be described in the segregation index σ .

Of the introduced terms, several have nothing to do with a theory of segregation: people, their preferred language, city blocks, and the distribution of languages in neighborhoods of a fixed size around a certain city block can easily be talked about without ever thinking of the removal of people and households (but these can be registered no matter what their reasons are). The final segregation index can also be calculated from a census, which assigns every person both city block and language, no matter where the persons came from and why they came. The only term which cannot easily be identified is the threshold value (given that it is constant for all people), as not even people who decide to move will be able to give their personal threshold a numerical definition (even if this threshold were their private threshold), and perhaps they even do not know how many neighbors use which language. Hence, θ would not be an element of the list that defines a partial potential model M_{pp} .

Unlike laws in classical physics, it is difficult if not impossible to write down the axiom—the characteristic part of the definition of a full model M —that connects the threshold θ and the final segregation index σ in closed form. But computer simulations of this simplified theory of language-inspired segregation yield the function which estimates the underlying threshold θ which will have led to an observed final segregation index σ . One might object here that Schelling's theory oversimplifies real segregation processes, as it does not take into account other influences—but this, albeit with much better approximation, also applies to laws of classical mechanics, which in their simplest forms ignore frictional or electromagnetic forces which might interfere with the mechanical forces a certain law describes.

The structuralist paradigm negates the difference between observable and theoretical terms as theoreticity always refers to a theory in question and is not an absolute feature of a term. Identifying persons, their first language, their dwellings and their neighborhoods and the segregation index of a certain region necessitate their own theories, but not a theory of language-induced segregation. In most theories of complex systems, a closed description of the axioms of a theory in closed mathematical form is difficult if not impossible, but the symbol system of simulation programming languages is an alternative.

Constraints, Links, and Theory Nets

Constraints of a theory collected in the set GC are about restrictions to its applicability. In the earlier

language-induced segregation example, this could be the constraints that all neighborhoods are of the same density and structure, that there are only two languages (i.e., the theory would not immediately apply to regions where the population can be separated into more linguistic groups), that the thresholds for both language groups are the same (although Schelling's theory can easily be extended to more complex versions), and that these three features are constant over time (i.e., the theory would not apply to regions in which a considerable fraction of the population became bilingual).

Links of a theory element collected in the set *GL* connect it to other theory elements. In the earlier example, the segregation index was used as if it were a property that can be measured in a relatively simple way. But to determine the index, some statistics is necessary. Even to determine the equality of the structure of a city block according to language use, the knowledge of at least two languages and their mutual understandability is at stake. Hence, in a way the theoretical links replace the correspondence rules of earlier approaches, but with the important difference that the observational part of a correspondence rule is free from any theory. Links are defined as sets of tuples of terms which connect correspondent terms of the two theories in question.

One cannot only link two theories together but also build theory nets that potentially encompass wide areas within and across disciplines. Thus, the discussion can be avoided about reducing an observational law—say a law connecting the homogeneity of a certain territory with respect to the use of languages to the level of segregation to a law whereby the propensity to move to another part of the territory depends on the percentage of people in the neighborhood speaking a language other than one's own or having much more (or less) wealth or educational status. Such a theory combining psychological theories about the development of sympathetic feelings toward other people with theories from behavioral economics about decision-making under utility considerations avoids the discussion about reductionism as the assumption that social science could somehow be “reduced” to psychology, the latter to neurobiology, and so on. Instead, theoretical terms of a theory in one of these disciplines could be linked to (instead of reduced to) theoretical terms of another discipline.

In the social sciences, most theories have many more terms than in the simple example from Schelling's theory—but his considerations were originally meant to show that even a threshold, of 62% speaking one's native language, can lead to strong segregation such that segregation is an ubiquitous phenomenon.

Nevertheless, a structuralist reconstruction of middle range theories is possible, too. One could think of a theory, call it *idtST*, a segregation theory taking individual tolerance levels depending on communication among neighbors into account. Such a theory must contain terms such as the change of the individual threshold controlling the propensity to move to another city block due to becoming accustomed to a culture other than one's own. In this case, an additional term needs to be introduced to make the individual threshold change depending on the size of the own group (which is still thought to be a binary category) according to a formula such as $\theta(p, t+1) = \theta(p, t)(1-\varepsilon) + \varepsilon(p)\varphi(t)$ defining θ —instead of being constant as in the earlier example—as a function of its former value and the former value of the proportion of a person's own group, ε being a new theoretical term with a link to some psychological theory about becoming accustomed to different cultures. Such a psychological theory on attitude or opinion formation (*AOF*) would then help researchers measure the degree to which people belonging to one of the two groups change their opinion about the other group with a set of questions which could be converted to an estimate of ε . A theory about measuring attitudes with algebraic algorithms such as principal component analysis (PCA) would then be linked to *idtST*, and this intertheoretic link would help to reinterpret the PCA-theoretical terms ε as *idtST*-nontheoretic terms. The function that connects $\theta(p, t)$ on one hand with $\varphi(t)$ and $\varepsilon(p)$ on the other hand would then be the actual *AOF*-theoretical term, and the theory would have to provide an axiom that governs the development of the individual threshold changes and of the segregation index of the whole. Such an axiom, again, can only be described with the help of computer simulation, not in closed mathematical form as is usual for physical theories, as the basic entities of the social sciences are much more heterogeneous than the particles of classical physics.

Applications in Various Sciences

The “nonstatement” view movement started within physics; hence, the first candidates to be reconstructed were taken from classical physics and thermodynamics, although a simple economic theory was among the first candidates from social sciences. Less formalized disciplines came later, and examples are sparse. This is understandable, as the reconstruction of a theory that was formulated mathematically long ago is much easier than of a verbally formulated theory with all its ambiguities. With further developments in computational

social science, this situation will certainly change in the years to come.

STUDENT'S *t* TEST

The Student's *t* test is, arguably, the most used statistical procedure. Because it is, by far, the most frequently used test for comparing differences between sample means for two independent groups (e.g., a treatment group receiving a treatment vs. a control group receiving no treatment), or when comparing average performance over time (e.g., before treatment and after treatment), this entry first introduces the test in these two contexts.

Inferences About $\mu_1 - \mu_2$ Based on Independent Samples

The null and alternative hypotheses for a two-sided test (i.e., a nondirectional test) regarding equality of population means μ_j ($j = 1, 2$) for the two groups (e.g., treatment [group 1] versus control [group 2]) are:

$$H_0 : \mu_1 - \mu_2 = k,$$

$$H_1 : \mu_1 - \mu_2 \neq k.$$

The directional hypotheses are:

$$H_0 : \mu_1 \geq \mu_2 = k,$$

$$H_1 : \mu_1 \leq \mu_2 \neq k,$$

Or

$$H_0 : \mu_1 \leq \mu_2 = k,$$

$$H_1 : \mu_1 > \mu_2 \neq k.$$

To test either null hypothesis (only one set of null and alternatives hypotheses are used in any one situation), the Student's two independent sample test statistic is the statistic of choice, and is equal to

$$t^* = \frac{(\bar{X}_1 - \bar{X}_2) - E(\bar{X}_1 - \bar{X}_2)}{\sqrt{\text{est } \sigma_{\bar{X}_1 - \bar{X}_2}^2}}$$

Where

- $\bar{X}_1$ and $\bar{X}_2$ are the means of the samples of observations from populations one and two, respectively,
- $E(\bar{X}_1 - \bar{X}_2)$ refers to the expected value of the difference between the two sample means, a value given by the null hypothesis, which typically is stipulated to be zero (though the null hypothesis can be that the population difference equals any real number, e.g., $H_0 : \mu_1 - \mu_2 = 100$), and
- $\text{est } \sigma_{\bar{X}_1 - \bar{X}_2}^2$ stands for the estimate of the variance of the difference between two independent sample means.

Because the standard deviation of the difference between two independent sample means equals

$$\sqrt{\frac{\sigma_1^2}{N_1} + \frac{\sigma_2^2}{N_2}}, \sqrt{\text{est } \sigma_{\bar{X}_1 - \bar{X}_2}^2} = \sqrt{\text{est } \left(\frac{\sigma_1^2}{N_1} + \frac{\sigma_2^2}{N_2} \right)}.$$

The test statistic was derived under the restriction that the population variances for the groups are equal. Accordingly, the statistic can be expressed as

$$t^* = \frac{(\bar{X}_1 - \bar{X}_2) - E(\bar{X}_1 - \bar{X}_2)}{\sqrt{\text{est } \sigma_0^2 \left(\frac{1}{N_1} + \frac{1}{N_2} \right)}},$$

where σ_0^2 is the common value of variance, and N_1 and N_2 are the sample sizes for groups 1 and 2, respectively.

Thus, the t statistic, given the usual null hypothesis of equal population means, is equal to

$$t^* = \frac{\bar{X}_1 - \bar{X}_2}{\sqrt{\text{est } \sigma_0^2 \left(\frac{1}{N_1} + \frac{1}{N_2} \right)}}$$

Where

$$\text{est } \sigma_0^2 = s_p^2 = \frac{(N_1 - 1)s_1^2 + (N_2 - 1)s_2^2}{N_1 + N_2 - 2}$$

and s_1^2 and s_2^2 are the unbiased estimates of the common population variance from groups 1 and 2, respectively, and are thus pooled into one estimate, s_p^2 .

William Gosset, publishing under the pseudonym of "Student," derived the probability density function for a t variable, which is

$$f(t) = G(v) \left[1 + \frac{t^2}{v} \right]^{-(v+1)/2}.$$

This probability density function is often called the t distribution. An examination of the density function reveals a lot about characteristics of the distribution of t variables. First, the probability of observing any value of t (the statistic), by chance and chance alone, is determined by just one parameter v (nu). Thus, the t distribution is referred to as a one parameter family of distributions; that is, by knowing v , which is also referred to as the degrees of freedom, one can determine the probability of having observed a value of t , that is, the value of the test statistic. One should also note that the value of t enters the density function as a squared value; consequently, the distribution of t values must be symmetric; that is, positive and negative values of t with the same squared value have the same probability of occurrence. In addition, because all the constants in the density function are positive and the term involving t (in the square brackets) is raised to a negative value, the largest positive density value is when $t = 0$. From the previous equation, it can be observed that that the t distribution is a symmetric unimodal distribution, bell shaped in form, resembling a normal distribution.

Student's two independent sample t statistic is distributed as a t variable with degrees of freedom (v) equal to $N_1 + N_2 - 2$. Degrees of freedom have been defined as either the number of observations that are

free to take on any numerical value or the number of independent observations minus the number of parameters estimated from the data. In the context of Student's two independent sample t test, using our first definition of degrees of freedom, there are $N_1 - 1$ free observations when computing the variance for the scores in group 1 and $N_2 - 1$ for group 2. (This is the case because the sum of deviation scores around the mean, the numerator in computing a variance, sums to zero.) Accordingly, $(N_1 - 1) + (N_2 - 1) = N_1 + N_2 - 2$.

Let $t_{(\theta, v)}$ denote the point in the t distribution such that the probability of a t value below that point is θ . To assess statistical significance one uses one of the following decision rules.

Fail to reject $H_0: \mu_1 - \mu_2 = 0$ if $|t^*| < t_{(1-\alpha/2, v)}$;

Reject $H_0: \mu_1 - \mu_2 \geq 0$ and conclude

$\mu_1 - \mu_2 \neq 0$ if $|t^*| \geq t_{(1-\alpha/2, v)}$;

Or

Fail to reject $H_0: \mu_1 - \mu_2 = 0$ if $t^* > t_{(\alpha, v)}$;

Reject $H_0: \mu_1 - \mu_2 \leq 0$ and conclude

$H_1: \mu_1 - \mu_2 < 0$ if $t^* \leq t_{(\alpha, v)}$;

Or

Fail to reject $H_0: \mu_1 - \mu_2 = 0$ if $t^* < t_{(1-\alpha, v)}$;

Reject $H_0: \mu_1 - \mu_2 = 0$ and conclude

$H_1: \mu_1 - \mu_2 > 0$ if $t^* \geq t_{(1-\alpha, v)}$.

In each of these expressions, α is the probability of a Type I error, that is, the probability of rejecting H_0 when it is correct. In principle, a researcher should choose α before collecting the data by considering the maximum probability he or she is willing to risk for falsely rejecting H_0 . In practice α is usually set at .05. Choosing α sets the critical value $[t_{(1-\alpha/2, v)}, t_{(\alpha, v)}, \text{ or } t_{(1-\alpha, v)}]$ in the Student's t distribution for deciding if the data support H_1 .

Gosset derived this statistic and density function under the conditions that the data in the population are normal (the normality assumption) in form (which results in the random variables in the numerator and denominator of the statistic being independent of one another). As well, in this two-group case, there is the requirement that the population variances ($\sigma_1^2 = \sigma_2^2 = \sigma_0^2$) are equal to one another and thus equal to a constant value (the homogeneity of variance assumption), and that the data points are independent of one another (the independence of observations

assumption). Collectively, these conditions are often referred to as the validity requirements of the test statistic. The importance of the validity assumptions is that they must be satisfied for the probabilities associated with any particular value of t to be accurate (i.e., exact). When one or more assumptions do not hold, then the probabilities are not exact, and accordingly, the probability of a value of t is equal to some other value than what would be obtained from the density function.

The issue of whether derivational assumptions of a statistic are satisfied, or not, for some set (population) of observations, has been a matter of concern for decades. As noted earlier, the researcher selects α before collecting the data, and α determines the critical value $[t_{(1-\alpha/2, v)}, t_{(\alpha, v)}, \text{ or } t_{(1-\alpha, v)}]$ in the Student's t distribution. If, for example, the critical value is $t_{(1-\alpha/2, v)}$ (see equation presented previously) and the derivational assumptions are correct, then the probability that $|t^*|$ exceeds $t_{(1-\alpha/2, v)}$ is guaranteed to be α . But if the derivational assumptions are not correct, the critical value might be incorrect. Clearly, then, if a certain critical value in the distribution of t (e.g., one that cuts off the lower and upper 2.5% of the distribution) [i.e., $1 - (.05/2)$] is not the correct (exact) value, because one or more of the validity assumptions did not hold, the critical values (numerical values) of t that cut off the upper and lower 2.5% of the distribution are inaccurate. Correspondingly, the probability of falsely rejecting the null hypothesis is unknown—meaning that the actual probability of committing a Type I error can be less than or greater than one wants. This situation is undesirable because an experimenter wants to control this type of mistake associated with hypothesis testing. A later section of this entry addresses alternative courses of action that experimenters can adopt to circumvent the biasing effects of non-normality and/or variance heterogeneity.

Confidence Intervals and Power (Sensitivity) to Detect Treatment Effects

Two additional issues should be discussed, briefly, within the context of computing any test statistic: setting an interval around the unknown population difference and determining the required sample size to detect treatment effects.

With respect to the first issue, it should be noted that many authorities on the analysis of data strongly recommend that in addition to testing hypotheses, researchers should also compute confidence intervals (CIs) around the unknown population parameters being examined. (The zeitgeist certainly in the social

sciences is that CIs and effect size statistics are paramount to understanding the phenomenon under investigation.) The CI takes into account sampling variability in that it specifies a range of values that are equally reasonable as estimates of the unknown parameter. (In this case the difference between two means.)

For the case with two independent groups, a $100(1 - \alpha)\%$ CI on $\mu_1 - \mu_2$ around $\bar{X}_1 - \bar{X}_2$ is formed as follows:

$$(\bar{X}_1 - \bar{X}_2) \pm t_{[1-(\alpha/2), v]} s_{\bar{X}_1 - \bar{X}_2}.$$

It is also interesting to note that values that fall within the interval would not have been rejected if they had been specified as k in the null hypothesis $H_0: \mu_1 - \mu_2 = k$. One might also compute one-sided CIs:

$$(\bar{X}_1 - \bar{X}_2) + t_{[1-\alpha, v]} s_{\bar{X}_1 - \bar{X}_2}$$

$$(\bar{X}_1 - \bar{X}_2) - t_{[\alpha, v]} s_{\bar{X}_1 - \bar{X}_2}$$

where s stands for standard deviation.

The second issue that warrants some discussion is the power to detect treatment effects when they are present. In addition to attending to limiting Type I errors, researchers should, when designing a study, give considerable attention to what they must do to optimize their chances of detecting a treatment effect that might be present.

Several factors affect the sensitivity of a statistic to detect treatment effects when present, and they include the following: (a) the magnitude of the true effect, (b) the level of significance (α), (c) the amount of noise (error) in the system (all extraneous noncontrolled sources of variation), and (d) sample size. Factors (a) and (c) should be optimized in any research endeavor if researchers show due diligence with regard to controlling all known sources of extraneous variance and creating independent variables that potentially maximize the effect that they are investigating. Even though manipulating the level of significance is most reasonable for increasing the power to detect real treatment effects (e.g., increasing the value of α , increases the power to detect effects), researchers tend to be reluctant to do so. Thus, the one factor that is most amenable for increasing the power of a statistical test is the size of sample. Increasing sample size increases the power to detect effects (all other factors constant). In the past, most treatises on determining sample size to increase the power to detect treatment effects discussed formula and tables or charts to determine how many subjects were required in the study (that is, $N = N_1 + N_2$); this approach involved specifying the magnitude of the treatment that one desires to detect, that is, specifying the noncentrality parameter. To examine treatment effects, a different probability distribution of t is

required—the noncentral *t* distribution; the previously presented *t* distribution, which exists under the null hypothesis, is referred to as the central *t* distribution. However, many in the field now rely on statistical software to determine the required sample size. An excellent program, G*POWER, has been written by Franz Faul and Edgar Erdfelder, and it can be obtained from the G*POWER website.

Inferences About $\mu_1 - \mu_2$ Based on Dependent (Correlated) Samples

The inferential procedure (i.e., comparing the Student's *t* statistic to the critical value) for assessing whether the means in the population are equal for two dependent groups (e.g., comparing husbands and wives on an attitudinal measure) or equal across two times of measurement (e.g., assessing the number of trials to complete a task and subsequently reassessing the subjects after a 2-week interval) is similar to the case with two independent groups. The only difference is the formula for Student's test statistic and the degrees of freedom. In the dependent groups scenario, the data analysis and the test statistic can be conceptualized from either a one-sample or two-sample approach.

One-Sample Conceptualization for the Analysis

For this approach the data for, say, husbands ($X_{i1} : i, \dots, N$) and wives ($X_{i2} : i, \dots, N$) is used to create a new variable $d_i = X_{i1} - X_{i2}$, which is a difference score; thus, a set of scores from two samples has now become a set of scores from one sample. A test statistic is constructed in the usual manner, that is,

$$t^* = \frac{\bar{d} - E(\bar{d})}{\text{est } \sigma_{\bar{d}}},$$

where

$\bar{d}$ is the sample mean of the d_i s,

$E(\bar{d})$ is the expected value of $\bar{d}$, the value specified under the null hypothesis (which is typically zero), and

est $\sigma_{\bar{d}}$ is the estimate of the standard deviation of $\bar{d}$.

After substituting a sample estimate for the unknown standard deviation and assuming the usual null hypothesis that the mean of the difference scores is equal to zero in the population, the test statistic is defined as

$$t^* = \frac{\bar{d}}{s_{\bar{d}}},$$

where $s_{\bar{d}} = \frac{s_d}{\sqrt{N}}$ and s_d is the unbiased variance of the difference scores. This *t* statistic is distributed as a *t* variable with degrees of freedom (*v*) equal to $N - 1$, where N equals the number of difference scores.

Accordingly, the decision rules relating to the null and alternative hypotheses are (at this point, and on, to save space, only nondirectional hypotheses are enumerated.)

Fail to reject $H_0 : \mu_{d_i} = 0$ if $|t^*| < t_{(1-\alpha/2, v)}$.

Reject $H_0 : \mu_{d_i} = 0$ and conclude

$\mu_{d_i} \neq 0$ if $t^* \geq t_{(1-\alpha/2, v)}$.

Two-Sample Conceptualization for the Analysis

When conceptualized as a two-group problem, the standard deviation of $\bar{X}_1 - \bar{X}_2$ for dependent samples is different than in the two independent group case because the correlation between the two group of scores (husbands vs. wives; measurements at time one vs. those at time two) must be taken into account. It can be shown that this standard deviation is equal to

$$\sigma_{\bar{X}_1 - \bar{X}_2} = \sqrt{\sigma_{\bar{X}_1}^2 + \sigma_{\bar{X}_2}^2 - 2\rho\sigma_{\bar{X}_1}^2\sigma_{\bar{X}_2}^2},$$

where

$\sigma_{\bar{X}_1}^2$ and $\sigma_{\bar{X}_2}^2$ are the population variances of the means for groups 1 and 2, respectively, and ρ is the correlation between the two sets of measurements. (In fact, $\rho\sigma_{\bar{X}_1}^2\sigma_{\bar{X}_2}^2$ equals the covariance between $\bar{X}_1$ and $\bar{X}_2$.)

The test statistic can be represented as

$$t^* = \frac{(\bar{X}_1 - \bar{X}_2) - E(\bar{X}_1 - \bar{X}_2)}{\sqrt{\text{est}(\sigma_{\bar{X}_1}^2 + \sigma_{\bar{X}_2}^2 - 2\rho\sigma_{\bar{X}_1}^2\sigma_{\bar{X}_2}^2)}}.$$

After replacing the unknown parameters with their least squares sample estimates and assuming the usual null hypothesis of a zero difference between the dependent means, the statistic equals

$$t^* = \frac{(\bar{X}_1 - \bar{X}_2)}{\sqrt{s_{\bar{X}_1}^2 + s_{\bar{X}_2}^2 - 2rs_{\bar{X}_1}^2s_{\bar{X}_2}^2}},$$

where $s_{\bar{X}_1}^2$ and $s_{\bar{X}_2}^2$ equal $\frac{s_{X_{i1}}^2}{N}$ and $\frac{s_{X_{i2}}^2}{N}$, respectively, and r is the sample estimate of the population correlation coefficient.

As should be the case,

$$\frac{s_d}{\sqrt{N}} = \sqrt{s_{\bar{X}_1}^2 + s_{\bar{X}_2}^2 - 2rs_{\bar{X}_1}^2 s_{\bar{X}_2}^2}.$$

The decision rule to assess statistical significance is

Fail to reject $H_0 : \mu_1 - \mu_2 = 0$ if $|t^*| < t_{(1-\alpha/2, v)}$.

Reject $H_0 : \mu_1 - \mu_2 = 0$ and conclude

$\mu_1 - \mu_2 \neq 0$ if $|t^*| \geq t_{(1-\alpha/2, v)}$,

where $v=N-1$, and N is the number of paired observations.

Confidence Intervals and Power (Sensitivity) to Detect Treatment Effects

As was the case in the two independent groups scenario, CIs and power analyses should also be considered by experimenters when comparing two dependent groups. The two-sided CI for μ_{d_i} is

$$\bar{d} \pm t_{(1-\alpha/2, v)} s_{\bar{d}},$$

while the one-sided intervals are

$$\begin{aligned} &\bar{d} + t_{(1-\alpha/2, v)} s_{\bar{d}} \\ &\bar{d} - t_{(\alpha, v)} s_{\bar{d}}. \end{aligned}$$

The intervals from the two-sample perspective merely replace $(\bar{X}_1 - \bar{X}_2)$ for $\bar{d}$ and $s_{(\bar{X}_1 - \bar{X}_2)}$ for $s_{\bar{d}}$. G*POWER can once again be used to determine the required number of observations (pairs) that are required to detect an effect of a given size.

Additional Applications

In addition to being used to test hypotheses about pairs of means, *t* test statistics and the Student's *t* distribution are used in many other situations. For example, when the experimenter needs to test hypotheses about three or more means, a need that arises in designs with more than two treatments, it is common for experimenters to test contrasts, where a contrast is a weighted sum of means in which the weights sum to zero. For example, if an experiment involved two active treatments (with population means μ_1 and μ_2) and a control treatment (with population mean μ_c), then the researcher might be interested in testing each of the possible pairwise comparisons (e.g., $H_0 : \mu_1 - \mu_c = 0$) or a complex comparison such as $H_0 : .5\mu_1 + .5\mu_2 - \mu_c$, which compares the average of the means for the two active treatments with the mean for the control treatment. Each of these

hypotheses can be tested by using a *t* test statistic. The choice of critical value is a complex issue, but in many cases will be a point of Student's *t* distribution.

The Student's test statistic and distribution are also used in testing hypotheses about Pearson product-moment correlation coefficients, partial correlation coefficients, and regression coefficients. For example, if ρ is the population Pearson product-moment correlation coefficient and the researcher is interested in testing $H_0 : \rho = 0$, then the Student's test statistic is

$$t^* = r \sqrt{\frac{N-2}{1-r^2}},$$

where r is the sample Pearson product-moment correlation and N is the number of pairs of scores. The rules for determining whether t is significant are the same as when means are compared; however, the degrees of freedom are $v = N - 2$. As these few examples illustrate, the *t* test statistics and Student's *t* distribution are widely used in research.

Robust Alternatives to the Classic *t* Statistic

As previously indicated, the two independent sample *t* statistic was derived assuming that the data in the population are normally distributed, that the variances of the two populations are equal (and equal to one constant value), and that the observations are independent of one another. The last requirement is typically not an issue when experimenters follow good experimental procedures (e.g., not allowing the result from any subject to be influenced by that of another subject). However, with regard to normality and homogeneity of variances, most commentators of validity requirements believe that data rarely, if ever, conform to these validity requirements. Thus, as mentioned previously, the probability of a Type I error will not equal the theoretical value (i.e., $\alpha \neq .05$).

For decades, many authors have proposed solutions that are intended to obviate the deleterious effects of derivational assumptions not being satisfied. This issue is generically referred to as the robustness of a statistical test. Robust statistical tests are those that are generally insensitive to assumption violations. In other words, the actual probability of a Type I error and the nominal value (the value set by the experimenter) are similar in value, where nonrobust tests are adversely affected by assumption violations (i.e., there is a discrepancy between the actual and nominal values of significance).

With regard to variance heterogeneity, remember that in the case with two independent groups, the *t* statistic can be defined as

$$t^* = \frac{(\bar{X}_1 - \bar{X}_2) - E(\bar{X}_1 - \bar{X}_2)}{\sqrt{\text{est}\left(\frac{\sigma_1^2}{N_1} + \frac{\sigma_2^2}{N_2}\right)}}$$

We simplified this statistic by assuming equality of variances; factored out, accordingly, the common variance; and used a pooled value to estimate this unknown common population variance. However, when variances cannot be presumed to be equal, it has been recommended that group variances not be pooled and one merely estimates σ_1^2/N_1 and σ_2^2/N_2 . Testing the usual null hypothesis, and replacing unknown population parameters with sample estimates, the test statistic equals

$$t_w^* = \frac{\bar{X}_1 - \bar{X}_2}{\sqrt{\frac{s_1^2}{N_1} + \frac{s_2^2}{N_2}}},$$

which is approximately distributed as a *t* variable with degrees of freedom equal to

$$v_w = \frac{\left(\frac{s_1^2}{N_1} + \frac{s_2^2}{N_2}\right)^2}{\frac{\left(\frac{s_1^2}{N_1}\right)^2}{N_1 - 1} + \frac{\left(\frac{s_2^2}{N_2}\right)^2}{N_2 - 1}},$$

where *W* in the subscripting of the statistic and degrees of freedom refers to Welch, an author who provided one solution (perhaps the most widely used one) for comparing two independent groups in the possible presence of unequal variances. The decision rule for assessing the null and alternative hypotheses is

Fail to reject $H_0 : \mu_1 - \mu_2 = 0$ if $|t^*| < t_{(1-\alpha/2, v_w)}$.

Reject $H_0 : \mu_1 - \mu_2 = 0$ and conclude

$H_1 : \mu_1 - \mu_2 \neq 0$ if $|t^*| \geq t_{(1-\alpha/2, v_w)}$.

One-sided tests can also be examined.

The empirical literature indicates that the Welch solution typically is not substantially affected by heterogeneous variances (i.e., the actual and nominal values for the Type I error rate are not too discrepant from one another), even when group sizes are unequal. Moreover, the power of this statistic to detect non-null treatment effects compares favorably with the regular *t* statistic even when variances happen to be equal, a case

in which the regular test should be uniformly the most powerful.

The reader should note that Welch's solution is for testing mean equality in the presence of unequal variances and does not address the issue of non-normality. That is, not only might the population variances be unequal, but the observations might as well be non-normal in shape. The empirical literature indicates that when data are non-normal, the actual probability of committing a Type I error might deviate from the nominal value (i.e., an inexact test), and, as well, the power to detect effects might be substantially diminished. For this scenario, many solutions have been proposed since the 1950s. One solution, namely replacing the usual least squares estimators for the mean and variance with robust estimators—trimmed means and Winsorized variances, and applying these estimators with Welch's nonpooled statistic, is discussed.

To compute a trimmed mean, one removes an a priori determined percentage of the largest and smallest observations and computes the mean from the remaining observations. The population trimmed mean is denoted by μ_{ij} and the corresponding sample estimate as $\bar{X}_{ij}$. A common trimming percentage is 20%, which means that, in total, 40% of the data are trimmed (for a justification of 20% trimming, see Wilcox (2005, p. 57).

When trimmed means are introduced to researchers, a common reaction is that one throws away data when the trimmed means are used, and therefore the trimmed mean cannot be a better choice than the usual least squares mean. But the trimmed mean has advantages that the least squares mean does not. Consider a situation in which the sampled distribution is symmetric. Then, both the trimmed mean and least squares mean estimate the same parameter, the population mean, and an important criterion for selecting between the two estimators is the standard error. It can be shown that when the data are sampled from a long-tailed distribution, the trimmed mean will have a smaller standard error than does the mean. Granted, if the data are sampled from a short-tailed or normal distribution, the mean will have a smaller standard error. However, the advantage for the mean under these conditions is often not large, whereas the advantage for the trimmed mean can be substantial when the data are sampled from a long-tailed distribution. Thus, one argument for the trimmed mean is that it can have a substantial advantage in terms of accuracy of estimation when sampling from long-tailed symmetric distributions, although it has a slight disadvantage when sampling from normal and short-tailed distributions.

Additionally, the trimmed mean is preferable when the data are subject to outliers. In contrast, the mean is

not resistant to outliers, and a single outlying observation can destroy its effectiveness as an estimator. If the distribution from which the data are sampled is skewed, then the argument against the mean is that it is not a good indicator of the central point of the distribution because the extreme scores drag it away from the center. Because the trimmed distribution will be more nearly symmetric than the nontrimmed distribution, the trimmed mean will be a better indicator of the center of the distribution. Some researchers find these arguments for using the trimmed mean, rather than the mean, persuasive; however, others might not. But researchers who use the mean should be aware that they are using an estimator that has poor accuracy (in some situations), is not resistant to outliers, and might not be a good indicator of the center of the distribution.

To compute a Winsorized variance, the smallest nontrimmed score replaces the scores trimmed from the lower tail of the distribution, and the largest nontrimmed score replaces the scores removed from the upper tail. The nontrimmed and replaced scores are called Winsorized scores. A Winsorized mean is calculated by applying the usual formula for the mean to the Winsorized scores, and a Winsorized variance is calculated as the sum of squared deviations of Winsorized scores from the Winsorized mean divided by $N_j - 1$. The Winsorized variance is used because it can be shown that the standard error (deviation) of a trimmed mean is a function of the Winsorized variance. A sample Winsorized variance is denoted by $s_{w_j}^2$. See Wilcox (2005) for formulas corresponding to the verbal descriptions of the trimmed mean and Winsorized variance.

Let

$$\tilde{s}_{w_j}^2 = \frac{(n_j - 1)s_{w_j}^2}{h_j - 1}$$

be the scaled Winsorized variance, where h_j stands for the effective sample size, that is, the size after trimming the data. In computing the robust Welch-James (WJ) statistic with robust estimators, the quantity $\tilde{s}_{w_j}^2$ plays the role that s_j^2 plays in computing the WJ statistic based on least squares estimators. Specifically, the robust WJ statistic is

$$t_{wjt}^* = \frac{\bar{X}_{1t} - \bar{X}_{2t}}{\sqrt{\frac{\tilde{s}_{w_1}^2}{h_1} + \frac{\tilde{s}_{w_2}^2}{h_2}}}$$

The critical value is obtained from the *t* distribution by using the estimated *df*

$$\hat{v}_t = \frac{\left(\frac{\tilde{s}_{w_1}^2}{h_1} + \frac{\tilde{s}_{w_2}^2}{h_2} \right)^2}{\frac{\tilde{s}_{w_1}^4}{h_1^2(h_1 - 1)} + \frac{\tilde{s}_{w_2}^4}{h_2^2(h_2 - 1)}}.$$

Thus far, this entry has illustrated inferential procedures that differ in terms of the means and variances used to compute the *t* statistic but that use the theoretical *t* distribution to obtain the critical value; however, a nonparametric bootstrap can be used to obtain the critical value. The strategy behind the use of the bootstrap in hypothesis testing is to shift the sample distributions of the scores for each group and variable by subtracting the group mean (least squares or trimmed) from each score and using the shifted empirical distributions to estimate an appropriate critical value.

In particular, for each *j*, obtain a bootstrap sample by randomly sampling with replacement N_j observations from the shifted values, yielding $X_1^*, \dots, X_{N_j}^*$. Let t^* be the value of a test statistic (t_w or t_{wjt}) based on the bootstrap sample. For a two-tailed test, the *B* values of $|t^*|$, where *B* represents the number of bootstrap simulations, are put in ascending order, that is, $|t_{(1)}^*| \leq \dots \leq |t_{(B)}^*|$, and an estimate of an appropriate critical value is $|t_{wjt(q)}^*|$, $q = (1 - \alpha)B$, rounded to the nearest integer. For example, if $\alpha = .05$ and the number of bootstrap samples is 1,000, then $q = (1 - \alpha)B$ is 950 and $|t_{wjt(q)}^*|$ is the 950th value in the rank order of the *B* values of $|t^*|$. One will reject $H_0: \mu_1 - \mu_2 = 0$ or $H_0: \mu_{1t} - \mu_{2t} = 0$ when $|t^*| \geq |t_{(q)}^*|$, where $|t^*|$ is the value of the heteroscedastic statistic (t_w^* or t_{wjt}^*) based on the original nonbootstrapped data.

CIs and power analyses can also be performed with this robust *t* test statistic (see Wilcox, 2005; Luh & Guo, 2007).

SUMS OF SQUARES

In mathematics, the sum of squares can refer to any set of numbers that has been squared and then added together (i.e., $\sum X^2$). However, in the statistical analysis of quantitative data, the sum of squared differences or deviations (normally the difference between a score and the mean) is of particular interest. This formulation is usually referred to in research by the term *sums of squares*. This type of sum of squared values is extremely important in the analysis of the variability in data and in understanding the relationship between variables.

If there is no variability in a set of numbers, then they are all the same. However, this is unlikely to be the case in any research. Indeed, researchers actively investigate changes in their data resulting from experimental manipulations. So a procedure is required to produce a value to express the amount of variability within a data set. The sum of squares calculation achieves this outcome. For example, consider the numbers 2, 4, and 6. The range gives us a crude measure of the spread of these numbers: between 2 and 6 we have a range of 4, but this ignores the distribution of the scores within that range. More subtly, to indicate the variation within the data, we can compare each score to the mean ($\bar{X}$), which in this case is 4, to produce a difference or deviation from the mean. So the deviations are $2 - 4 = -2$, $4 - 4 = 0$, and $6 - 4 = 2$. It could be assumed that simply adding up these deviations would provide a useful measure of total variation in the data set. Unfortunately, this is not the case, as this total will always be zero, with the deviations of numbers below the mean

canceling out the deviations of the numbers above the mean, as in the previous example, where $-2 + 0 + 2 = 0$. A solution to this problem is to square the deviations before they are summed, which always produces a positive nonzero value when there is some variability in the data. For the example, the calculation is $(-2)^2 + 0^2 + 2^2 = 8$. This is now a measure of the variability within the data, which can be expressed mathematically as $\sum (X - \bar{X})^2$, the sum of the squared deviations from the mean, or the sum of squares. This is an extraordinarily useful measure and is integral to most of the statistical techniques used to analyze quantitative data.

Sums of squares are absolutely critical to quantitative data analysis, as variability in the data can be calculated and attributed to different sources, which allows researchers to make appropriate judgments about the relationship between the variables under investigation.

Variance and Standard Deviation

The previous sum of squares formula lies at the heart of the most common statistic for expressing variability within research data, the standard deviation. With a population of numbers, the mean squared deviation can be calculated by dividing the sum of squares by the number of scores n . This mean square value is called the variance. However, in research, samples are normally selected to estimate population parameters so, more usually, the sum of squares is divided by the degrees of freedom ($n - 1$) to produce the variance,

$$\frac{\sum (X - \bar{X})^2}{n - 1},$$

as this provides a better estimation of the population value. The square root of the variance is referred to as the standard deviation:

$$\sqrt{\frac{\sum (X - \bar{X})^2}{n - 1}}, \text{ which is } \sqrt{\frac{\text{sum of squares}}{\text{degrees of freedom}}}.$$

This is the standard measure of the variation of the scores in a sample. In the previous example, the standard deviation is 2. Note that the sum of squares is often expressed by

$$\sum X^2 - \frac{(\sum X)^2}{n}$$

in the formula for the variance or standard deviation. This is equivalent to

$$\sum (X - \bar{X})^2.$$

Linear Correlation and Regression

Sums of squares are also central in the calculation of linear correlation and regression, as a measure of the variability in the data. Note that in a correlational analysis, researchers are looking to determine whether there is a relationship between two or more variables—whether they vary together—by examining the variation within the research data. For example, it might be predicted, not surprisingly, that the amount of time spent studying correlates positively with performance in an examination. On plotting a graph (a scatterplot) of “study time” versus “examination result” for a group of students, it is observed that, generally, the more a student studies, the higher the result in the examination, indicating a positive correlation. However, the results are unlikely to all lie neatly along a straight line on the graph. More usually, the scores fall within a broad band. Yet the prediction is that the relationship between the two variables is linear (i.e., predicting a linear model), and so it is argued that the reason any result deviates from the straight line is *error* (i.e., random variation). To calculate the best linear model for the data (i.e., the regression line), it is necessary to find the line that produces the smallest overall error. This is done by using the sum of squares formula. With study time as the X axis and examination result as the Y axis, the sum of squares formula becomes $\sum(Y - Y')^2$, where Y is the actual examination result and Y' is the predicted examination result lying on the straight line, the linear model. The sum of squares now gives a measure of the overall deviation of the points from that predicted straight line. To find the line of “best fit” for these data, a line that minimizes this sum of squares must be computed. To do this, a procedure called the least squares method is employed, and the regression line can be calculated.

The sum of squares is crucial both to the calculation of the degree of correlation (correlation coefficient, r) and in the calculation of the regression line. Within the formulas for each of these calculations lie measures of variability in the data: sums of squares. A correlation coefficient of +1 indicates that there is no error or residual data to be accounted for, as all the points on the graph lie along a straight line. However, we are unlikely to find this with research data. Even a strong correlation will still have an error. Here, error, or residual, indicates the portion of each result that cannot be explained by the linear model (the regression line). Imagine one student studied for 20 hours and scored 63 in the examination. From the calculation of the regression line, it is predicted that anyone studying for 20 hours will receive a score of 61 in the examination. Thus, for this student, 61 of the 63 scores can be

explained by the regression, but the residual or “extra” variability in the score of 2 cannot be explained by the model so has to be attributed to error variability. Calculating the sums of squares for the regression: $\sum(Y' - \bar{Y})^2$ (i.e., the variation in the scores explained by the regression line, where $\bar{Y}$ is the mean examination result), and dividing this by the sums of squares for the observed examination results: $\sum(Y - \bar{Y})^2$, shows how much variability in the actual examination results can be explained by the regression line. Actually, this calculation is called the coefficient of determination and equals R^2 , the square of the correlation coefficient. Thus, a correlation of $r = 0.7$ gives a coefficient of determination of $R^2 = 0.49$, indicating that 0.49% of the variation in the examination results can be explained by the regression line and 0.51% of the variation in the data is not explained by this model. The key point here is that the calculation of different sums of squares produces this information.

The Analysis of Variance

The comparison of sums of squares in explaining the variability within data is crucial to the analysis of variance, which is one of the most important statistical techniques of quantitative data analysis. In a correlation, continuous variables are jointly examined, such as the relationship between study time and examination performance. In an analysis of variance, the effect of different categories of an independent variable (such as different teachers) on a continuous dependent variable (such as examination performance) is studied. For example, a researcher might wish to compare the effect of different teachers on the students’ examination performance at the end of the semester. The students are randomly allocated to different classes and they all follow the same syllabus to control for confounding. Again, the question to be answered by the data analysis is: What is the explanation of the variability in the data? The answer to this question lies in the calculation of sums of squares.

In the analysis of variance, the sums of squares for different sources of variation are calculated, which is the key to the analysis. For example, 20 students in each class of three classes are taught by teachers Anderson, Berkowitz, and Chavez. All students take the same examination at the end of the semester. The variability of the examination results for all 60 students can be worked out by simply finding the overall mean score and calculating the sum of squares. This is the total sum of squares or total variability in the data. However, the variability of subsets of the data can be produced by calculating different sums of squares. For example, only the 20 students in Anderson’s class can

be selected, the class mean obtained, and the sum of squares for this class produced. As Anderson has taught all these students, any differences between the student examination results are assumed to be caused by random factors such as individual differences rather than differences in the teacher. This can be done for the other two teachers as well. These three figures provide the variation of the examination results *within* a class. The hypothesis is that there will be systematic differences between the classes on their examination results as an effect of the teacher is predicted. The mean examination result for each class has already been calculated. By calculating a sum of squares based on these means, the variability in the scores *between* the classes—and hence between the teachers—can be produced.

Now, the average amount of variability—the variance or mean square—caused by each source of variation can be compared. The variance resulting from the differences between the classes can be compared with that arising from within the classes by dividing the first by the second variance. Essentially, this comparison is examining the amount of variability arising from the systematic differences (plus any random factors) compared with the variability arising from random factors alone. Again, random variation is often termed *error*. Clearly, if variation in the examination results arising from the difference between the classes exceeds the error variation by a significant amount, then this supports the hypothesis that the students were performing differently with different teachers.

The analysis of variance, like the regression, is based on a linear model. Just as a more complex regression analysis can be performed by multiple regression, there are also more complex analyses of variance than the simple example considered previously. Indeed, the analysis of variance is a very general test that deals with multiple independent variables as well as multiple dependent variables, where complex interactions can be investigated. Hence, the underlying model is referred to as the *general linear model*. The key point of any modeling is to calculate how much of the variation in any observed data can be accounted for by the model and how much is error or residual. Thus, statisticians have recommended which are the most appropriate sums of squares to use in the analysis of variance for different types of research design, in particular, what to do when there are different sample sizes or when there are missing cells in the data. In all cases, they are looking for the best way of representing the research data in terms of the variability in the scores that can be explained by a model and that which cannot. Once this information is available—and the different sums of squares provide it—then a researcher can decide

whether the variation explained by the model is significant or whether he or she has confidence in the model as an explanation of the variability in the data.

SURVEY

A survey is a data collection method in which individuals answer specific questions about their behavior, attitudes, beliefs, or emotions. Surveys are frequently used by multiple disciplines, including social and behavioral sciences, political sciences, public health, and business. Surveys are commonly used in nonexperimental (correlational) research but might also be incorporated into experiments. Nonexperimental surveys can be either cross-sectional (a single data collection), repeated cross-sectional (two or more data collections with different samples), or panel surveys (multiple data collections from the same sample). However, unless an experimental design is used, survey research does not allow for the drawing of causal inferences.

Types of Survey Questions

Surveys are composed of multiple questions assessing the constructs of interests. Typically, questions regarding demographic characteristics of participants (e.g., age, sex, race, marital status, income, education level) are also included. If new questions are developed, they should be first evaluated in a pilot study to ensure that they are clearly worded and correctly understood, reliable, and valid. The main types of survey questions include open-ended and closed-ended questions. The latter type can be divided into dichotomous, nominal, rank-ordered, ordinal, and continuous, depending on the characteristics of the response options.

Open-Ended Versus Closed-Ended Questions

Open-ended questions require participants to formulate answers in their own words. Examples of such questions are “What is the main stressor in your life?” and “What do you think should be done to control crime in inner cities?” Space is typically provided for participants to write their answers. Although open-ended questions typically elicit more complete and deeper answers than closed-ended questions, they are much more difficult to analyze quantitatively. The answers need to be first coded into categories that are either predetermined or developed through content analysis of the obtained responses. The development of the scoring system and coding of individual answers should be performed by multiple “experts” who are knowledgeable in the subject field and trained to perform these tasks. High inter-rater agreement in coding responses is necessary to achieve reliability of scoring. Compared with closed-ended questions, there is a higher risk of participants misunderstanding open-ended questions and providing irrelevant answers or choosing not to answer these questions. For these reasons, most survey questions are closed ended or only partially open ended.

Closed-ended questions list several response options from which the respondent needs to choose. For instance, the question “What is the main stressor in your life?” might be followed by these response categories:

- ☐ Finances
- ☐ Work
- ☐ Relationship with spouse
- ☐ Other relationships
- ☐ Children

Because closed-ended questions provide a limited number of specific responses, they are much easier to summarize and analyze. These answers are also more relevant and comparable than open-ended responses. However, the participant is forced to choose from alternatives that might not provide the most accurate answer. This problem is addressed in partially open-ended items that provide a set of closed-ended responses (as in closed-ended questions), as well as an open-ended option, such as

☐ Other (Specify): _____

Types of Closed-Ended Questions

Depending on the format of the response categories, closed-ended questions might be dichotomous,

nominal, ordinal, continuous, or rank ordered. Dichotomous questions offer only two possible answers (e.g., yes/no, true/false). Nominal questions include three or more response options that cannot be ordered. For example, the question on the main stressor given in the previous example is a nominal question. In contrast, ordinal items include three or more response categories that can be ordered on a continuum ranging from low to high levels. A set of such ordered responses is typically called a *rating scale*. Examples include the following:

How stressful is your job?

- ☐ Not at all
- ☐ Somewhat
- ☐ Very much

I often fidget with my hands and feet.

- ☐ Strongly disagree
- ☐ Disagree
- ☐ Agree
- ☐ Strongly agree

Rating scales sometimes involve numeric values attached to the descriptors, as in the following example:

How would you rate your health?

1	2	3	4	5
Poor	Fair	Good	Very good	Excellent

Continuous questions are a variation of rating scales. Instead of several specific answer options, participants place their answer anywhere on a solid line with descriptors (called *anchors*) on either side:

Strongly disagree	Strongly	Agree
-------------------	----------	-------

Finally, rank-ordered questions ask respondents to rank a set of responses based on their preference or importance. An example would be:

Rank the following leisure activities in order of your preference (1 = *most preferred* and 5 = *least preferred*)

- ☐ Reading
- ☐ Watching TV
- ☐ Playing sports, exercising
- ☐ Traveling
- ☐ Going out

The most important feature of rank-ordered questions is that they force participants to discriminate among the categories. In contrast, when each option is independently rated (e.g., How much do you enjoy reading? How much do you enjoy watching TV?), respondents might provide the same rating for some or all categories. Although ranking questions are cumbersome to analyze statistically, they might represent a good choice when the order of several alternatives is of main interest.

Tips on Creating a Survey

The following formatting guidelines will improve the clarity of a survey and result in more complete and accurate answers:

1. Use questions that are short and specific (vs. vague or too general) and include simple rather than complex words. This will increase the likelihood that respondents will correctly understand the questions.
2. Ask only one question in each item. Asking about multiple things will confuse participants and make interpretation of responses difficult. For instance, instead of asking "Do you think parents and teachers should provide civics education for children?," ask two separate questions, one about parents and one about teachers.
3. Visually separate questions from answers. This is typically done by using boldface font for the question and regular font for the answers.
4. List all response options in a single column, with the check boxes, blank lines, or numbers to be checked or circled ordered in a parallel column on the same side of the response options (left or right) throughout the survey. This gives all responses equal "weight" and makes it easier to find and record the best answers.
5. Order questions so that related items are presented together as a group, and that topics are logically ordered throughout the survey. Good organization keeps participants focused on each topic and makes the questionnaire easier and more enjoyable to complete.
6. Begin the questionnaire with easy to understand, noncontroversial questions. Place more personal and sensitive questions (e.g., about substance use or sexual behavior) later in the survey. Doing so will reduce the likelihood of respondents abandoning the questionnaire early or not completing the more sensitive questions.
7. Pilot the survey on a small group of individuals to ensure correct understanding and interpretation of the questions.

Methods of Administration

Surveys can be administered to participants in multiple ways, including through the internet, telephone, mail, or face to face, either individually or in a group setting. The advantages and disadvantages of each method are summarized in the following subsections.

Internet

Internet surveys are increasingly popular. These surveys can be posted on a website and links to them can be distributed by e-mail, social media, or text messages. Compared with mail surveys, internet questionnaires can be more complex and interactive, with complex skip patterns. Several companies, such as Qualtrics or SurveyMonkey, offer survey services on the internet. These services include survey development, distribution, and analysis, as well as access to respondent panels. Although the initial setup costs can be quite high, the data collection itself is inexpensive. The main advantage of internet surveys is the ability to reach a large number of participants across virtually unlimited geographic area. Online platforms, such as Amazon Mechanical Turk (MTurk), can be utilized to recruit diverse samples for survey studies at low cost.

A key advantage of internet surveys is that they automatically create data sets that can be readily analyzed, thus eliminating the tedious and error-prone step of manual data entry. However, samples obtained with internet surveys tend to be nonrepresentative of the general population, as not all segments of the population have access to the internet (e.g., the samples might overrepresent younger and more educated individuals). In addition, the researcher has little control over who completes the survey and under what conditions. Finally, unless certain protections are taken (e.g., use of passwords), some individuals might complete the survey multiple times, thus biasing the results.

Telephone

Surveys can be administered by telephone, either using live interviewers or interactive voice response systems in which participants respond to prerecorded questions using touch-tone phones or by providing spoken answers. Live interviewers are more expensive but can help clarify questions or response options. However, interviewer bias becomes a potential problem. This bias arises when interviewers' behavior (e.g., how they ask questions or how they react to answers) affects participants' responses. To prevent such bias, interviewers need to be well trained and monitored throughout the data collection process to pose

questions in a neutral manner and in the same way for each participant.

Telephone surveys are more cost efficient than in-person interviews, especially when participants are dispersed across a wide geographic area, and they are thus well suited for surveying national or international samples. However, a sampling bias is likely because not all individuals have a phone and many screen their calls using caller ID and answering machines. Given the high rates of unsolicited phone calls in recent years, state and federal laws might prohibit such calls and many respondents might be unwilling to answer questions over the phone. However, if reached, individuals might be more likely to respond to a telephone survey compared with a mailed questionnaire.

Mail

After receiving the survey by mail or directly from the researcher, participants complete it at their convenience and return it by mail. This method of administration is convenient and low in cost, and it allows sampling across a wide geographic area. However, respondents cannot ask for clarification and the researcher has no control over who completed the survey and under what conditions. Mail surveys are also limited to a standard set of questions and do not easily accommodate complex skip patterns. Other major problems of mail surveys include very low response rates and a high risk of nonresponse bias. This bias arises when those who return the survey are significantly different from those who do not respond. As a result, the results from the survey are typically not representative of the larger population that was surveyed.

To increase the return rate of mail surveys, the following two strategies have been shown most effective:

1. Multiple mailings, including a notice preceding the survey, the actual survey, a thank you/reminder letter, and a replacement survey. The mailings should explain the importance of the survey and the respondent's participation and assure confidentiality of answers. Telephone numbers can also be provided that the participants can call if they have questions.
2. Small monetary incentive (e.g., \$1) included with the questionnaire. Interestingly, including a small incentive with the survey seems more effective than the promise of a larger incentive contingent on the completion of the survey.

Face to Face

In face-to-face interviews, live interviewers meet with participants individually in a research office,

participants' home, or another location. Although this administration method is expensive, it gives researchers more control over the interview process and typically results in higher participation and completion rates, even for long and complex surveys. Participants are able to ask for clarification, thus reducing bias resulting from misunderstanding or misinterpretation of questions. In addition, this is the only method of administering a survey where interviewers can react to participants' nonverbal communication (e.g., facial expression suggesting confusion) and adjust the interview accordingly (e.g., explain the question or provide assurance). Using face-to-face interviews, structured questionnaires can be easily supplemented by unstructured or semi-structured interviews collecting more in-depth information. However, interviewer bias is a potential problem, so extensive training and monitoring of the interviewers is essential. To obtain valid information, it is important that face-to-face interviews be conducted privately, because the presence of others (e.g., family members, friends) might result in biased answers, especially for sensitive questions.

In recent years, many complex surveys have used computer-assisted personal interviewing (CAPI) to make the data collection process more efficient. Using CAPI reduces the likelihood of interviewer errors, allows for direct programming of complex skip patterns, and automatically records data, thus eliminating the need for manual data entry. Sensitive questions might be asked without the interviewer's involvement using audio computer-assisted self-interview to maximize the validity of the responses.

Group Administered

Typically used in classroom or other group settings, group administration involves many participants completing the questionnaires by themselves at the same time. This method is fast and easy and typically results in high response rates, although a perceived pressure to participate is a concern that should be addressed. The researcher is typically present to answer any questions, and respondents should be encouraged to ask for clarifications if needed. In a group setting, extra care needs to be taken to ensure confidentiality (e.g., by seating respondents apart from one another or using alternative forms for adjacent individuals). A potential problem is that some participants might not answer as truthfully as when asked in a face-to-face interview.

Advantages and Disadvantages of Surveys

Surveys represent an easy and efficient way to collect information from a large number of individuals. It is

the methodology of choice when the information of interest cannot be obtained from other sources (e.g., questions on personal beliefs) or would be too difficult or costly to ascertain through other means (e.g., from official records). Survey methodology is flexible and can be used to study a broad range of phenomena, including people's behavior, attitudes, beliefs, and emotions. Questions can be tailored to the research topic and can use a variety of formats and response options. The use of standardized, closed-ended questions makes participants' answers easily comparable and quantifiable. Researchers can choose from several administration methods depending on available resources and the type of research and population under study.

In contrast, survey research suffers from many limitations. Respondents might not know the answers to the questions posed or they might interpret the questions and response options differently. For instance, people might be asked to judge certain actions of local politicians of which they have very little knowledge. A given statement (e.g., "The mayor is an effective leader") might have different meaning for different individuals, depending on their beliefs of what characteristics make an effective leader. Individual participants might also have different thresholds for the distinction between "agree" and "strongly agree" or "disagree" and "strongly disagree."

Additionally, participants might not be motivated or willing to give true answers, especially to sensitive questions. Even if they are adequately motivated, they might fail to provide valid answers because of inaccurate self-perceptions or biased recall of past events from memory. Some individuals also adopt a *response set*, which is a tendency to provide affirmative or disconfirming answer regardless of the question content (called *yay-saying* and *nay-saying*). The best protection against such response sets is to vary the direction of the response options across questions (e.g., start with "strongly agree" on some and "strongly disagree" on others). The order of questions might also affect participants' responses. Such order effects can be analyzed and adjusted for statistically if the order of questions is varied across individuals.

A final problem common in survey research (and pervasive across all human subject research) is that of representativeness. The generalizability of research results is a direct function of how representative the sample is of the sampled population. Even if a solid sampling strategy is used, individuals who consent to participate might differ from those who decline. Consequently, the results of the research might only apply to people similar to those who participated, and not to those similar to the refusers. Many of these limitations

can be addressed or minimized by careful survey design, extensive pilot testing, sound sampling strategies, and allocation of resources to maximize response rates and validity of the obtained data.

SURVEY SAMPLING

Survey sampling involves selecting members from a target population to be included in a sample for a survey. The survey is usually a questionnaire such as an online, mail-in, phone, or in-person survey. Survey sampling has impacted the way we view society and the issues facing society. Before the beginning of the 20th century, conducting a census was the only acceptable method to gain knowledge about a population. A census was time-consuming and expensive, as it surveys every member of the population. Nowadays, statistical methods such as survey sampling have created cheaper and more efficient ways to gauge public opinion and measure society's issues.

Survey sampling includes sample selection, data collection, and estimating to make inferences about the population as a whole. This entry discusses the components of survey sampling.

Sample Selection

Sample selection typically includes probability-based samples or nonprobability samples. Probability-based samples use a random selection method such as random sampling or systematic sampling. With this method, members are chosen based on a known probability. Nonprobability samples utilize a nonrandom selection method such as the researcher's judgment, the

proximity of subjects, the convenience of scheduling, or other nonrandom factors. Using nonprobability samples, one cannot calculate the probability of choosing a member. Probability-based samples are typically preferred over nonprobability samples. If nonprobability samples are used, their use should be justified in the researcher's narrative. The target population size is used to determine the sample size. External factors, such as budget, time available, and the desired margin of error, could help determine the sample size.

Data Collection

Survey data are collected as individual sample participant responses to a questionnaire online, by mail, by phone, or in person. There are advantages and disadvantages to each type of data collection method. The researcher must consider factors such as cost, geographic reach, response rates, and bias to determine the best data collection method for their survey sample.

Estimation

Researchers use an estimation process to indicate the value of an unknown quantity in a population of sample data. Estimation results can be expressed as a single value (point estimate) or a range of values (confidence interval). The confidence interval range also produces a margin of error, indicating that the researcher is confident that their estimation will be accurate within a given margin of error.

Advantages and Limitations

Through survey sampling, researchers are most interested in the inferences they can make from the sample and their application across an entire population. Although a census gathers responses from a more significant number of people, a survey sample offers a greater scope than a census. Survey sampling makes it possible to study a larger geographical area's population or examine an area in greater depth, thus eliminating resource constraints.

Advantages

Survey sampling is a useful tool for data collection. This can include a wide variety of people and a wide variety of topics. Because it is versatile, survey sampling can provide a deeper understanding of just about any issue. Survey sampling can also be time- and cost-efficient, allowing researchers to ask many questions without increasing time or cost factors. Often, it is the

only available method for obtaining data from a large population.

Disadvantages

Response rates may be a limitation for survey sampling, as mail-in surveys often have low response rates. Language barriers can also be a disadvantage for survey sampling. It is also essential that researchers ask explicit questions so that results are not tainted. If interviewing the sample population or conducting phone surveys, the cost of training staff to conduct the surveys may also be a limitation.

Final Thoughts

Survey sampling is an efficient and effective method to understand a general population or topic better. By selecting a subset of the population, researchers can analyze the data and generalize the broader population results.

SURVIVAL ANALYSIS

Survival analysis, generally speaking, is the modeling of time-to-event data. Traditionally, survival analysis has been used to study the survival of biological organisms,

including human beings and laboratory animals. In this instance, survival analysis seeks to determine the amount of time until the death of the organism. The death is considered the event, and the time until the event is what is modeled. In such instances, survival analysis can determine the proportion of organisms alive at a certain point in time. Furthermore, factors to increase (or shorten) the life span of the organism can be determined. Survival analysis has been applied to many other fields to model data that are not specifically the “life” and “death” of an organism. For instance, survival analysis has been used in engineering and manufacturing to determine the life span of a mechanical process. Death, in this case, is the failure of the mechanism. The social sciences have applied survival analysis to determine the time to events such as marriage, childbirth, and so on. As such, survival analysis is a tool that can be used in a variety of situations, where what is of interest is the time until a particular event can happen.

Regardless of the application, what is central in survival analysis is that the event, be it the death of an organism, the failure of a machine, or the failure of a marriage, is unambiguous. Death is clearly unambiguous, as is marriage. However, the failure of a machine is more ambiguous as failure could be considered partial. Therefore, it is important to define the event in clear terms, and in a way that it is measurable in an absolute way and not open to interpretation. Furthermore, it is assumed that the event can only happen once to a member of the population. Again, in the case of the death of an organism, this is clear. In the case where a machine fails, it can be less clear, depending on the nature of the definition of failure. Many different parts of the machine could fail, and therefore a clear definition of the event should be determined so that the event can only happen once. In the examples of social sciences, this assumption makes it obvious that saying the time to marriage is insufficient; certainly people get married more than once in today’s society. However, the event could be defined as first marriage. Doing so also renders the research question more interesting: Given that people marry multiple times, considering the time until marriage in general might be less informative than the time until one gets married for the first time. Precision in the definition of the event can lead to making the second assumption more tenable.

To conduct a survival analysis it is essential to understand the concept of censored observations. Censored observations include observations for which the event has not yet occurred. There are other types of censored observations, but the case where the censorship is caused by not having experienced the event is simplest, and as such will be used for the illustration

here. Consider the case where the survival of an organism is of interest. If all the organisms in our sample have died, then looking for a way to predict the survival of an organism is simple: compute the median survival time. This will give us a good indication of the survival time of the organism. (Note that the mean survival time is not likely to be as useful as the median, because survival time data are rarely normally distributed and often are skewed.) In these cases, there is no need for advanced statistical tools. However, if some of the organisms have died while others have not, then a predictive model can be useful. It is important to note, however, that the reason that some organisms have not died (i.e., experienced the event) is because of a limitation of time in the study and that given enough time all organisms would die.

The Model

The underlying model for survival analysis is the survival function. The survival function, $S(t)$, is given by

$$S(t) = P(T > t), \quad (1)$$

where P denotes the probability, T is the random variable that denotes the survival time, and t is some fixed time. So, conceptually, the survival function is the probability that the survival time is greater than some fixed time. Typically, it is assumed that $S(0) = 1$, which means that the probability that the survival is greater than 0 is 1. There are cases where this is not reasonable, however, and it is not a necessary condition.

The survival function must be nonincreasing, meaning that as t increases, the probability of survival decreases or stays the same; the probability of survival cannot increase over time. Furthermore, it is assumed that as t gets increasingly large, $S(t)$ approaches zero. This would not be the case where eternal life is possible, but generally speaking, is assumed to be true. In addition to the survival function, survival analysis is also concerned with the hazard function.

The hazard function is the instantaneous rate at which events occur, given no previous events. Conceptually that means

$$h(t) = P(\text{Survive in } [t, t + \Delta t] \mid \text{Survive past } t). \quad (2)$$

Formalizing the expression in Equation 2 yields

$$\begin{aligned} h(t) &= \frac{P(t \leq T < t + \Delta t)}{P(T > t)} \\ &= \frac{P(t \leq T < t + \Delta t \mid T > t)}{\Delta t} \\ &= -\frac{1}{S(t)} \frac{S(t + \Delta t) - S(t)}{\Delta t}. \end{aligned} \quad (3)$$

Taking the limit of Equation 3 yields

$$\begin{aligned} h(t) &= \lim_{\Delta t \rightarrow 0} \frac{P(t \leq T < t + \Delta t \mid T > t)}{\Delta t} \\ &= -\frac{1}{S(t)} S'(t) = -\frac{d[\ln(S(t))]}{dt}, \end{aligned} \quad (4)$$

which is equivalent to

$$S(t) = e^{-\int_0^t h(u) du}. \quad (5)$$

The cumulative hazard function, which is denoted $H(t)$, provides the accumulated risk up to a specified time and is given by

$$H(t) = \int_0^t h(u) du. \quad (6)$$

It is worth noting the difference between the hazard function and the survival function. The survival function, on the one hand, provides the probability of surviving longer than time t , that is, $P(T > t)$ for some value of t . The hazard function, on the other hand, provides the probability of dying at time t exactly.

Estimation

The goal of survival analysis is to estimate $S(t)$, the survival function, and $H(t)$, the hazard function. The estimation of $S(t)$ and $H(t)$ depends on the assumptions that are reasonable to make for the analysis. If it is reasonable to assume that all subjects conform to the same survival function, then estimating $S(t)$ is fairly straightforward, and is the focus of this document. $S(t)$ can be estimated either using a parametric survival function or a nonparametric survival function. The nonparametric approach requires fewer assumptions and is estimated based on the empirical data, whereas the parametric approach naturally relies on choosing a distribution that best describes the data, and as such, the fit of the model chosen to the data becomes an issue. Nonparametric methods are usually preferred for their flexibility in modeling the data. As such, a discussion of the nonparametric approach will be given first, followed by the parametric approach.

Nonparametric Approach

In the nonparametric approach, the empirical cumulative distribution of the survival times is used to estimate the survival function. The most popular approach of nonparametric estimation of the survival function is the Kaplan-Meier approach. To understand the Kaplan-Meier approximation, it is necessary to understand some terms. Consider the case where there are x subjects. Let t_j denote the time of death of subject j , d_j

denote the number of deaths that have occurred in the time interval $[t_{j-1}, t_j]$, and n_j denote the number of subjects at risk of dying at time t_j . To compute the Kaplan-Meier survival function, the following formula is used for each value of t in the interval $t \in [t_j, t_{j+1})$. The function is given by

$$S(t) = \prod_{i=1}^j \left[1 - \frac{d_i}{n_i} \right], j = 1, 2, 3, \dots, \quad (7)$$

where d_i and n_i are defined previously. The resulting function is a step function, with a step at each t_j . This is best understood using an example.

Example

Consider the hypothetical example of testing a new drug that is designed to treat cancer. Two groups are chosen for the study: a treatment group that received the new drug and a control group that did not. The number of days that each patient survived in the trial was recorded. There were 12 people in the treatment group and 13 people in the control group. The study lasted for 6 months or 180 days. Ten subjects died in each group by the end of the study. The number of days of survival for the treatment group was: 40, 45, 53, 72, 145, 175, 176, 178, 179, 180, and 180. One participant was living at the end of the study and one had dropped out after 40 days. These cases would represent censored data, as their survival times are unknown. The number of days of survival for the control group was: 10, 11, 12, 15, 20, 25, 34, 65, 72, and 169. Of the remaining three participants, two were living at the end of the study and one dropped out after 100 days. These three cases are considered censored data as well.

For the two groups, the Kaplan-Meier statistics can be computed and are provided in Table 1.

The Kaplan-Meier estimate for $S(t)$ can be computed for each of the t_j as follows:

$$\begin{aligned} S(t_1) &= S(40) = \prod_{i=1}^1 \left[1 - \frac{0}{8} \right] = 1.0 \\ S(t_2) &= S(45) = \prod_{i=1}^2 \left[1 - \frac{d_i}{n_i} \right] = \left[1 - \frac{0}{8} \right] \left[1 - \frac{1}{7} \right] \\ &= .857, \end{aligned} \quad (8)$$

and so forth.

The cumulative hazard function, $H(t)$, is typically estimated using the following approach of Arthur V. Peterson:

$$H(t) = -\ln[S(t)] \quad (9)$$

However, some software packages use the Nelson-Aalen estimate given as follows:

$$H(t) = \sum_{t_i \leq t} \frac{d_i}{n_i} \quad (10)$$

The Nelson-Aalen approach will always lead to a slightly lower number; however, there is no theoretical advantage to choose one method over the other.

Both the Peterson and Nelson-Aalen approaches were applied to the data in the previous example, and the values for $S(t)$ and $H(t)$ for the subjects in both groups are provided in Table 2.

Because the goal is to compare the survival rates of the two groups, it is also informative to look at the mean and median survival times for the two groups. The median survival time is usually preferred, as the

survival data tend not to be symmetric, but skewed. Table 3 provides the mean and median survival times, along with 95% confidence intervals for each of the values.

As can be observed by looking at Table 3, the mean and median survival times are much higher for the treatment group relative to the control group. Furthermore, the confidence intervals for the median survival time do not overlap, indicating that the differences are statistically significant. Therefore, the treatment seems to lead to greater survival than no treatment.

Parametric Approach

As indicated by the name parametric, the parametric approach requires the specification of a distribution that best describes the empirical data. The idea is to find a

Table 1 Kaplan-Meier Statistics Control and Treatment Groups

180	0.21	1.58	1.43

continuous function that best approximates the empirical survival function. As noted in the previous section, the empirical survival function is a noncontinuous step function. The parametric function offers the advantages of being a continuous function with known moments of the distribution and known distribution form, which allows for ease in estimating the quantiles of the distribution and estimating the expected survival time. Furthermore, if the model is appropriate for the data, then a more precise estimate of the survival function is provided than that obtained with the Kaplan-Meier approximation. Popular distributions used to approximate the empirical function are the Weibull, exponential, log-normal, and log-logistic models. In using one of these distributions, the parameters of the distribution are estimated from the data. The shape of the survival function is often the by-product of choosing the shape of the hazard function, as the survival function is a function of the hazard function, as is evident from Equation 1. For example, a constant hazard function would have the form

$$h(t) \equiv a > 0. \quad (11)$$

In this equation, a is a constant and can take the value of any real number. If the hazard function is of this form, then the corresponding function for $S(t)$ would be given by

$$S(t) = e^{-\int_0^t a du} = e^{-at}, \quad (12)$$

which is clearly the exponential function. It is not very realistic for the hazard function to be a constant function, as that would imply that the probability of dying at a specified time t is constant across all values of t . Therefore, a more flexible set of distributions is usually specified.

The two parameter exponential distribution is commonly used as a hazard function. The form of this function is given by

$$h(t) = \alpha \beta t^{\beta-1}. \quad (13)$$

This provides a broad class of distributions as it has a scale parameter α and a shape parameter β . If both $\alpha, \beta > 0$, then the resulting survival function is given by

$$S(t) = e^{-\alpha t^\beta}, \quad (14)$$

which is the Weibull distribution and has broad applications in many fields.

Different choices of the hazard function will yield different survival functions. The choice of the distribution will be dependent on the nature of the data.

SYSTAT

SYSTAT is a statistical analysis and graphics software package for use on computers with Windows operating systems. It can handle most forms of analysis, from descriptive statistics through advanced regression, analysis of variance (ANOVA), and path and hierarchical model analyses. Earlier versions were offered for DOS, Unix, and Mac OS but are no longer supported. This entry briefly reviews the history, organization, and functioning of SYSTAT.

History

SYSTAT was created in 1980 by Lee Wilkinson, a psychology professor at the University of Illinois, Chicago. The software was originally written in Fortran on the Cromemco Z2 S-100 microcomputer. In 1983, SYSTAT

Table 3 Mean and Median Survival Rates With 95% Confidence Intervals

Group	Estimate	Lower Limit	Upper Limit
MEAN			
Treatment	142.09	108.77	175.42
Control	74.56	36.29	112.83
MEDIAN			
Treatment	176.00	140.40	211.61
Control	34.00	0.00	86.85

was incorporated and Version 1 was released on 5¼" floppy disks with photocopied documentation presented in a green ring binder. Subsequent versions were presented on 3½" disks with printed books, on a CD, and currently, via download.

Unlike packages such as SPSS and SAS developed for mainframes, SYSTAT was developed for microcomputers. It uses efficient commands that are similar from one procedure to the next, unlike R, and offers many options and opportunities for customization.

SYSTAT is quite popular in scientific and educational circles. Adoption was stimulated by the release of MYSTAT in 1987, a freeware program that in 2021 continues to be offered with no expiration date. MYSTAT provides 21 statistical procedures and can handle up to 500 variables and an unlimited number of cases.

By 1993, SYSTAT had grown to 50 employees and was headquartered in Evanston, IL. In 1995, it was sold to the SPSS Science division. Version 7, was released in 1997, Version 8 in 1998, and Version 9 in 1999. By 2002, SPSS had changed its focus to business analytics and sold SYSTAT to Cranes Software in Bangalore, India, with an office in Chicago, IL, to support SYSTAT. In 2005, Version 11 was released with a codebase revamped from Fortran into C++. Version 13.0 was introduced in 2009.

Capabilities and Operation

SYSTAT claims to offer more scientific and technical graphing options than any other desktop statistics package plus presentation-quality graphics. SYSTAT offers more than 250 button choices gathered into 32 toolbars, which are customizable. SYSTAT exact tests is available for an additional fee. SYSTAT also can present graphs in two- or three-dimensional formats, including dynamic operations, as well as provide multivariate displays and overlays.

SYSTAT offers three primary workspaces: Output on the left, Data on the right, and Command below. The size and positioning of the workspaces are customizable.

Data can be entered directly into SYSTAT's native spreadsheet. Variables up to 23 digits wide with up to 14 decimal places can be imported from Excel, SPSS, SAS, Minitab, Statistica, Stata, JMP, dBase, ASCII, ArcView, Lotus, DIF, and Statview files. Variable properties, such as name and type, can be modified through the column headings on the Data page, and descriptive statistics calculated. Such information also can be accessed through a separate Variables page.

SYSTAT data can be transformed using basic programming procedures through buttons or typed syntax. For example, "Let" statements take the form of

"Let Y = Function (X)", where Function is any of 33 mathematical procedures such as addition, natural logarithm, and arc tangent. Conditional transformations can be executed through "If...then let" statements and Recode statements. Other Data handling options include Rank, Center, Standardize, Trim, Sort and Select. Reorganizing the order of variables in the data file and merging data files containing new variables or cases are straightforward operations.

Analytic procedures are accessed through the Analyze menu, which offers 21 options, 15 of which have additional pull downs, indicated by ►:

One Way Frequency Tables	Correlations ►
Basic Statistics	Regression ►
Stem & Leaf	Analysis of Variance ►
Row Statistics ►	Multivariate Analysis of Variance ►
Fitting Distributions ►	General Linear Model ►
Tables ►	Mixed Models ►
Log-Linear Models ►	Discriminant Analysis ►
Non-Parametric Tests ►	Cluster Analysis ►
Multinomial Tests	Factor Analysis
Hypothesis Testing ►	Confirmatory Factor Analysis
Time Series ►	

The menus are customizable, which can be helpful for users who may find the location of some procedures nonintuitive.

An Advanced menu provides an additional 14 procedures, including

Missing Value Analysis	Perceptual Mapping
Quality Analysis ►	Partially Ordered Scalogram Analysis with Coordinates (POSAC)
Survival Analysis ►	Test Item Analysis ►
Responses Surface Methods ►	Signal Detection Analysis
Path Analysis (Ramona)	Network Analysis
Conjoint Analysis	Spatial Statistics
Multidimensional Scaling	Trees

A Quick Access menu provides 15 of the most popular analytic and graphics choices without the submenus.

Executing a specific statistical analysis is accomplished in two ways. The graphic user interface approach involves choosing a procedure from the

menu, choosing variables from the database, and then selecting the appropriate options. In the Correlation module, for example, there is a choice of six types of data and each data type provides access to a different submenu. Binary data provide 14 options ranging from Anderberg to Yule's Q. Additional choices include the generation of a full or a partial matrix, listwise (the default) versus pairwise deletion of missing values; uncorrected, Bonferroni or Dunn-Sidak corrected probabilities; and saving the matrix.

Experienced users who prefer not to scroll through a variable list can enter syntax in the Command workspace. A Pearson statement of the following form, for example, will generate a matrix of correlations of Item1 and Item2 with Item3–Item7 with pairwise deletion and Bonferroni correction:

```
PEARSON ITEM1 ITEM2*ITEM4 ITEM5 ITEM6
ITEM7 / PAIRWISE BONF
```

Three brief lines of syntax will execute a classical Test Item Analysis, with output described in the next section.

```
TESTAT
MODEL ITEM1 ITEM2 ITEM3 ITEM4 ITEM5
ITEM6 ITEM7
ESTIMATE / CLASSICAL
```

Commands executed via menus are retained as syntax in a Log file, which can be saved and modified for new analyses in the Command workspace.

SYSTAT is like an iceberg, with many procedures that are not immediately visible on the top-level menus.

Information about SYSTAT's hidden functions is available in the digital documentation, which is accessible through the Help tab. Help/Contents/Statistics, for example, explains the use, syntax, and form of output for 45 procedures and their many options. A parallel Graphics section offers the details of 16 graphic and plotting routines.

Output

SYSTAT provides abundant output. The bivariate correlation procedure, for example, produces separate correlation (Table 1) frequency, and probability tables (Table 2) and bar charts and scatterplots for the intersection of each variable (Figure 1). These Quickgraphs are intended to inform the investigator and are not publication quality.

Test Item Analysis produces the following: Test Score Statistics, Internal Consistency Data, Standard Error of Measurement of Total Score for 15 z score Intervals, and Item Reliability Statistics. The one-way ANOVA generates six tables and two graphs.

Researchers who are accustomed to the closely integrated output of a package like SPSS, which, for example, presents the r value, number of cases and probability value for each correlation in the same table, may see the large number of separate tables and figures produced by SYSTAT as a limitation. But, a researcher who wishes to present only the correlations in a report, and does not want to have to delete lines of extra data, may see the disaggregation as a virtue.

The SYSTAT graphics output provides many useful features. Selecting the "Influence" option in a bivariate scatterplot, for example, uses dot size to indicate the

Item7	0.111	0.486	0.496	0.626	0.159	0.152	0.000

Figure 2 Influence Option Illustrates the Effect of Individual Cases on Regression Line

impact of each case on the regression line (see Figure 2).

The Multidimensional Scaling graph provides a dynamic display, which can be rotated in three dimensions to gain a thorough understanding of the relations of the data, and the preferred angle can be saved in 2D for publication. SYSTAT graphics files can be saved in nine formats including JPEG and Windows metafiles.

Although SYSTAT provides a wide range of statistical options, it has its limitations. It does not offer the missing values analyses or multiple imputations of SPSS. Practitioners of latent variable structural equation modeling who are accustomed to Karl Jöreskog and Dag Sörbom's LISREL may find that SYSTAT's Reticular Action Model Or Near Approximation (RAMONA) offers less intuitive model specification features and less rich graphical outputs. Similarly, those who conduct multilevel modeling and are accustomed to Stephen W. Raudenbush and Anthony S. Bryk's hierarchical linear model (HLM) program may be disappointed that SYSTAT mixed module cannot fit two-, three- and four-level models with continuous, count, ordinal, and nominal outcome variables. SYSTAT is not intended to replace all other statistical software, but SYSTAT can accomplish most of the statistical analyses desired by contemporary researchers.

SYSTEMATIC ERROR

Systematic error is any measurement error that has an effect on an observed score which is consistent across individuals. *Systematic* errors affect the validity of an instrument or measurement system (while *random* errors affect reliability). Using the example of a weighing machine, readings that are consistently off in one direction reflect systematic error, although additional nuances will be subsequently discussed. The causes of systematic error could include leading or biased questions, which are often aspects of the measurement process that typically cause respondents to be unwilling to provide an accurate response. Being unwilling to provide an accurate response, respondents might provide a response that is inaccurate yet consistent. For example, with a leading question, respondents might consistently provide a response that is more acceptable. With a question requiring estimation of the amount of beer consumed, respondents might systematically underestimate the true value if they want to downplay their amount of drinking. This entry discusses several types of systematic error.

Additive Versus Correlational Systematic Error

One way of visualizing systematic error is in terms of a thermometer or a weighing machine that consistently deviates from the true value in a specific direction by a constant sum, say, as a result of an error in calibrating the zero point on the device. Such an error is a type of systematic error called *additive systematic error*. Additive systematic error inflates or deflates responses by a constant magnitude and might result in reduced correlations with other items. It should be noted that additive systematic error can be constant across responses and therefore has no effect on relationships, or it can be partial in the sense that the additive effect deflates or inflates responses to one end of the scale and restricts variance. Such additive error

could be caused by several factors, such as leading questions, interviewer bias, unbalanced response categories, consistently lenient or stringent ratings resulting from wording or other factors, or a tendency to agree or disagree. Factors that cause responses to be consistently off in one direction across respondents lead to additive systematic error.

A more problematic form of systematic error is *correlational systematic error*, which consistently deflates or inflates the relationship between two or more variables. Correlational error occurs when individual responses vary consistently to different degrees over and above true differences in the construct being measured; that is, it is a result of different individuals responding in consistently different ways over and above true differences in the construct. Using the weighing machine example, if readings are off in a certain direction and also in proportion to somebody's weight, then that is an example of correlational error (e.g., if the weighing machine shows an additional 5 pounds for a 100-pound person and an additional 10 pounds for a 200-pound person). An item might have correlational systematic error resulting from a common method, such as extreme response anchors (e.g., hate–love), leading to the use of middle response categories. Correlational systematic error occurs if different individuals interpret and use response categories in consistent but different ways. Examples include an item with correlational systematic error caused by a common method, such as extreme response anchors, leading to the use of middle response categories, or an item with moderate response anchors (e.g., like–dislike), leading to the use of extreme response categories. Correlational systematic errors can be caused by the use of response scales of a similar format across items, including what are referred to in the literature as method factors. For example, a certain set of response categories is employed (say, *very good* to *very bad*) and respondents interpret the categories in certain ways (*very good* means more or less positive for different respondents). In this scenario, the covariance across items will be, at least partially, a result of the method factor or the use of identical response formats. Similarly, correlational systematic error might arise as a result of other aspects of the research method, such as variation in the interpretation of the instructions and the questions.

Additive systematic error in an administration can have either no effect or a negative effect on stability and test–retest correlations. Additive systematic error is likely to have no effect or to attenuate relationships because of decreased variance. Correlational systematic error can strengthen or weaken observed relationships. Consistent differences across individuals over and above the construct being measured might be positively

correlated, negatively correlated, or not correlated with the construct.

Within-Measure Correlational Systematic Error and Across-Measure Systematic Error

Correlational systematic error can be distinguished within measures versus across measures. The latter, *across-measure systematic error*, refers to correlational systematic error that occurs between measures of different constructs. *Within-measure correlational systematic error* occurs between different items of a measure. It can be the result of responses to items being influenced by the use of a common method or by different trait or specific method factors that might or might not be related to the trait being measured. For instance, all the positively worded items in a scale might be influenced by individual differences in tendencies to agree. Within-measure correlational systematic error can have a positive influence on stability, such as the consistent measurement of a different but stable method factor or construct. An example of within-measure correlational systematic error is halo error in the completion of items within a measure—a tendency to provide similar responses across items that are thought to be related.

Whereas within-measure correlational systematic error occurs between items of a measure, across-measure correlational systematic error occurs across measures of different constructs. Essentially, across-measure correlational systematic error occurs if measures of different constructs are influenced by a trait or a method factor, or by different but related traits or method factors, thus inflating or deflating true correlations between them. A common method factor that affects both measures is a source of across-measure correlational systematic error. For example, the use of the same paper-and-pencil method (that taps, say, a response style of using certain parts of the scale) is likely to inflate correlations. Likewise, if subsequent measures are influenced by earlier ones, then the scales completed first introduce measure. For example, hypothesis guessing might result from responses to the first measure influencing responses to the second measure.

SYSTEMATIC SAMPLING

The techniques of inferential statistics are used to make educated guesses about the unknown characteristics of a population based on the known properties of a sample. There are many different kinds of samples, such as simple random samples, stratified random samples, multistage cluster samples, quota samples, and convenience samples. Another kind of sample is a systematic sample. Such samples differ from each other in terms of quality, availability, and popularity.

Systematic sampling refers to the process used to extract a sample from the population. From an ordered list of the population's N members (people, animals, or things), every k th member is selected to be included in the sample, where k is the interval between selected members of the list. The value of k is selected by the researcher to create a sample of a desired size, n . To determine k , N is divided by n .

A simple example might help to clarify how one creates a systematic sample. First, suppose a researcher has a population of 200 members and wants to have a sample of size 25. In this case, $N = 200$, $n = 25$, and $k = \frac{200}{25} = 8$. In this situation, every 8th member on the list of the 200 elements of the population would be included in the sample. The 25 members of the sample would hold positions 8, 16, 24, ..., and 200 in the list (presuming that the first sampled position on the list is position 8).

This entry describes the process of selecting a systematic sample and discusses the advantages and disadvantages of such a sample.

Selection Process

Need for a Sampling Frame

To create a systematic sample, there first must be a list of every member of the population. This list is called a *sampling frame*. Examples of sampling frames include the list of all admitted students who enroll in a given university as freshman during the fall of a particular year, the list of all gorillas housed in metropolitan zoos on a particular date in a given country, and the list of all new homes in a particular county that are sold during a given month. In each of these examples,

the list of the population's members is the sampling frame.

In some studies, a sample is created by identifying every k th person who walks by a researcher who is stationed at a particular spot in a city. After these individuals are identified (and questioned on some topic of interest), with the value of n perhaps predetermined, the responses from the n people are treated as sample data. This kind of sample is not a systematic sample for one simple reason: No sampling frame was created or used. Systematic samples, by definition, require sampling frames.

The Starting Point

Because most lists that define sampling frames are created in an alphabetical, geographical, or time-based manner, it is important to have a randomly determined starting point among the initial k positions on the list. If this is not done, no member of the population has a chance to be included if its position in the sampling frame is smaller than k . Clearly, a systematic sample cannot be considered to be random if a portion of the population is prevented from entering the sample.

In the example presented previously (in which $N = 200$ and $n = 25$), k was determined to be 8. Suppose the starting point is randomly determined to be 3. This would mean that members of the population in positions 3, 11, 19, ..., and 195 in the sampling frame would become members of the sample. This sample would be a true random sample; each member of the population has an equal chance of ending up in the sample, regardless of its location in the sampling frame.

Noninteger Values of k

If the ratio of N to n yields a noninteger value of k , then it is not proper to round k to the nearest integer. Doing this will cause one of two problems to occur. If k is rounded down, then one or more members of the population listed at the end of the sampling frame will have no chance of being included in the sample. If k is rounded up, then the selected sample might end up being smaller than desired.

To illustrate the proper procedure, suppose N is 206 and the desired n is 25. Here, k is equal to 8.24. As before, a random starting point would be identified among the initial 8 members of the sampling frame. (The number 8 came from rounding the computed value of k to the nearest integer.) Next, multiples of the noninteger value of k are added to that starting number and rounded off to determine the 2nd, 3rd, ..., and last members of the sample. For example, if the starting

number for our illustration is 4, then entries into the sample would come from positions:

Starting position is 4...

$$4 + 8.24 = 12.24 \text{ rounds to } 12$$

$$12.24 + 8.24 = 20.48 \text{ rounds to } 20$$

$$20.48 + 8.24 = 28.72 \text{ rounds to } 29$$

So, the entries would come from positions 4, 12, 20, 29, ..., 202 in the sampling frame.

Circular Systematic Samples

A slightly different method of extracting a systematic sample involves thinking of the sampling frame as a circle rather than as a vertical or horizontal line segment. Using this method, the value of k is first determined (and rounded, if necessary, to the nearest integer). Then, beginning with a random starting point between 1 and N , every k th member of the sampling frame goes into the sample, with this process continuing seamlessly from the "end" to the "beginning" of the sampling frame in those situations where the starting point is not one of the initial k positions in the sampling frame.

Suppose a researcher wants to extract a sample of $n = 25$ from a population in which $N = 418$. Here, $k = 16.72$ and the rounded $k = 17$. If the randomly determined starting point happens to be 391, the circular systematic sample would contain members from the sampling frame located in positions 391, 408, 7, 24, ..., and 381. Here, position 7 comes from adding 17 to 408 under the stipulation that the string of integers reverts to 1 after reaching 418. This sample (like all circular systematic samples) is truly random because every member of the population has an equal chance of being included in the sample. These samples also have the characteristic of being the desired size, n , even in those cases where $N \neq nk$.

Advantages and Disadvantages

There are two main advantages of systematic samples. First, this kind of sample is easy to create in those situations where (a) N/n is an integer or (b) a circular approach is taken if N/n is not an integer. In these situations, only one random number is needed in the process of selecting the sample. Second, a systematic sample has the appearance of being both good and fair because the sample is created by selecting members from various "sections" of the defined population. This kind of face validity might cause summaries of the sample data to be accepted more readily by lay people

who realize that simple random sampling potentially can identify n members of a population who hold consecutive positions in the sampling frame.

The main disadvantage of systematic sampling is the possibility of some form of cycle (i.e., periodicity) in the sampling frame. For example, if every 10th home in a neighborhood is selected to form a systematic sample, and if each of these homes (but not others) has a fire hydrant located directly in front of it, then this sample might be badly biased if a researcher asks the sampled homeowners to indicate how worried they are about having a fire destroy their homes. Or, suppose a systematic sample of $n = 10$ work days is taken from a 50-week period of time, with workers measured on those 10 days in terms of productivity, illness, or some other variable of interest. With $k = 5$, the sampled days could all be Mondays, and the sample data could easily misrepresent the workers' status throughout the 50-week duration of the study.

The problems caused by cycles existing in the sampling frame can be circumvented in one of two ways. One solution is to rearrange randomly the members of the population prior to the time the systematic sample is drawn. The other solution is useful in those situations where it is inconvenient or impossible to rearrange the sampling frame. In such situations, potential problems caused by known or hidden cycles can be eliminated by (a) randomly selecting a starting point in the existing sampling frame and (b) randomly selecting a member from each of the k -sized intervals that are positioned after the starting point.

***t* TEST, INDEPENDENT SAMPLES**

An independent samples *t* test is a hypothesis test for determining whether the population means of two independent groups are the same. The researcher begins by selecting a sample of observations and estimates the population mean of each group from the sample means. The researcher then compares these two sample means via the formula

$$t = \frac{\bar{x}_1 - \bar{x}_2}{\sqrt{\frac{s_p^2}{n_1} + \frac{s_p^2}{n_2}}},$$

where $\bar{x}_1$ is the sample mean of group 1, $\bar{x}_2$ is the sample mean of group 2, s_p^2 is the pooled estimate of variance (formula given in the example problem), n_1 is the sample size of group 1, and n_2 is the sample size of group 2. This *t* value can then be used to determine the likelihood that any difference between the two sample means is real versus caused by chance.

For example, assume a researcher is interested in the effect of stress on students' performance. She randomly assigns participants to either a "stress" or "no stress" group and examines how each of the two groups performs on a standardized test by calculating the sample mean for each group. Because the researcher is not interested in the samples per se but in all students, she needs to determine whether any difference between her sample means is real or a result of chance. The independent samples *t* test will assist her in making this determination.

Note that the equation presented earlier tests whether the population means are different. It is also possible to use the independent samples *t* test to

examine whether the difference between the population means is greater than a constant, *c* (rather than 0). In this situation, the numerator of the formula for *t* changes to $(\bar{x}_1 - \bar{x}_2 - c)$. In most cases, however, the independent samples *t* test is used to determine whether the population means are equal, and the rest of the discussion is confined to that situation.

Uses

The independent samples *t* test is appropriate whenever the researcher wants to know whether two population group means are different and when the observations in each of the groups are independent of the observations in the other group. In some cases, these groups are composed from naturally occurring populations. For example, a researcher might be interested in comparing the spatial ability of men and women. In this case, all men and women in the country (or at his or her university, etc.) would comprise the two populations (one of men and one of women). The researcher would then construct a sample of men and of women, calculate the sample means, and conduct an independent samples *t* test to determine whether any differences between the sample means are real or caused by chance.

In many cases, however, the populations are not naturally occurring but instead are determined by some element of the study. This is particularly common in experimental research, where the researcher manipulates a variable (stress in the preceding example) and assigns participants to one of the two resulting groups. In this case, the groups that result from the manipulation do not reflect actual known populations. Instead, they reflect hypothetical infinite populations that result from the experimental manipulation.

The conclusions that can be drawn from the independent samples *t* test are somewhat different

depending on whether the populations are naturally occurring or result from an experimental manipulation (for example, it is easier to demonstrate causality when a variable has been manipulated). Nonetheless, the independent samples *t* test functions identically in the two situations, testing whether the population means of two independent groups are equal.

Interpreting the *t* Value

The result of an independent samples *t* test is a *t* value. This *t* value is compared with the *t*-distribution that would occur if the two population group means were equal. This possibility (that the two population group means are equal) is known as the null hypothesis. The logic that underlies the independent samples *t* test is to compare the *observed* value of *t* (that is, the value of *t* calculated from the independent samples *t* test) with the *t*-distribution that would occur if the null hypothesis were true. If the observed value of *t* is in keeping with this distribution, then the null hypothesis might well be true (i.e., the population means are equal). If the observed value of *t* is not in keeping with this distribution, then the null hypothesis is likely *not* true (i.e., the population means are not equal).

The precise form of the *t*-distribution is determined by degrees of freedom (*df*), which in turn is determined by the sample size (specifically, $df = n_1 + n_2 - 2$). Basically, the larger the number of observations, the better one is able to estimate the variability in the data, so the *t*-distribution most closely resembles the *z* distribution with a large number of observations.

The *t*-distribution for 100 *df* is presented in Figure 1. Intuitively, the observed value of *t* reflects how different from each other the sample means are. Since the absolute distance between the means can be determined by many factors (e.g., the range of possible scores, size of one's sample), this difference is "standardized" by

$\sqrt{\frac{s_p^2}{n_1} + \frac{s_p^2}{n_2}}$, which is the standard error of the difference

between the means. Thus, the value of *t* indicates how far apart the sample means are, in standardized form. The *t*-distribution (such as the one presented in Figure 1) provides the range of possible *t* values that would reasonably be expected to be found, *assuming the null hypothesis is true* (i.e., assuming the population means are equal). Put differently, even if the population means are equal, the *sample* means will likely be different just by chance. The *t*-distribution describes precisely how different the sample means would be just by chance.

To determine whether the population means could be equal, then, one compares the *observed t* value with the *t*-distribution constructed under the assumption

Figure 1 *t*-Distribution with 100 *df*

that the population means are equal. Assume, for example, that the observed *t* value is .50. As can be observed in Figure 1, there is a high probability of obtaining this *t* value if the population means are equal. If, however, the observed *t* value were 4.0, then there is a near-zero probability of obtaining this *t* value if the population means are equal. Thus, in that latter situation, the researcher would conclude that the population means are *not* equal.

In the previous examples, it was relatively straightforward to determine visually whether the observed value of *t* was in keeping with the *t*-distribution. A more precise indication is provided by a *p* value, which provides the likelihood of obtaining the observed *t* value by chance (i.e., assuming the null hypothesis is true). If the *p* value is low, then the chance of having obtained one's results just by chance (i.e., if the population means really are equal) is low, and the researcher concludes that the population means are likely not equal. In this situation, the result of the *t* test is often described as "statistically significant," because it indicates that any difference between the sample means is real and not just a result of chance. Conversely, if the *p* value is high, then the likelihood of having obtained one's results just by chance is high, and the researcher concludes that the population means might be equal. In many disciplines, .05 is used as a cutoff to determine whether the *p* value is low or high. Using this cutoff of .05 ensures that—of all times when the population means are equal—the researcher will only erroneously conclude that the population means are *not* equal 5% of the time. In statistical terms, the researcher will only make a Type I error 5% of the time when the null hypothesis is true.

The exact *p* value is provided by any standard statistical program as a result of conducting an independent samples *t* test. If, however, the independent samples *t* test is conducted by hand, calculation of the *p* value is not straightforward. Thus, the observed *t* value is sometimes compared with a "critical" value of *t*. This critical *t* value is the value of *t* that would produce a *p* value of .05. Thus, *t* values greater than the critical value of *t* produce *p* values less than .05 and

lead to the rejection of the null hypothesis (concluding that the population means are not equal), and t values less than the critical value of t produce p values greater than .05 and lead to acceptance of the null hypothesis (concluding that the population means are equal). Critical values of t can be found in many statistical textbooks.

One-Tailed Versus Two-Tailed Tests

The exact method for calculating the p value (and critical value of t) depends on whether one is conducting a directional (one-tailed) test or a nondirectional (two-tailed) test. For a nondirectional test, the researcher tests whether the population means are different (i.e., whether either mean is greater than the other one). In the previous stress example, for instance, the researcher might be interested in determining whether stress increases or decreases performance. In that situation, the researcher would perform a nondirectional, two-tailed test. Conversely, if the researcher were interested in testing whether stress *decreases* performance, the researcher would conduct a directional, one-tailed test.

The choice of whether to perform a one-tailed or two-tailed test influences the resulting p value. As long as the results come out in the predicted direction, the one-tailed test will produce a smaller p value (and, equivalently, a smaller critical value of t) than will a two-tailed test, thus making it easier to find statistically significant results. However, it is important to emphasize that the decision to conduct a one-tailed test must be made for theoretical reasons and prior to an examination of the data. If, for example, the researcher predicted that stress would decrease performance and found that the sample mean of the stress group was greater than the sample mean of the no-stress group, the researcher must conclude that his or her hypothesis was not supported, rather than conduct a two-tailed test. For this reason, it is sometimes recommended that researchers typically conduct two-tailed tests, to allow for conclusions on either side of the t -distribution.

Assumptions

The three primary requirements for the independent samples t test to produce accurate results are as follows: independent observations, equal variances in the two groups, and normality. In addition, when the populations are naturally occurring (rather than resulting from an experimental manipulation), it is important to have unbiased sampling from the populations of interest.

The first assumption is independent observations. Observations in a study are *independent* to the extent

that each observation is not predictive of another observation in the study. For example, assume that for ease of conducting the study, our researcher interested in the effect of stress on standardized test performance ran a session testing 20 participants in the stress condition, then 20 participants in the no stress condition, and so on. Also assume that in one of the stress sessions, one participant raced through the test, finished quickly, and left early. If the other participants in that session responded by going through the test more quickly than they would have otherwise (and thus did not perform as well), the assumption of independent observations would be violated. Note that the difficulty here is not with the person who raced through the test—this person's poor score would just constitute random error in the study. The problem occurs when the other 19 people's scores in the stress condition are affected as well, thus meaning that each observation is not independent of each other and presumably leading to worse performance in that condition.

The second assumption of the independent samples t test is homogeneity (equality) of variance in each of the populations. Part of the formula for calculating the t value involves calculating s_p^2 , which is the pooled estimate of variance. This pooled estimate of variance reflects the best estimate of the population variance, which is assumed to be equal for each of the two groups. To determine whether the two groups actually have equal variances, one approach is to conduct Levene's test, which is provided in many statistical packages. Finding significance with Levene's test indicates that the two variances are *not* equal, although as with all hypothesis tests, a variety of factors (e.g., sample size) will influence the likelihood of achieving significant results. An alternative approach is to compare the ratio of the sample variances of the two groups. Although these should differ to some extent just by chance, one recommendation is that if the ratio of the variances (note: this is variances, not standard deviations) is more than 4:1 for small sample sizes or 2:1 for large sample sizes, then the assumption is likely violated. Note, however, that as long as the sample sizes in each of the two groups are roughly the same, violation of the equal variance assumption seems to have little influence on the results. Thus, it is generally recommended not to be concerned with this assumption unless the sample sizes in each of the groups are substantially different. If that is the case and the assumption seems to be violated, then there are multiple options for handling this situation. One option is to conduct some type of transformation on the data. A second option is to conduct a hypothesis test that does not require the equality of variance assumption (e.g., to use a modified t statistic that does not require

calculation of s_p^2 or a nonparametric equivalent such as the Mann–Whitney U test).

The third assumption of the independent samples t test is that each sample was drawn from a population that follows a normal distribution. Partly because of the Central Limit Theorem, however, this assumption can typically be violated as long as the sample sizes are reasonably large. “Reasonably large” is often defined as $n > 30$; however, as long as the departure from normality is not too severe, considerably smaller sample sizes are acceptable.

Finally, if the populations are naturally occurring (rather than resulting from an experimental manipulation), it is important to have unbiased sampling from the populations of interest. Note this requirement must be met for the results of the study to be meaningful descriptively as well as inferentially. If unbiased sampling is not used, then the researcher might find statistically significant results not because the population means are actually different but instead because of the biased sampling procedures used.

Power

As with any hypothesis test, even when the population group means are different from one another, the independent samples t test might not detect this difference (i.e., the results might not be statistically significant). The ability to find statistically significant results when there is a real difference between the population means is referred to as the *power* of the test. It is beneficial to conduct one’s study with as high a power as possible, to provide the greatest chance of being able to detect a difference if one exists.

Given a certain alpha level and choice of one-tailed versus two-tailed test, the following three factors influence the power of the independent samples t test: the difference between the population means (larger differences = greater power), the amount of variability in the population (smaller variability = greater power), and the size of the samples (larger sample size = greater power). Jacob Cohen provides statistical tables that can be used to determine one’s power and to determine how large a sample size is needed to provide a given power.

Example Problem

A pharmaceutical researcher is interested in determining which of two drugs is more effective at reducing cholesterol levels. He enlists the participation of 18 participants who have high cholesterol and randomly assigns 9 of them to receive Drug A and the other 9 to

receive Drug B. At the end of one year of treatment, he measures their cholesterol levels, which are provided below:

Drug A : 250, 200, 230, 260, 180, 250, 290, 220, 190

Drug B : 260, 220, 170, 160, 250, 190, 250, 190, 200

The first step in testing his hypothesis is to calculate the sample means for each group, which are

$$\bar{x}_{\text{DrugA}} = \frac{\sum_{i=1}^n x_i}{n_{\text{DrugA}}} = \frac{2070}{9} = 230,$$

$$\bar{x}_{\text{DrugB}} = \frac{\sum_{i=1}^n x_i}{n_{\text{DrugB}}} = \frac{1890}{9} = 210.$$

Just based on the sample means, it seems that Drug B was more effective than Drug A at producing low cholesterol levels. However, this difference could have occurred just by chance. To examine this issue, the researcher would conduct an independent samples t test. The formula for the independent samples t test applied to this situation is:

$$t = \frac{\bar{x}_{\text{DrugA}} - \bar{x}_{\text{DrugB}}}{\sqrt{\frac{s_p^2}{n_{\text{DrugA}}} + \frac{s_p^2}{n_{\text{DrugB}}}}}.$$

The next step is to calculate the pooled estimate of variance. The formula for s_p^2 is

$$s_p^2 = \frac{s_1^2(n_1 - 1) + s_2^2(n_2 - 1)}{n_1 + n_2 - 2}, \text{ or in this case,}$$

$$s_p^2 = \frac{s_{\text{DrugA}}^2(n_{\text{DrugA}} - 1) + s_{\text{DrugB}}^2(n_{\text{DrugB}} - 1)}{n_{\text{DrugA}} + n_{\text{DrugB}} - 2}.$$

The variance of each of the groups is

$$s_{\text{DrugA}}^2 = \frac{\sum_{i=1}^n (x_i - \bar{x}_{\text{DrugA}})^2}{n_{\text{DrugA}} - 1} = 1300,$$

$$s_{\text{DrugB}}^2 = \frac{\sum_{i=1}^n (x_i - \bar{x}_{\text{DrugB}})^2}{n_{\text{DrugB}} - 1} = 1350.$$

$$\text{Thus, } s_p^2 = \frac{1300(8) + 1350(8)}{18} = 1325.$$

Plugging into the formula for t gives

$$t = \frac{\bar{x}_{\text{DrugA}} - \bar{x}_{\text{DrugB}}}{\sqrt{\frac{s_p^2}{n_{\text{DrugA}}} + \frac{s_p^2}{n_{\text{DrugB}}}}} = \frac{230 - 210}{\sqrt{\frac{1325}{9} + \frac{1325}{9}}} \\ = \frac{20}{17.16} = 1.17.$$

Because the researcher is interested in testing whether either drug would outperform the other one, he would conduct a two-tailed independent samples t test. The p value for this test (as provided by most statistical packages) is .26. As this p value is moderately large, he or she would conclude that, although descriptively Drug B outperformed Drug A, this difference might have occurred just by chance.

Alternatively, if a statistical package was not available to determine the precise p value, the observed value of t can be compared with the critical value. In this case, as observed in most statistics textbooks, the critical t value is 2.12. Because $1.17 < 2.12$, the researcher would reach the same conclusion (as will always be the case) and conclude that the difference between the sample means might have occurred just by chance.

Thus, given the results of his study, the researcher would conclude that both drugs are equally effective. Of course, this study does not conclusively settle this issue, but the results of his study do not provide convincing evidence that either drug is better than the other one.

t TEST, ONE SAMPLE

A one-sample t test is a hypothesis test for determining whether the mean of a population is different from some known (test) value. The researcher begins by selecting a sample of observations from the population

of interest and estimates the population mean by calculating the mean of the sample. The researcher then compares this sample mean with the test value of interest via the formula

$$t = \frac{\bar{x} - \mu}{s/\sqrt{n}},$$

where $\bar{x}$ is the sample mean, μ is the test value, s is the sample standard deviation, and n is the sample size. This t value can then be used to determine the likelihood that any difference between the sample mean and the test value is real versus a result of chance.

For example, a researcher studying the better-than-average effect might be interested in determining whether students, on average, think they are more athletic than the average student. Thus, the researcher has participants rate on a 1–7 scale (where 1 = below average, 4 = average, 7 = above average) their athletic ability and calculates the sample mean. Because the researcher is not interested in the sample per se but in the population of college students, he or she needs to determine whether any difference between the sample mean and “4” (the test value) is real or caused by chance. The one-sample t test will assist in making this determination.

Uses

The one-sample t test is appropriate whenever the researcher wants to determine whether the mean of some population differs from some test value. Note the one-sample t test closely resembles the one-sample z test. The difference is that the z test is used when the standard deviation of the population being studied is known, whereas the t test is used when the standard deviation of the population is not known.

An important characteristic of the one-sample t test (as well as of the one-sample z test) is that there is only one population that is being studied. This differentiates a one-sample test from other types of hypothesis tests (e.g., the independent samples t test) where there are two (or more) population parameters to be estimated. For example, a researcher interested in whether the average score of males differs from the average score of females would not use a one-sample t test, because there are two population parameters (the mean score of both males and females) to be estimated in that situation.

The one-sample t test can be used whenever the researcher is interested in determining whether the population mean differs from some specific value (the test value). This test value is generally determined in one of two ways. First, as in the previous example, the

test value is chosen to reflect some value of theoretical interest, in that case, the “average” perceived ability. In the second situation, the test value reflects a known population value (or one estimated with a great deal of precision). For example, assume a medical researcher is interested in determining whether a medication affects the number of hours a night that a person sleeps. He finds information from the National Sleep Foundation saying that the average working American adult sleeps 6 hours and 40 minutes (400 minutes) on a work night. He then samples 100 working Americans who take the medication and records how long each of these people sleep on a work night. The mean number of hours slept from this sample could then be compared with 400 minutes via a one-sample *t* test. Note, however, these are just example uses for the one-sample *t* test. In any situation where the researcher wants to test the mean of a sample against some particular value, a one-sample test is appropriate.

Interpreting the *t* Value

The result of a one-sample *t* test is a *t* value. This *t* value is compared with the *t*-distribution that would occur if the population mean were equal to the test value. This possibility (that the population mean is equal to the test value) is known as the *null hypothesis*. The logic that underlies the one-sample *t* test is to compare the *observed* value of *t* (that is, the value of *t* calculated from the one-sample *t* test) to the *t*-distribution that would occur if the null hypothesis were true. If the observed value of *t* is in keeping with this distribution, then the conclusion is that the null hypothesis might be true (i.e., the population mean is equal to the test value). If the observed value of *t* is not in keeping with this distribution, then the conclusion is that the null hypothesis is *not* true (i.e., the population mean is not equal to the test value).

The precise form of the *t*-distribution is determined by degrees of freedom (*df*), which in turn is determined by the sample size (*n*; specifically, $df = n - 1$). Basically, the larger the sample size, the better one is able to estimate the standard deviation of the population, so the *t*-distribution most closely resembles the *z* distribution with a large sample size. With a smaller sample size, the *t*-distribution is spread out somewhat to reflect the uncertainty in the estimate of the population standard deviation.

The *t*-distribution for 100 *df* is presented in Figure 1. Intuitively, the observed value of *t* reflects how far from the test value the sample mean is. Because the absolute distance from the mean can be determined by many factors (e.g., the range of possible scores or size of one's sample), this difference is “standardized” by

Figure 1 *t*-Distribution with 100 *df*

$s/\sqrt{n}$, which is often referred to as the standard error of the mean. Thus, the value of *t* indicates how far the observed mean is from the test value, in standardized form. The *t*-distribution (such as the one presented in Figure 1) provides the range of possible *t* values that would reasonably be expected to be found, *assuming the null hypothesis is true* (i.e., assuming the population mean equals the test value). Put differently, even if the population mean equals the test value, the *sample* mean will likely deviate from the test value to some extent just by chance. The *t*-distribution describes precisely how far the sample mean would deviate from the test value just by chance.

To determine whether the population mean could be equal to the test value, then, one compares the *observed t* value with the *t*-distribution constructed under the assumption that the population mean equals the test value. Assume, for example, that the observed *t* value is .50. As can be observed in Figure 1, there is a high probability of obtaining this *t* value if the population mean equals the test value. If, however, the observed *t* value were 4.0, then there is a near-zero probability of obtaining this *t* value if the population mean equals the test value. Thus, in the latter situation, the researcher would conclude that the population mean must *not* equal the test value.

In the previous examples, it was relatively straightforward to tell visually whether the observed value of *t* was in keeping with the *t*-distribution. A more precise indication is provided by a *p* value, which provides the likelihood of obtaining the observed *t* value by chance (i.e., assuming the null hypothesis is true). If the *p* value is low, then the chance of having obtained one's results just by chance (i.e., if the population mean really equals the test value) is low, and the researcher concludes that the population mean is likely not equal to the test value. In this situation, the result of the *t* test is often described as “statistically significant,” because it indicates that any difference between the sample mean and test value is real and not just a result of chance. Conversely, if the *p* value is high, then the likelihood of

having obtained one's results just by chance is high, and the researcher concludes that the population mean might be equal to the test value. In many disciplines, .05 is used as a cutoff to determine whether the *p* value is low or high. Using the cutoff of .05 ensures that—of all times when the population mean equals the test value—the researcher will only erroneously conclude that the population mean is *not* equal to the test value 5% of the time. In statistical terms, the researcher will only make a Type I error 5% of the time when the null hypothesis is true.

The exact *p* value is provided by any standard statistical program as a result of conducting a one-sample *t* test. If, however, the one-sample *t* test is conducted by hand, then calculation of the *p* value is not straightforward. Thus, the observed *t* value is sometimes compared with a “critical” value of *t*. This critical *t* value is the value of *t* that would produce a *p* value of .05. Thus, *t* values greater than the critical value of *t* produce *p* values less than .05 and lead to rejection of the null hypothesis (concluding that the population mean is not equal to the test value), and *t* values less than the critical value of *t* produce *p* values greater than .05 and lead to acceptance of the null hypothesis (concluding that the population mean equals the test value). Critical values of *t* can be found in many statistical textbooks.

One-Tailed Versus Two-Tailed Tests

The exact method for calculating the *p* value (and critical value of *t*) depends on whether one is conducting a directional (one-tailed) test or a nondirectional (two-tailed) test. For a nondirectional test, the researcher is testing whether the population mean is either greater than or less than the test value. In the previous medical example, for instance, the researcher was interested in determining whether the number of hours of sleep either increased or decreased with medication. Thus, the researcher would perform a nondirectional test. If the sample mean was much greater than the test value and provided a large positive value of *t* (see the first equation in this entry), then the researcher would conclude that the medicine increased sleep. Conversely, if the sample mean was much less than the test value and provided a large negative value of *t*, then the researcher would conclude that the medicine decreased sleep. Because the researcher is willing to conclude that there's an effect in either direction (i.e., on either side of the *t*-distribution), this test is referred to as a two-tailed test.

In contrast, with a directional test, the researcher is testing on only one side of the *t*-distribution. For example, in the previous example of the better-than-average effect, the researcher would likely test whether

the average student thinks he or she is more athletic than average. Thus, the researcher would perform a directional test, predicting that the population mean was greater than the test value (4 = average, in this example). In this situation, the researcher is only interested in positive values of *t*. If the sample mean was much greater than 4, producing a large positive value of *t*, then she would conclude that the average student thinks he or she is more athletic than average. Otherwise (with a small positive *t* value, or a negative *t* value of any size), she would conclude that people do *not* think they are better than average in athletic ability. Because the researcher is only willing to conclude that there's an effect on one side of the distribution, this test is referred to as a one-tailed test.

The choice of whether to perform a one-tailed or two-tailed test influences the resulting *p* value. As long as the results come out in the predicted direction, the one-tailed test will produce a smaller *p* value (and, equivalently, a smaller critical value of *t*) than will a two-tailed test, thus making it easier to find statistically significant results. However, it is important to emphasize that the decision to conduct a one-tailed test must be made for theoretical reasons and prior to an examination of the data. If, for example, the researcher predicted that the population mean would be greater than 4 and found that the sample mean was 2.8, the researcher must conclude that the hypothesis was not supported, rather than switch to a two-tailed test. For this reason, it is sometimes recommended that researchers typically decide in advance to conduct two-tailed tests to allow for conclusions on either side of the *t*-distribution.

Assumptions

The three primary requirements for the one-sample *t* test to produce accurate results are unbiased sampling, independent observations, and normality.

The first requirement is unbiased sampling from the population of interest. Note that this requirement must be met for the results of the study to be meaningful descriptively as well as inferentially. Consider the researcher interested in testing whether students on average think they are more athletic than the average student. If she only samples students (say, student athletes) who *are* more athletic than average, then she will conclude that students think they are more athletic than average solely because of the biased sampling of participants. Similarly, in the medical researcher's study, if the Americans taking the medication are somehow systematically different from the average American (for example, having more stressful jobs that reduce the amount of sleep at night), then the medical researcher

might find that the participants in his study sleep less than the typical American even if there is actually no effect of the medicine. In short, it is crucial to ensure that the sample constructed for one's study is representative of the population of interest.

A second assumption of the one-sample *t* test is independent observations. Observations in a study are *independent* to the extent that each observation is not predictive of another observation in the study. For example, assume that in the previous hypothetical sleep study, the researcher decided to study five members from the same family for ease of data collection. These values would probably *not* be independent, because each family member is likely to require similar amounts of sleep.

The third assumption of the one-sample *t* test is that the sample was drawn from a population that follows a normal distribution. Partly because of the Central Limit Theorem, however, this assumption can typically be violated as long as the sample size is reasonably large. "Reasonably large" is often defined as $n > 30$; however, as long as the departure from normality is not too severe, considerably smaller sample sizes are acceptable.

Power

As with any hypothesis test, even when the population mean is different from the test value, the one-sample *t* test might not detect this difference (i.e., the results might not be statistically significant). The ability to find statistically significant results when there *is* a real difference between the population mean and the test value is referred to as the *power* of the test. It is beneficial to conduct one's study with as high a power as possible to provide the greatest chance of being able to detect a difference if one exists.

Given a certain alpha level and choice of one-tailed versus two-tailed test, three factors influence the power of the one-sample *t* test: the difference between the population mean and test value (larger differences = greater power), the amount of variability in the population (smaller variability = greater power), and the size of the sample (larger sample size = greater power). In practice, it is typically easiest to control the size of the sample, so researchers usually try to conduct their studies with as large a sample as possible. Jacob Cohen provides statistical tables that can be used to determine one's power and to determine how large a sample size is needed to provide a given power.

Example Problem

A used car dealer is trying to determine at what price to sell a 2000 Honda Civic. He thinks that most of

his customers overestimate the typical retail price of these cars (the suggested retail price is approximately \$8,000, according to the Kelley Blue Book). If he is correct and his customers do overestimate the typical retail price, then he figures he can raise the price of these cars with minimal impact on his selling rate. To determine whether his belief is correct, he asks his next 16 customers to estimate the suggested retail price of the Honda Civic. Their estimates are below (in thousands):

10, 7, 9, 15, 6, 10, 5, 12, 11, 9, 4, 16, 5, 9, 6, 10

The first step in testing his hypothesis is to calculate the sample mean, which is

$$\bar{x} = \frac{\sum_{i=1}^n x_i}{n} = \frac{144}{16} = 9.0.$$

Just based on the sample mean, the used car dealer's prediction is confirmed—the average prediction (\$9,000) was greater than the suggested retail price (\$8,000). However, this difference could have occurred just by chance. To examine this issue, the car dealer would conduct a one-sample *t* test. The formula for the one-sample *t* test is

$$t = \frac{\bar{x} - \mu}{s/\sqrt{n}}.$$

The next step is to calculate the standard deviation (*s*). The formula for the standard deviation is

$$\begin{aligned} s &= \sqrt{\frac{\sum_{i=1}^n (x_i - \bar{x})^2}{n - 1}} \\ &= \sqrt{\frac{(10 - 9)^2 + (7 - 9)^2 + \dots}{15}} \\ &= \sqrt{\frac{180}{15}} = 3.46. \end{aligned}$$

Plugging into the formula for *t* gives

$$t = \frac{\bar{x} - \mu}{s/\sqrt{n}} = \frac{9 - 8}{3.46/\sqrt{16}} = \frac{1}{.865} = 1.16.$$

Because the used car dealer is interested in determining whether people overestimate the actual price, he would conduct a one-tailed one-sample *t* test. The *p* value for this test (provided by most statistical packages) is .12. Because this *p* value is moderately large, he would conclude that, although the average prediction

in his sample was greater than \$8,000, this difference might well have occurred just by chance.

Alternatively, if a statistical package was not available to determine the precise *p* value, the observed value of *t* can be compared with the critical *t* value. In this case, as found in most statistics textbooks, the critical *t* value is 1.75. Because $1.16 < 1.75$, the used car dealer would reach the same conclusion (as will always be the case) and establish that the difference between the sample mean (\$9,000) and the test value (\$8,000) might have occurred just by chance.

Thus, given the results of his study, the used car dealer would conclude that people do *not* overestimate the price of 2000 Honda Civics. Of course, this study does not conclusively settle this issue, but the results of his study do not provide convincing evidence that people overestimate these prices.

t TEST, PAIRED SAMPLES

A paired samples *t* test is a hypothesis test for determining whether the population means of two dependent groups are the same. The researcher begins by selecting a sample of paired observations from the two groups. Thus, each observation in each group is paired (matched) with another observation from the other group. The researcher then calculates the difference between each of these paired observations and conducts a one-sample *t* test on these difference scores via the formula

$$t = \frac{\bar{x}_d}{s_d / \sqrt{n_d}},$$

where $\bar{x}_d$ is the sample mean difference score, s_d is the standard deviation of the sample difference scores, and n_d is the number of paired observations in the

sample (i.e., the number of difference scores). This *t* value can then be used to determine the likelihood that any difference between the two sample means is real versus a result of chance.

For example, assume a researcher is interested in the effect of stress on students' performance. She has each of her participants take part in both a "stress" and a "no stress" condition and compares how each participant performs in the two conditions. Because the researcher is not interested in the sample comparisons per se but in all students, she needs to determine whether any difference between the two conditions she finds in her sample is real or caused by chance. The paired samples *t* test will assist her in making this determination.

Note that the formula given above tests whether the population means are different (i.e., whether the population mean difference score equals zero). It is also possible to use the paired samples *t* test to examine whether the difference between the population means is greater than a constant *c* (rather than 0). In this situation, the numerator of the formula for *t* changes to $(\bar{x}_d - c)$. In most cases, however, the paired samples *t* test is used to determine whether the population means are equal, and the rest of the discussion is confined to that situation.

Uses

The paired samples *t* test is appropriate when the researcher wants to know whether the population means of two dependent groups are the same or different. This test is similar to the independent samples *t* test, which also tests whether the population means of two groups are the same or different. The difference between the two tests involves whether the observations in the two groups are paired with each other.

There are multiple reasons why the observations in the two groups might be dependent (paired). The most straightforward situation is when participants take part in both conditions, which is sometimes referred to as a within-subjects design. The stress scenario discussed previously was an example of such a situation; each participant took part in both the stress and no-stress conditions. However, when the observations are paired in any manner, a paired *t* test is appropriate. For example, assume a political strategist is testing the effectiveness of two potential television advertisements. He takes pairs of states with similar voting records and runs one of the two advertisements in one state and the other advertisement in the other state, examining voter preference after seeing the advertisement. For example, New Jersey and Delaware might be considered one pair, Mississippi and Alabama a second pair, and so on.

The advantage of this procedure over randomly assigning each state (participant, etc.) to a condition is that the responses to similar states can be compared. This procedure serves to reduce the amount of variability in the data set, because differences within the states (participants, etc.) are controlled.

Interpreting the *t* Value

The result of a paired samples *t* test is a *t* value. This *t* value is compared with the *t*-distribution that would occur if the two population group means were equal (i.e., if the mean population difference score was zero). This possibility (that the two population group means are equal) is known as the null hypothesis. The logic that underlies the paired *t* test is to compare the *observed* value of *t* (that is, the value of *t* calculated from the paired *t* test) with the *t*-distribution that would occur if the null hypothesis were true. If the observed value of *t* is in keeping with this distribution, then it can be concluded that the null hypothesis might be true (i.e., the population means are equal). If the observed value of *t* is not in keeping with this distribution, then it can be concluded that the null hypothesis is *not* true (i.e., the population means are not equal).

The precise form of the *t*-distribution is determined by degrees of freedom (*df*), which in turn is determined by the number of paired observations (n_d ; specifically, $df = n_d - 1$). Basically, the larger the number of paired observations, the better one can estimate the standard deviation of the difference scores, so the *t*-distribution most closely resembles the *z* distribution with a larger number of difference scores.

The *t*-distribution for 100 *df* is presented in Figure 1. Intuitively, the observed value of *t* reflects how different from each other the sample means are. Because the absolute distance between the means can be determined by many factors (e.g., the range of possible scores and size of one's sample), this difference is "standardized" by $s_d/\sqrt{n_d}$, which is the standard error of the mean difference score. Thus, the value of *t* indicates how far apart the sample means are, in standardized form. The *t*-distribution (such as the one presented in Figure 1) provides the range of possible *t* values that would reasonably be expected to be found, *assuming the null hypothesis is true* (i.e., assuming the population means are equal). Put differently, even if the population means are equal, the *sample* means will likely be different just by chance. The *t*-distribution describes precisely how different the sample means would be just by chance.

To determine whether the population means could be equal, then, one compares the *observed t* value with the *t*-distribution constructed under the assumption

Figure 1 *t*-Distribution with 100 *df*

that the population means are equal. Assume, for example, that the observed *t* value is .50. As can be observed in Figure 1, there is a high probability of obtaining this *t* value if the population means are equal. If, however, the observed *t* value were 4.0, then there is a near-zero probability of obtaining this *t* value if the population means are equal. Thus, in that latter situation, the researcher would conclude that the population means are *not* equal.

In the previous examples, it was relatively straightforward to tell visually whether the observed value of *t* was in keeping with the *t*-distribution. A more precise indication is provided by a *p* value, which provides the likelihood of obtaining the observed *t* value by chance (i.e., assuming the null hypothesis is true). If the *p* value is low, then the chance of having obtained one's results just by chance (i.e., if the population means really are equal) is low, and the researcher concludes that the population means are likely not equal. In this situation, the result of the *t* test is often described as "statistically significant," because it indicates that any difference between the sample means is real and not just a result of chance. Conversely, if the *p* value is high, then the likelihood of having obtained one's results just by chance is high, and the researcher concludes that the population means might be equal. In many disciplines, .05 is used as a cutoff to determine whether the *p* value is low or high. Using the cutoff of .05 ensures that—of all times when the population means are equal—the researcher will only erroneously conclude that the population means are *not* equal 5% of the time. In statistical terms, the researcher will only make a Type I error 5% of the time when the null hypothesis is true.

The exact *p* value is provided by any standard statistical program as a result of conducting a paired *t* test. If, however, the paired *t* test is conducted by hand, calculation of the *p* value is not straightforward. Thus, the observed *t* value is sometimes compared with a "critical" value of *t*. This critical *t* value is the value of *t* that would produce a *p* value of .05. Thus, *t* values greater than the critical value of *t* produce *p* values less

than .05 and lead to rejection of the null hypothesis (concluding that the population means are not equal), and t values less than the critical value of t produce p values greater than .05 and lead to acceptance of the null hypothesis (concluding that the population means are equal). Critical values of t can be found in many statistical textbooks.

One-Tailed Versus Two-Tailed Tests

The exact method for calculating the p value (and critical value of t) depends on whether one is conducting a directional (one-tailed) test or a nondirectional (two-tailed) test. For a nondirectional test, the researcher is testing whether the population means are different (i.e., whether either mean is greater than the other one). In the previous stress example, for instance, the researcher might be interested in determining whether stress either increases or decreases performance. In this case, the researcher would perform a nondirectional test. If the sample mean of the no-stress group was much greater than the sample mean of the stress group, the researcher would conclude that stress decreased performance. Conversely, if the sample mean of the stress group was much greater than the sample mean of the no-stress group, the researcher would conclude that stress increased performance.

To see how this works mathematically, consider Figure 1. We will call the no-stress group Group 1 and the stress group Group 2 (the choice is arbitrary). In that case, when stress decreases performance in the sample ($\bar{x}_{\text{no-stress}} > \bar{x}_{\text{stress}}$), the researcher will obtain a positive value of t , and when stress increases performance in the sample ($\bar{x}_{\text{no-stress}} < \bar{x}_{\text{stress}}$), the researcher will obtain a negative value of t . In either case, as long as the difference between the sample means is sufficiently large, the researcher will obtain a large (positive or negative) value of t , leading to rejection of the null hypothesis and the conclusion that there really is a difference between the groups. Because the researcher is willing to conclude that there is an effect in either direction (i.e., on either side of the t -distribution), this test is referred to as a two-tailed test.

In contrast, with a directional test, the researcher is testing on only one side of the t -distribution. For instance, in the previous example, the researcher might be interested in testing (only) whether stress decreases performance. In this case, the researcher would perform a directional test, predicting that the population group mean for the no-stress group would be greater than the population group mean for the stress group. In this situation, the researcher is only interested in positive values of t . If the sample mean for the no-stress group was much greater than the

sample mean for the stress group, producing a large positive value of t , the researcher would conclude that stress decreases performance. Otherwise (with a small positive t value or a negative t value of any size), the researcher would conclude that stress does *not* decrease performance. Because the researcher is only willing to conclude that there is an effect on one side of the distribution, this test is referred to as a one-tailed test.

The choice of whether to perform a one-tailed or two-tailed test influences the resulting p value. As long as the results come out in the predicted direction, the one-tailed test will produce a smaller p value (and, equivalently, a smaller critical value of t) than will a two-tailed test, thus making it easier to find statistically significant results. However, it is important to emphasize that the decision to conduct a one-tailed test must be made for theoretical reasons and prior to an examination of the data. If, for example, the researcher predicted that stress would decrease performance and found that the sample mean of the stress group was greater than the sample mean of the no-stress group, the researcher must conclude that the hypothesis was not supported, rather than switch to a two-tailed test. For this reason, it is sometimes recommended that researchers typically decide in advance to conduct two-tailed tests to allow for conclusions on either side of the t -distribution.

Assumptions

The two primary requirements for the paired samples t test to produce accurate results are independent observations and normality.

The first assumption of the paired t test is independent observations. Observations in a study are *independent* to the extent that each observation is not predictive of another observation in the study. Note that it is the scores within each group that must be independent of each other (or more precisely, the difference scores that need to be independent). For example, assume that in the previous hypothetical stress study, the researcher tested multiple members of one family. It is plausible that the difference scores would not be independent, because it is likely that stress would influence the family members in a near identical way.

The second assumption of the paired t test is that the population distribution of difference scores is normal. Partly because of the Central Limit Theorem, however, this assumption can typically be violated as long as the sample size is reasonably large. “Reasonably large” is often defined as $n > 30$; however, as long as the departure from normality is not too severe, considerably smaller sample sizes are acceptable.

Power

As with any hypothesis test, even when the population group means are different from one another, the paired samples *t* test might not detect this difference (i.e., the results might not be statistically significant). The ability to find statistically significant results when there *is* a real difference between the population means is referred to as the *power* of the test. It is beneficial to conduct one's study with as high a power as possible, to provide the greatest chance of being able to detect a difference if one exists.

Given a certain alpha level and choice of one-tailed versus a two-tailed test, there are three factors that influence the power of the paired *t* test: the difference between the population means (larger differences = greater power), the amount of variability in the population difference scores (smaller variability = greater power), and the size of the samples (larger sample size = greater power). Jacob Cohen provides statistical tables that can be used to determine one's power and to determine how large a sample size is needed to provide a given power.

As discussed previously, the process of "pairing" (whether via a within-subjects design or some other procedure) serves to reduce the variability in the study (because what is relevant is the variability in the difference scores, not the variability within each of the groups). Thus, the power of the paired *t* test is typically greater than that of other tests that do not use this pairing procedure (such as the independent samples *t* test).

Example Problem

A nutritionist is interested in determining whether eating breakfast improves cognitive performance. He enlists the participation of 16 4th-graders and has them take an IQ test on one day after eating breakfast and on another day when they have not eaten breakfast, counterbalancing appropriately. The scores are in Table 1, under the columns labeled "Breakfast" and "No Breakfast."

The first step in testing his hypothesis is to calculate the difference scores for each participant. These are provided in the column labeled "Difference." Note that positive scores indicate better performance in the breakfast condition, and negative scores indicate better performance in the no-breakfast condition.

The next step is to calculate the mean difference score, which is

$$\bar{x}_d = \frac{\sum_{i=1}^n x_i}{n_d} = \frac{48}{16} = 3.0.$$

Table 1 *t* Test, Paired Samples

Participant	Breakfast	No Breakfast	Difference
1	95	88	+7
2	112	116	-4
3	98	99	-1
4	102	93	+9
5	81	75	+6
6	127	120	+7
7	110	113	-3
8	94	89	+5
9	103	96	+7
10	89	84	+5
11	133	129	+4
12	109	113	-4
13	99	91	+8
14	104	107	-3
15	91	85	+6
16	114	115	-1

Note that this mean difference score could also be calculated by subtracting the mean no-breakfast score from the mean breakfast score.

Just based on the sample means, it seems that eating breakfast led to higher IQ scores. However, it is possible that this effect occurred just by chance. To examine this issue, the nutritionist would conduct a paired samples *t* test. The formula for the paired samples *t* test is

$$t = \frac{\bar{x}_d}{s_d / \sqrt{n_d}}.$$

The next step is to calculate the standard deviation of the difference scores (s_d). The formula for s_d is

$$\begin{aligned} s_d &= \sqrt{\frac{\sum_{i=1}^n (x_i - \bar{x}_d)^2}{n_d - 1}} \\ &= \sqrt{\frac{(7-3)^2 + (-4-3)^2 + \dots}{15}} \\ &= \sqrt{\frac{338}{15}} = 4.747. \end{aligned}$$

Plugging into the formula for t gives

$$t = \frac{\bar{x}_d}{s_d/\sqrt{n_d}} = \frac{3}{4.747/\sqrt{16}} = \frac{3}{1.187} = 2.53.$$

Because the nutritionist is interested in testing whether eating breakfast improves cognitive performance, he would conduct a one-tailed paired t test. The p value for this test (provided by most statistical packages) is .01. Because this p value is low, he would conclude that his results did not occur by chance and that eating breakfast likely does improve cognitive performance.

Alternatively, if a statistical package was not available to determine the precise p value, the observed value of t can be compared with the critical t value. In this case, as found in most statistics textbooks, the critical t value is 1.75. Because $2.53 > 1.75$, the nutritionist would reach the same conclusion (as will always be the case), that the sample mean difference of 3 points did not just occur by chance.

Thus, given the results of his study, the nutritionist would conclude that eating breakfast increases performance on the IQ test. Of course, this study would not conclusively prove that this is the case; however, the likelihood that this difference occurred just by chance is low.

TAU EQUIVALENCE

It is often advantageous to measure a single construct through multiple assessments that capture its interrelated conceptual features. When multiple scores are used to assess a construct, however, researchers should consider how similarly the scores behave relative to that construct. For instance, a researcher might

administer a computer literacy test consisting of five modules assessing different computing skills, yet the scores of each module might relate differently to the construct of computer literacy. Deciding on what assumptions are met about the equivalence of each module's scores as reflections of computer literacy is a crucial step, as these assumptions directly impact how the internal consistency of the computer literacy test is computed. In this context, tau equivalence refers to the stringency of assumptions used in calculating the internal consistency of a scale, bearing on how similarly scores behave relative to a scale. This entry reviews the fundamentals of tau equivalence, presents examples of varying degrees of equivalence, describes how to evaluate these assumptions in practice, and discusses the advantages and disadvantages of tau equivalence.

Criteria for Tau Equivalence

Tau equivalence refers to the criteria by which *internal consistency* is defined. The criterion may simply be that scores are sufficiently related to the underlying construct, yet may be more stringent depending on how similarly one expects scores to behave. Scores can be assumed to (a) share identical relationships with an underlying construct, (b) share the same means as the underlying construct, or (c) have equivalent amounts of measurement error. The stronger these assumptions, the more similarly one expects the scores will behave relative to the scale they comprise. In evaluating the reliability of measurement instruments, it behooves researchers to consider to what extent scores are assumed to behave similarly (i.e., are tau equivalent) when determining the criteria for internal consistency.

The most restrictive form of tau equivalence involves the assumptions of a strictly parallel measurement model, presented in panel A of Figure 1. According to classical test theory, scores (X 's) are broken down into independent components of variability due to the construct ($\text{Var}(\tau)$) and variability due to measurement errors ($\text{Var}(\epsilon)$), with all error terms varying independently from one another ($\text{Cov}(\epsilon_i, \epsilon_j) = 0$) and from the construct ($\text{Cov}(\epsilon_i, \tau) = 0$). In the strictly parallel model, the construct contributes equally to each score, such that a one-unit change in the construct corresponds to the same expected change (λ) in each score (i.e., the factor loading). In addition, the degree of measurement error (ϵ) is assumed equal across scores, such that variability due to the "true" construct and measurement error is identical across scores. Finally, the means of scores ($E(X)$'s) are expected to be identical (β_0).

Figure 1 Measurement Models With Varying Degrees of Equivalence

The assumptions of a strictly parallel model are rarely satisfied; consequently, researchers may relax assumptions about how the scores will behave. The remaining panels of Figure 1 present a series of increasingly relaxed measurement models where the loadings, error variances, and means are allowed to vary across scores. The model in panel B relaxes the means, such that different scores may be systematically higher or lower, on average, relative to the underlying construct (shown as β_{01} – β_{03}). This may occur if certain test modules are systematically easier, such that participants' scores tend to be higher on some modules relative to others, despite all modules being equal indicators of the underlying test domain. The model in panel C additionally relaxes the error variances, such that different scores may be associated with more or less error (shown as $\text{Var}(\epsilon_1)$ – $\text{Var}(\epsilon_3)$). Returning to the computer literacy test example, modules assessing knowledge of specific applications may be influenced by a wider variety of random factors, such as situational exposure to different computer applications, or operating system differences, than modules assessing knowledge of how to use a keyboard. In this case, scores on modules asking about specific applications will include more random or “error” variance versus

scores on modules asking about keyboard use. Finally, the model in panel D relaxes the loadings (λ_1 – λ_3), allowing each score to have a unique relation with the underlying construct. In this model, a one-unit change in the construct contributes differing amounts of expected change to each score. This model is the “congeneric model” commonly assumed in confirmatory factor analysis.

Assessing Tau Equivalence

To determine how strongly tau equivalence can be assumed, a series of measurement models can be fitted to one's data with increasingly relaxed assumptions. The chi-square test of model fit provides a statistical test of whether each model matches what is observed in the data, while chi-square difference test for nested models can be used to compare more restrictive models to less restrictive ones. Additional fit indices in structural equation modeling may be consulted relative to established benchmarks. The best fitting model of tau equivalence is ideally one that shows adequate fit to the observed data and does not significantly worsen fit relative to less restrictive models.

Advantages

Tau equivalence provides valuable information for evaluating internal consistency. The Cronbach’s alpha coefficient (α) relies on “essential tau equivalence,” such that the contributions of the underlying construct are assumed equal across scores (panel C in Figure 1). If this assumption is not fulfilled, α underestimates internal consistency. Beyond the models described here, similar concepts may be evaluated using item response theory models allowing for binary and ordinal item scores. Altogether, considering tau equivalence provides insight into how assessment scores align with an underlying domain and helps guide the interpretation of composite measurements.

Limitations

The models described here assume continuously scaled scores with independent, identically distributed (i.e., symmetric) errors. Furthermore, an adequate sample size is needed to assess model fit. Such considerations may limit the researcher’s ability to explicitly assess tau equivalence. Nevertheless, descriptive statistics such as covariances between each score and the scale’s total, and the means of scores, can provide valuable information about tau equivalence before estimating the reliability of a scale.

“TECHNIQUE FOR THE MEASUREMENT OF ATTITUDES, A”

Often, researchers in the social sciences would like to quantitatively describe or explain people’s attitudes or beliefs about an issue. The problem is that attitudes or beliefs—such as “hope,” “customer satisfaction,” or “conservatism”—are qualitative and cannot be directly measured the way weight, height, or speed can be measured. This is the problem that Rensis Likert and others were up against in the early 20th century, and which Likert addressed in his article “A Technique for the Measurement of Attitudes.”

Until 1932, the best procedures available for measuring attitudes were those developed by Louis Thurstone. In Thurstone’s approach, as many as 200 experts, called judges, each rated a large number of statements for their favorableness toward a certain position or object. Through a process of elimination, 20 to 30 statements would be retained and ordered along a scale representing the attitude toward the position or object, from negative through neutral to positive. Based on its position on the continuum, each statement was then assigned a scale score. Thereafter, to measure a person’s attitude toward that object or issue, he or she would be asked whether they agree with each statement. The person’s attitude score was obtained by taking the average scale scores of all the statements that person agreed with.

Likert identified two shortcomings in Thurstone’s procedure. First, it required many judges and a long, laborious process. Second, the use of the attitude scales made several statistical assumptions that had not been verified. In his 1932 article, “A Technique for the Measurement of Attitudes,” Likert introduced a streamlined approach to improve on Thurstone’s methods. His main goal was to simplify the process by creating the scale from participants’ responses and thus

eliminating the influence of the judging group. Whereas previous methods engaged separate processes for assigning scale scores to statements and attitude scores to individuals, in Likert's study, each statement became a scale in itself, and a person's responses to each statement were assigned a score. These response scores were then combined by using a median or mean to obtain an attitude score.

Although Likert's 1932 article is most noted for the scales that carry his name, the issue he tackled was not purely a matter of simplifying measurement but of determining whether in fact social attitudes could be measured reliably and validly. If so, it should be possible not only to measure a general attitude but also to justify its difference from other attitudes. Likert's 1932 study showed, to his own surprise, that general social attitudes could be measured validly and reliably.

The remainder of this entry describes the development of the Likert scales and examines their shortcomings.

Development of the Measure

In this article, Likert presents the results from a study conducted under Gardner Murphy to examine five major "attitude areas": international relations, race relations, economic conflict, political conflict, and religion. The participants in the study included about 650 students at universities in the United States. Every participant took a survey twice, about a month apart. The second survey included some items from the first survey in addition to many new items.

To construct the survey, Likert and his colleagues consulted existing surveys, as well as newspaper and magazine editorials and articles, for statements that would effectively distinguish people as sitting at different points along the continua under investigation. Thus, for example, international relations items ranged from anti-internationalism to pro-internationalism. Three kinds of items were presented to participants. Some items, such as "Should there be a national referendum on every war?" were posed as "Yes/?/No" questions. For the second kind of statement, five responses were designed to span the range of attitudes. An example of this kind of question is as follows:

How much military training should we have?

- We need universal compulsory military training.
- We need citizen military training camps and reserve officers training camps but not universal military training.
- We need some facilities for training reserve officers but not as much as at present.
- We need only such military training as is required to maintain our regular army.
- All military training should be abolished.

The third kind of statement included those whose response options ranged from "strongly disapprove" through "disapprove," "neutral," "approve" to "strongly approve." An example of this kind of statement is as follows: "The United States should have the largest military and naval air fleets in the world."

Likert expected that attitudes would be specific, although not completely independent of each other. For instance, for the race-relations attitude, which given the historical period was defined as "Negro-white relations," Likert expected that the white male participants' attitudes toward segregation, toward eating with the Negro, and toward lynching would be independent. The assumption was that attitudes were so specific that it would take a large number of items to capture anything approximating a general attitude. To his surprise, however, clear group factors appeared in the data: "The clear-cut generality of certain attitudes, such as pro-Negro, internationalism, etc., shows that it is precisely in the field of *affiliation with or against* certain social groups that the most definite results are obtained" (pp. 13–14). He based this finding on the high split-half reliabilities (.86–.88) of statements related to each attitude but addressing specific aspects of it, and on the finding that correlations between different attitude scales were much lower (.34–.63).

Another major contribution of the article was the finding that a simple scoring method worked just as well as the more labor-intensive sigma method devised by Edward L. Thorndike. First, Likert applied the sigma method to transform responses to each item into sigma values. Sigma values are similar to standardized (z) scores, except that the sigma method assumes that 100% of responses fall between -3 and $+3$ sigma. An individual's attitude score was the average of the sigma values of his or her responses. He then applied an alternative approach, which he dubbed the "simpler method," in which scores from 1 to 5 were assigned to the options from strongly disapprove to strongly approve, and scores of 2, 3, and 4 were assigned to the "Yes," "?," and "No" responses, respectively. The score for each individual was then calculated as the average of the numerical values of the options he or she had selected. When he examined the individual attitude scores generated by the sigma and simpler methods, he found that they were nearly perfectly correlated ($r_{xy} = .99$).

Likert then compared the results from his study with those obtained using the Thurstone method, and he found that scores derived from the simple method were

highly correlated with scores from the Thurstone method, even though different items were used in the two surveys.

This article also introduced substantive psychological findings. In Likert's words, “at least three general or group factors in social attitudes have been discovered within the student populations which participated in our study” (p. 36). “If the present method has any value at all, it has value as a device for laying bare the general favorableness or unfavorableness which certain individuals and groups display toward other individuals and groups” (p. 39).

Today, researchers commonly use Likert scales in the development of new instruments. For example, if the options on a rating scale are successively ordered, as in Likert scale, then a graded response item or a Rasch family of polytomous item response model can be applied. An item response model expresses a probabilistic relationship between examinee's performance on a test item and the examinee's latent trait.

Shortcomings

Despite its advantages, Likert scaling does possess several shortcomings. Likert's method for measuring attitudes assumes that participants' responses to items refer wholly to the properties of the attitude (or latent trait) being measured. Other researchers, such as Louis Guttman, have asserted that the rating a person assigns to an item reflects a property of the item as well as a property of the person doing the rating. For instance, if several people were asked to rate the weight of several objects, each rating would be determined by a combination of the object's weight and the particular person's strength. Guttman developed methods for evaluating whether the rating can be used to estimate the magnitude of the person trait.

Another major issue with Likert scales is that they tend to confound two dimensions of an attitude: direction (i.e., positive, neutral, or negative) and intensity (e.g., strongly or mildly), and thus, these scales do not yield unidimensional ordinal scores. In other words, Likert scales directly measure the interaction of direction and intensity and indirectly measure the main effects of direction and intensity. As such, the main effects are inferred from the interaction. This issue is particularly problematic when more than one dimension is present in the response key because there is no way to individuate the different dimensions. Researchers have attempted to address the problem of multiple dimensions by separating the cognitive (content) and affective (intensity) dimensions into two discrete response keys, one that asks participants whether they agree with the statements

and the other that asks participants how strongly they feel about the statements.

Likert scales commonly incorporate negatively worded items to circumvent the problem of response-set bias—the tendency of respondents to agree with a series of positively worded items. However, the added cognitive complexity associated with negatively stated items results in lower levels of validity and reliability.

A similar set of issues also might come into play when respondents disagree with positively (agree) worded statements. Although it is probably safe to assume that the level of agreement indicates the degree of the underlying attribute, disagreement is problematic, because respondents might disagree with a statement for any number of reasons aside from the attitude of interest. This issue is thus of particular concern when a respondent's disagreement is taken to indicate the presence of a particular trait.

Additional problems occur with the use of an odd number of response categories because individuals might equate the midpoint option with a “not applicable” response, whereas the researcher interprets the midpoint option as a midlevel-intensity response.

TEORIA STATISTICA DELLE CLASSI E CALCOLO DELLE PROBABILITÀ

Carlo Emilio Bonferroni was an Italian mathematician, who is known in the field of statistical simultaneous inference for the so-called Bonferroni inequalities that Bonferroni described in his book *Teoria Statistica Delle Classi e Calcolo Delle Probabilità* [Statistical Class Theory and Calculation of Probability]. This work has made significant contributions to probability theory and statistical inference.

The book, divided into three sections, is a systematic study of probability theory and its applications on set (class) theory. In the introduction, Bonferroni states that the probability of an event is a primitive physico magnitude that does not have a definition; however, it is possible to explain it in some postulate or axiom. The classical postulate assumes that if an event is separated by other incompatible, complementary, and equally possible events, then the probability of that event is the ratio between the number of cases favorable to it and the number of all events possible.

Relationship Among Probabilities

In the first section, Bonferroni, before enouncing his inequalities, describes the following probabilities and their relationship:

Simultaneous probabilities: In a set composed of m objects, if n characteristics $C_1, C_2, \dots, C_n$ are considered and indicated by m_i , the number of objects having the characteristic C_i , by m_{ij} the number of objects having simultaneously C_i, C_j and by m_{ijh} those having C_i, C_j, C_h etc. . . . then the probabilities are

$$p_i = \frac{m_i}{m}, p_{ij} = \frac{m_{ij}}{m}, p_{ijh} = \frac{m_{ijh}}{m}, \dots$$

Contrary probabilities: $p_{\overline{ij\dots k}}$ is the contrary probability to $p_{ij\dots k}$, that is the probability of an object without having the characteristics $C_i, C_j, \dots, C_k$. The probability is

$$p_{\overline{ij\dots k}} = 1 - p_{ij\dots k}$$

and in more general

$$p_{\overline{12\dots n}} = 1 - \sum_i p_i + \sum_{i,j} p_{ij} - \sum_{i,j,h} p_{ijh} + \dots + p_{12\dots n}.$$

If we define

$$S = 1, S_1 = \sum p_i, S_2 = \sum p_{ij}, S_3 = \sum p_{ijh}, \dots,$$

then it is possible to write

$$p_{\overline{12\dots n}} = S_0 - S_1 + S_2 - S_3 + \dots + mnS_n = S_0(1 + S)^{-1}.$$

Exclusive probability: A probability that an object has some characteristics excluding the others. It is defined by the product between the probabilities of those characteristics taken into consideration and the contrary probabilities.

r -exact multiplicity: The multiplicity of an object is defined as the number of characteristics that it possesses, from 0 to n .

r -minimum multiplicity: An object that possesses at least r characteristics.

r -maximum multiplicity: An object that possesses at most r characteristics, that is 0, 1, 2, . . . or r .

Incompatible characteristics, complementary characteristics: The characteristics C_i are incompatible when an object has at most one; for C_i, C_j , $p_{ij} = 0$. They are complementary if an object possesses at least one. The formula is

$$1 - S_1 + S_2 - S_3 \dots + S_n = 0.$$

The characteristics are incompatible and complementary when $1 - S_1 = 0$; that is, $\Sigma p = 1$.

$$\text{Identity: } (1 + S)(1 - P) = 1.$$

Contrary characteristics and duality law: If m objects are described by their contrary "not C_i " characteristics rather than by the characteristics C_i , the simultaneous probabilities are $q_i, q_{ij}, q_{ijh}, \dots$ and are opposites of the affirmative probabilities $p_i, p_{ij}, p_{ijh}, \dots$. For the *duality law*, each calculation developed on the affirmative probabilities is reproducible on the contrary probabilities.

$$T_0 = 1, T_1 = \Sigma q_i, T_2 = \Sigma q_{ij}, \dots, q_{\overline{1\dots n}} = T_0 - T_1 + T_2 - \dots + T_n = T_0(1 + T)^{-1}.$$

The duality law allows expression of both affirmative and contrary probability in a double way, through S and T :

$$T_n = 1 - S_1 + S_2 - S_3 \dots, \pm S_n$$

$$T_{n-1} = n - (n-1)S_1 + (n-2)S_2 - \dots \pm S_{n-1}$$

$$T_{n-2} = \left(\frac{n}{2}\right) - \left(\frac{n-1}{2}\right)S_1 + \left(\frac{n-2}{2}\right)S_2 - \dots \pm S_{n-2}$$

Limits on simultaneous probabilities: From $q_{12\dots n} = P_0 = 1 - S_1 + S_2 + S_3 + \dots + S_n$, Bonferroni developed his inequalities:

$$P_0 \leq 1, P_0 \geq 1 - S_1, P_0 \leq 1 - S_1 + S_2, P_0 \geq 1 - S_1 + S_2 - S_3, \text{etc.}$$

The first inequality is evident, whereas the second inequality as well as the third one can be obtained with the following procedure:

$$\begin{aligned} \text{For the second inequality: } q_{12} &= (1 - p_1)(1 - p_2) \\ &= 1 - S_1 + S_2 \geq 1 - S_1. \end{aligned}$$

$$\begin{aligned} \text{For the third inequality: } q_{123} &= (1 - p_1)(1 - p_2) \\ (1 - p_3) &= 1 - S_1 + S_2 - S_3 \leq 1 - S_1 + S_2. \end{aligned}$$

Applying the duality law and considering the relationship between T and S, the inequalities are

$$p_{12\dots n} \leq S_r - \left(\frac{n-r}{1}\right)S_{r-1} + \dots + \left(\frac{n-1}{r}\right), [r \text{ even}]$$

and

$$p_{12\dots n} \geq S_r - \left(\frac{n-r}{1}\right)S_{r-1} + \dots - \left(\frac{n-1}{r}\right), [r \text{ odd}].$$

These formulas are the basis of Bonferroni correction or adjustment used in the simultaneous statistical inference for multiple comparison tests.

Dependency and Independence

The second section studies the dependency or independence (total or partial) of characteristics in the classes, proposing an index of dependency:

$$I = \frac{p_{12} - p_1 p_2}{\sqrt{p_1 p_2 q_1 q_2}}.$$

Bonferroni defines a generated class of a probability distribution as that which possesses objects with n characteristics and r multiplicity and its probability is $P_r = p_{12\dots n(r)}$ (with r multiplicity and n characteristics). There are different generated classes; however, he establishes that these classes do not exist when the characters are totally independent.

Then, the author defines the “capacity” of an object of the class as the ratio between the multiplicity of an object X_i and all the characteristics of that object taken in consideration $x_i = \frac{X_i}{n}$. The author affirms that its

variability δ , expressed as $\delta^2 = \frac{1}{n^2} [(\sum p_i \sum p_i) + \sum p_{ij}]$, is always between 0 and $\frac{1}{2}$ and might reach extreme values; in the case of total binary independence, it will not exceed $\frac{1}{2} \sqrt{n}$.

General Laws of Probability

The last section treats the laws of probability. In a scheme of probabilities, the author studies the prevalent points (central point as well as maximum and minimum prevalent points) and their properties, analyzing the relationship between these points and the capacity variability. He establishes that when this variability tends to zero, the capacity tends toward the mean capacity.

Finally, he shows that through a set of simple classes, it is possible to obtain an independent total scheme of probability and apply it to the Poisson and Bernoulli scheme.

TEST

A test, broadly defined, refers to any tools, tasks, or stimuli that are used to measure or assess an individual's knowledge, understanding, skills, aptitudes, capacities, behavior, or other traits or characteristics in a specific domain, such as reading comprehension ability, mathematical problem-solving ability, physical fitness, personality, beliefs, perceptions, and attitudes. It is a core component of assessment in education, although it is not the only component. This entry provides a brief synopsis of the history and importance of tests,

different types of tests, and considerations related to reliability, validity, and fairness of tests.

History of Tests

Tests were first adopted in ancient China as a way to select individuals to fill governmental positions in the Sui dynasty in 605 CE. The approach was adopted in England in the early 19th century to serve similar purposes and was later used in education. The use of tests, or more specifically, standardized tests, in the United States was advocated in the mid-19th century by the famous educational reformer Horace Mann, who served as secretary of the Massachusetts State Board of Education at the time. Since then, tests have enjoyed widespread popularity around the world.

Importance of Tests

The use of tests has been a crucial part of educational reforms in the United States over the last several decades. For instance, tests were proposed to track and select students in the 1950s. They served for program accountability purposes in the 1960s and were used in minimum competency testing programs in the 1970s. They were further used for school, district, and standards-based accountability from the 1980s to the present, becoming high-stake tests, or tests that may have significant negative consequences. A typical example of the use of high-stake tests in the era of accountability is the implementation of the No Child Left Behind Act, the main law for K-12 general education in the United States from 2001 to 2015. It mandated states to test students annually at grades 3–8 and at least once in high school and report test results for the student population as a whole and subgroups. It also required states to track students' performance in a school to achieve adequate yearly progress (AYP). Any school that could not meet AYP 2 years in a row could face serious consequences, including shutdown.

The importance of tests in education can also be observed in many other countries, such as China. The most important test in China is probably the Nationwide Unified Examination for Admissions to General Universities and Colleges, which is offered to senior high school students every June to determine whether a student is admitted to higher education and to which college he or she is admitted.

Different Types of Tests

Depending on the contents, purposes, criteria, administration, and other aspects of tests, they can be categorized into different types. There are achievement tests

that assess individuals' knowledge or mastery of specific school subjects, such as language arts, mathematics, and science tests. There are aptitude tests that focus on individuals' potential for learning in a domain, such as the SAT. Tests can be made by states or educational testing organizations, such as the College Board and Educational Testing Service. They can also be made by teachers who teach a subject or class. Most tests made by states or educational testing organizations are standardized tests, which are administered and scored in a uniform and standard way. In contrast, teacher-made tests may be less rigorous than standardized tests. But they provide teachers with more convenience and flexibility.

There are tests that serve other purposes, such as diagnostic tests, which are used to identify individuals' strengths and weaknesses in a specific domain mainly during the learning process. Depending on the reference, tests are categorized into norm-referenced tests, in which test scores are reported based on the comparison with scores of other students taking the same test, and criterion-referenced tests, in which test scores are reported based on a students' level of mastery or whether they meet a criterion that reflects a proficiency level.

Tests can also be viewed as either summative or formative. The former provides a summary of a student's performance in a test, whereas the latter provides ongoing feedback of a student's learning progress. In this sense, standardized tests are norm-referenced and summative tests and diagnostic tests are criterion-referenced and formative tests.

Tests also vary by how they are administered. Paper-and-pencil was employed as the main format to administer state standardized tests before the 21st century. However, with the rapid development of technology, online and computer-based tests have become the dominant administration mode of state standardized tests since 2015. Computerized adaptive testing, which can choose test items from an item bank to match a test taker's estimated ability level, has become a common practice in modern assessment since 2000.

Reliability, Validity, and Fairness of Tests

Tests, like any other tools or instruments in education and psychology, should be examined for their psychometric properties. Besides being reliable and valid, tests should also be fair or unbiased. More specifically, the interpretation of the test scores should be as plausible and appropriate for one group as for other groups. For instance, if a test, such as the Test of English as a Foreign Language, is intended to assess the English proficiency level of students around the world, there may be

fairness issues for students who apply for universities in other countries when using only American accents in the listening session.

TEST-RETEST RELIABILITY

Test-retest reliability is one way to assess the consistency of a measure. The reliability of a set of scores is the degree to which the scores result from systemic rather than chance or random factors. Reliability measures the proportion of the variance among scores that are a result of true differences. True differences refer to actual differences, not measured differences. That is, if you are measuring a construct such as depression, some differences in scores will be caused by true differences and some will be caused by error. For example, if 90% of the differences are a result of systematic factors, then the reliability is .90, which indicates that 10% of the variance is based on chance or random factors. Some examples of chance or random errors include scoring errors, carelessness on the part of the respondent (e.g., not clearly marking an answer), and outside distractions on the day the test is administered (e.g., someone talking loudly near the testing room). Determining the exact true score for each subject is not possible; however, reliability can be estimated in several ways. Each method of determining reliability has advantages and disadvantages. This entry describes the ways to measure reliability and discusses the assumptions and considerations relevant to the application of test-retest reliability.

Methods

One way to measure reliability is to determine the internal consistency of a measure. If the various components or items of an instrument are measuring the same construct, then the scores on the components or items will tend to covary. That is, if the instrument is all keyed in the same direction, then people that are high on the construct (e.g., extroversion) will tend to answer all the items in one direction, and people low on the construct (e.g., those who are not extroverted) will tend to answer all the items in the opposite direction. Cronbach's alpha coefficient and split-half reliability are estimates of internal consistency reliability.

A second common estimate of reliability examines the stability of the scores. One way to measure the stability of a measure is to compare alternate or parallel forms of the instrument. High-alternate-form coefficients indicate the forms are comparable and reliable. Test-retest reliability is the most common way to measure the stability of a measure over time. It is conceptually and intuitively the simplest approach and one that most closely corresponds to the view of reliability as the consistency or repeatability of a measure. That is, if a researcher has the same people take the same test on more than one occasion (i.e., a first test occasion and a retest occasion), the correlation between each test administration will be the test-retest reliability. The test is thought of as parallel with itself. Some authors refer to the test-retest correlation obtained as the coefficient of stability.

With tests of achievement (e.g., a math test), aptitude (e.g., intelligence tests), and personality (e.g., a test of extroversion/introversion), the measure is typically administered only twice, so that only one estimate of the reliability coefficient is obtained. If the measure is administered several times, then the usual practice is to calculate the average or mean of the intercorrelations among the scores obtained on the various occasions as the estimate of the test-retest reliability coefficient.

Assumptions and Considerations

The applicability of test-retest reliability depends on two primary assumptions. The first assumption is that the participants' true scores are stable across the two testing occasions. That is, the researcher must be confident that respondents' true scores do not change from the first measurement to the second measurement. The second assumption is that the error variance of the first test is equal to the error variance of the second test.

The assumption of stability of the construct that is measured is an important consideration in whether test-retest reliability is chosen as the method to assess

the consistency of a measure. All changes from one testing period to another are treated as random errors. This type of reliability estimate assumes that the characteristic being measured is stable over time. Intelligence is one characteristic of a person assumed to be stable over time as is certain personality traits. Extroversion is one such personality trait as is the level of openness to new experiences. Other characters, however, are considered to be state, not trait, characteristics. That is, they are expected to fluctuate over time. Mood state is one such characteristic. Test-retest reliability is not an appropriate way to assess the reliability of a measure on mood state because any error variance would be caused by not only the unreliability of the measure but also the fact that mood is not a stable characteristic. For example, during the test-retest interval, one individual might have been physically ill and that influenced his mood. In contrast, another individual was given a major award during the same test-retest interval, which would inflate that person's mood level. As a result, individuals' mood states during the first assessment might be vastly different from the mood states at the second administration of the test. That is, the differences among their true construct levels are not stable across the two test administrations. For such state-like constructs, the test-retest method is a poor estimate of reliability. An internal consistency reliability method would be a better choice because the test might accurately reflect the difference in true score at that one occasion and therefore be reliable. However, the test-retest method might provide a low estimate of reliability because the moods have changed over the time interval between test administrations.

There are two major advantages of using the test-retest method of estimating reliability. The first is that only the test itself is required, unlike other methods of estimating reliability that require more than one form (i.e., parallel or alternate forms). The second advantage is that the particular sample of items or stimulus situations is held constant, which would seem to minimize the possibility of measuring traits other than what is designed by this instrument.

One problem with estimating reliability using the test-retest method is deciding on the appropriate time interval between test administrations. If the interval is too short (e.g., a few days), then participants might remember their responses the first time the test is administered, which might influence their responses on the second administration. These effects are also known as carryover effects, which would likely inflate the reliability estimate. For example, a student taking a vocabulary test might have answered "true" to the item "deft means possessing skill or ease in performance" in the first test administration, and the second time he or

she remembers this and answers "true" again. Another example is a supervisor in a retail store who assigned her supervisee John a rating of "above average" in June and assigns the same rating in January to demonstrate consistency in her evaluations. Of course, it is possible to have carryover effects that might increase the true scores over the time interval between administrations and, therefore, lower the test-retest reliability estimate. Sometimes, there are practice effects (also a type of carryover effect), so that on subsequent administrations of the same test, scores increase in a systematic fashion. The person might learn the specific content of the test or develop improved approaches to the material so that his or her score increases. These practice effects might be different for different individuals. Of two people with exactly the same score on one occasion, one person might think about the material between the administrations and find out the answers to certain questions. Therefore, on the second administration, one score might improve and the other will remain the same. So if the test-retest reliability coefficient is low, it is unknown whether the test is unreliable or differential systematic factors are at work.

One way to minimize carryover effects would be to increase the time interval between the two administrations of the test. Although this solves some problems, it creates others. Whereas it is true that the longer the time interval between administrations, the lower the probability of carryover effects such as the use of memory. However, it is also true that a longer time period might increase the likelihood that the participants will experience real change in the trait or characteristic being studied. Therefore, a low test-retest reliability correlation might be indicative of a measure with low reliability, of true changes in the persons being measured, or both. That is, in the test-retest method of estimating reliability, it is not possible to separate the reliability of measure from its stability. That is why it is usually suggested that the time between the two test administrations be relatively short (e.g., 1 or 2 weeks) so that it is more likely that only random error is being tapped and not true changes in the characteristic of interest. This is a serious disadvantage with the test-retest approach to estimating reliability. Therefore, this approach should be used with caution.

Test-retest reliability is an important consideration when a researcher is interested in measuring change over time. A simple measure of change is to have research subjects complete an instrument measuring the construct of interest at time 1. Then, an intervention to promote (hopefully) change is administered to the subjects. After the intervention, the instrument is given again. The difference between the two

administrations of the test, which is often known as the gain score, is then taken as a measure of change. To be confident that the gain score reflects actual change in the participants for the construct of interest, the role of measurement error must be considered. That is, the researcher must be sure that the change is not simply a result of random fluctuation in an unreliable test. To assess the meaningfulness of the change score, the researcher needs to know the standard error of measure (SEM) of the test. The SEM must be calculated using the test–retest reliability coefficient rather than an internal consistency coefficient because it is the stability of the test that is most important here. The formula for arriving at the measure of change is widely referred to as the reliable change index (RCI), as described by Neil Jacobson, William Follette, and Dirk Revenstorf. RCI is calculated as follows:

$$Z = (x_2 - x_1) / (SEM\sqrt{2}),$$

where Z is the RCI, x_1 is the time 1 administration of the test, and x_2 is the time 2 administration of the test. RCI is a normally distributed index with a mean of 0 and a standard deviation of 1. If the absolute value of RCI exceeds 1.96, the observed change has a probability of .05 or less, and thus, the researcher can assume that the change in scores from time 1 to time 2 was not caused by random error. The higher the test–retest reliability coefficient, the more meaningful the gain score.

THEN-TEST

Repeated measures studies are common in psychological research. For example, evaluation research in psychology frequently uses changes in self-report measures of constructs (e.g., well-being, health-related quality of

life) to determine the impact of interventions or programs on various outcomes. Similarly, longitudinal research examining changes over time in the natural course of adapting to health states (e.g., diagnosis of a health condition) also uses repeated self-report measures. Such research designs involve comparing the participants' scores on an initial questionnaire with their scores on the same measure at a later time. Sometimes, however, the initial pre-test data are not trustworthy and a second set of pre-test scores is collected after the fact. Respondents are asked to reflect on the past and respond how they think they would have responded "then." This measurement approach uses what is called a *then-test*.

Despite the ubiquity of the pretest–posttest method, unbiased comparison of the initial and later measurement requires that the measures are comparable. Concerns have been raised that potential biases might arise if the respondent's perspective on the construct of interest changes between the assessments; such changes might be caused by life events, the passing of time, or by the nature of the treatment or intervention. This "response shift" may be due to a change in internal standards (*recalibration*), a change in values (*reprioritization*), and/or a change in how the individual thinks about the construct being measured (*reconceptualization*).

Response shift poses a serious threat to the repeated measures design, as assessments over time may not be comparable due to any of these changes in the respondent. In essence, if response shift is present, then the basis for responding to the items on the measure is different at each assessment and the data at each time point may not be based on a common metric, which renders meaningful interpretation of change scores problematic. For example, during a stress management program, the respondent may come to think about stress differently: Consequently, their post program conceptualization of stress is not the same as before the program started, which means that the respondent's frame of reference for stress and the items on the scale are now different. How then can responses on the pre-test stress scale be meaningfully compared with the posttest stress scale score? Research on response shift arose in evaluations of educational programs in the 1970s and was brought into broader prominence by research on changes in health-related quality of life among patients with various health conditions in the 1990s.

The then-test method was developed to address these concerns and assess changes in internal standards to control for recalibration and reconceptualization of response shift when measuring change using self-report measures. It gained popularity because it was easy to implement and easy to analyze. However, concerns have

been raised about the conceptual and psychometric basis for the then-test method. This entry discusses how the then-test is used and its limitations in measuring response shift.

The then-test is most frequently used as part of a retrospective pretest design. In this method, participants complete the pretest at the first assessment, a posttest at the second assessment, and in addition a retrospective evaluation of the first assessment (*then-test*) is conducted at the second assessment. In the retrospective evaluation, participants are asked to complete the initial assessment again to give a renewed assessment of their initial levels on the measure. It is assumed that the scores on the posttest measure and the then-test version of the pretest will be comparable as they are based on the same internal standard and the same conceptualization of the construct because they are assessed at the same time. For example, the then-test for the stress management example would involve participants who have completed the program being asked to rate their levels of stress before they attended the program using the stress scale.

The difference between the then-test score and the pretest score quantifies response shift over time. The comparison of posttest and then-test scores eliminates treatment-induced response-shift effects and is proposed to provide an unbiased estimate of the change scores. The difference between the initial pretest measures and the then-test responses to the same measure gives an estimate of the magnitude and direction of the response shift. Of note, the method assumes that respondents are able to accurately recall their preintervention pretest status and functioning when completing the then-test to ensure that there is consistency in the description of functioning referenced at pretest and then-test. Depending upon the research question, the then-test can be used on entire measures or on selected items. Research examining educational interventions using then-tests reported larger intervention effects than those revealed by conventional pretest–posttest designs. Furthermore, the then-test scale response has been found to be more strongly associated with objective criteria of change. The research indicates that the then-test may provide an accurate and sensitive assessment of change.

A limitation of the then-test is that it requires extra measurement: In addition to the traditional pretest and posttest, the retrospective pretest must be completed. A more fundamental psychometric concern relates to the need for the then-test measure to have the same psychometric properties as the posttest measure; such measurement invariance is essential to ensure that the comparison of the then-test to the posttest values are valid.

From a conceptual perspective, the difference between the original pretest and the then-test has been

primarily interpreted in terms of response shift; however, the extent to which other possible psychological processes (e.g., social desirability, cognitive dissonance, implicit theories of change) can account for such differences has not been examined systematically. In addition, the then-test response might be confounded with recall bias as participants may not be able to accurately remember their prior mental states and functioning. Thus, the difference between the pretest and then-test may reflect inaccurate recall of the initial states rather than response shift.

THEORETICAL SAMPLING

Theoretical sampling is an approach used to guide data generation and collection in research. Theoretical sampling is the process of identifying and following leads that arise during data analysis to direct the generation and collection of further data. The originators of grounded theory, Barney Glaser and Anselm Strauss, first described the technique. Glaser and Strauss employed theoretical sampling as a key strategy in the development of grounded theory. The researcher maintains an open mind as the analysis evolves and continues to identify and efficiently utilize the most appropriate data sources to achieve the aims of the study. While most often associated with grounded theory, theoretical sampling has applications in other forms of research. This entry will discuss theoretical sampling, its purpose, and use.

Purpose of Theoretical Sampling

Sampling in research involves selection of the most appropriate sources of data to inform analysis and

achieve the aims of a given study. Most approaches to research determine during the planning stages of a study what data are required and how and where these can be obtained. In these cases, the researcher seeks to secure a selection of data sources that are representative of the broader context. Theoretical sampling differs in that the evolving analysis dictates what data sources are needed to further progress and complete the analysis. Its use in qualitative research is compatible with the inductive focus of this paradigm, as theoretical sampling ensures that data remain the primary driver of analytical processes in such studies.

Identifying Appropriate Data Sources

Theoretical sampling is an efficient means of sourcing data, particularly in qualitative research. Qualitative studies generally produce voluminous quantities of textual data. Theoretical sampling assists the researcher to maintain focus by directing the generation or collection of data that has specific value to the study. Theoretical sampling may dictate the type and source of data required as well as most appropriate method by which it can be obtained. For example, a researcher might identify through theoretical sampling that a particular type of data could best be gathered via focus group rather than individual interview or via observation rather than a survey.

Achieving Saturation

Most forms of qualitative research rely on data saturation to determine whether sufficient data have been generated or collected and whether the analysis is complete. Theoretical sampling enables the researcher to secure data that directly relate to the developing themes, codes, or categories that comprise their analysis, without having to wade through large quantities of repetitious data that have little value for the analysis. This concept is particularly important in grounded theory, where the researcher is specifically aiming to identify a core category and process to anchor the analysis.

Building Theory

A theory is a framework that explains abstract concepts. When undertaking research where the aim is to build theory, maintaining connection between the categories as they are developed is critical. Theoretical sampling facilitates this process, as it enables the researcher to describe the properties and dimensions of concepts and the nature of relationships between them. In methodologies such as grounded theory, the ability to explicate key components of a developing theory and explain

the process that connects them is critical in ensuring that the resultant product is grounded in the data.

Process of Sampling Theoretically

Theoretical sampling is both logical and intuitive. The researcher draws clues from the analysis that direct them to gather further data that will progress the study. While theoretical sampling itself is a straightforward activity, there are challenges associated with not knowing from the outset what sources of data will need to be accessed. This uncertainty has implications for resourcing and institutional ethics requirements. These challenges are not insurmountable, however, as long as the researcher is aware of the need to appropriately allow for contingencies when planning a study.

Commence Purposefully

Because theoretical sampling follows leads that arise during analysis, it generally cannot be employed until that analysis has commenced. The researcher usually starts gathering data using purposive sampling. Purposive sampling involves the selection of initial data sources based on the researcher's understanding of the broader phenomenon, as drawn from such things as the literature or previous experience. Following this purposive sampling, theoretical sampling can commence, even from the early stages of the analysis.

Follow Leads

The researcher uses theoretical sampling to identify what is missing from the analysis and determine where useful data can best be obtained to *fill the gaps*. Leads that appear in the data can take many forms. The researcher will often be directed to sources that assist in answering questions that arise during the analysis. Following leads in this way allows the researcher to populate properties and dimensions of the codes and categories that form the structure of the evolving analysis.

Think Outside the Box

Research data can take many forms. Interviews, focus groups, and surveys are common methods of data generation used by researchers in the qualitative domain. In employing theoretical sampling, the researcher is encouraged to think creatively about sources that can best answer questions or fill gaps identified in the analysis. Images, videos, artwork, artefacts, and music are all data sources that can be sampled theoretically. Thinking beyond textual data can reinforce the intent of

theoretical sampling, which is to do justice to the work of the analyst.

Example of Sampling Theoretically

Theoretical sampling in its simplest form involves taking questions that arise for the researcher during the process of gathering and analyzing data and seeking the best ways to answer those questions. Often researchers think of theoretical sampling as a method of determining *who* can provide the data sought. It can be more broadly employed, however, in identifying *what* needs to be answered and *where* such information can best be found.

For example, a researcher is exploring the process by which businesses manage to remain solvent during a pandemic. Interviews with business owners identify that employee loyalty is critical to sustainability. The researcher then seeks out employees of businesses (*who*) to establish their perspectives. In doing so, they find that loyalty is higher in employees who feel a sense of belonging in the workplace. This leads the researcher to ask questions in future interviews about factors that contribute to feelings of belonging (*what*). The analysis of this data reveals that a sense of belonging is particularly high in the retail industry. The researcher therefore questions how the nature of business being conducted may be a contributing factor and seeks to obtain data from other sectors, for example, hospitality (*where*).

While this is a simple example of the use of theoretical sampling, researchers are encouraged to think creatively about how they can employ this technique using a broad range of data in diverse study designs.

THEORY

Theory is generally understood as a systematic representation of a genuine problem, articulated as far as possible in mathematical terms in the natural sciences or logical (or strictly linguistic terms) in the life and social sciences. The systematic nature of theory is normally aimed at providing explanatory leverage on a problem, describing innovative features of a phenomenon or providing predictive utility. The empirical adequacy required of a theory is a controversial feature of theories and often differs radically across disciplines. As most research in the sciences and social sciences is theory driven, that is, is concerned with the refinement or refutation of theoretical claims, the design of that research will have an immediate impact on the nature of theory construction and the presumed relationship among theory construction, observation, and the outcome of empirical research.

Positivism and Its Impact on Theory

The traditions of research in the social sciences have consistently argued for a theory-driven approach to the design of investigations, particularly in its more experimental formulations. This tradition became established in the 20th century through the adoption of logical-positivist premises and a hypothetico-deductive framework in research that focused on observable features of the world as the final arbiter of research outcomes. Late 19th-century positivism, originally articulated by Auguste Comte, was influential in guiding the new social sciences, particularly psychology, in adopting research methods that would allow observed features of the world to determine the outcome of research questions. This was done to remove the influence of metaphysics and theology in science and originally had a salutary effect. However, this naïve version of positivism suffered from shortcomings that would make themselves felt in the 20th century. In particular, it ruled out the possibility of allowing entities such as atoms the status of real objects in science because they were unobservable. Ernst Mach, the Austrian physicist and philosopher whose philosophical views were important in the early social sciences, championed this version of positivism.

Positivism reduced the problem of theory to one of sensations, namely, the experience of an experimental outcome would in fact be the basis for a scientific theory. This was useful in removing the effects of metaphysics from science but hindered the progress of science as it came to rely ever more on unobservables. Logical positivism (in the version promulgated by the

Vienna Circle) sought to ameliorate this. The principle of verification advanced by the movement claimed that the meaning of a statement is determined by sense-experience. However, this sense-experience can be direct or indirect allowing for the introduction of concepts (theory) that are linked to observations while not directly observable themselves. Instead, protocol sentences (direct observation terms) were linked to axioms (theoretical terms) with logico-mathematical terms. One consequence of this view is the rigid separation of theory from observation or data. Although it was dominant until after World War II, this position created an important sense that theory was to be understood as a rigorous feature of experimental science. This was especially the case for theory that was formulated in mathematical terms or in terms of so-called laws. An additional concern that sprung out of the work of the logical positivists was a preoccupation with the unity of science. Dominant for much of the 20th century, the unity of science view was that all sciences are related through a thoroughgoing reductionism that would ultimately base all scientific theory on the laws of physics (although Otto Neurath, a logical positivist, was generally opposed to a crude reductionism of this sort).

Theory in the social sciences then was a highly restricted affair. Limited by its necessary ties to the nature of observations, restricted by logic, and pursued for its ends as a formalization of research, theory remained deeply tied to the immediate problems of the laboratory. For example, the learning theories in psychology that emanated from the behaviorist laboratories of Clark Hull, Edward C. Tolman, or Burrhus F. Skinner were, despite their elegance, often restatements or redescrptions of what the investigators thought the results of their experiments demonstrated. That is, the learning theories themselves were formulated in such a way as to ensure that the empirical demonstrations never deviated in large measure from the claims of the theory. Skinner famously called for an end to theories of learning altogether, although he continued to theorize apace.

Indeed, logical positivists themselves recognized that there was a problem with theory in their account. Carl Hempel's "paradox of theorizing" argues that if the terms and general principles of a scientific theory serve their purpose by establishing connections among observable phenomena, then they can be eliminated. This is because a chain of laws and interpretive statements that establishes such a connection should be replaceable by a statement that directly links observational antecedents to observational consequences. The dilemma then, for Hempel, was that if the terms and principles of a theory are unnecessary, then theory is unnecessary. Hempel claimed that perhaps theory is

still useful because of its inductive, predictive, or heuristic uses, but this did not limit the damage to notions of logical positivism. Obviously, no one was about to abandon theorizing. Furthermore, others such as Karl Popper already noted that theories seemed more like "conjectures" than the formal arrangements of the logical positivists. Imre Lakatos argued famously that the core of scientific theories is generally protected by what he called auxiliary hypotheses and, hence, theories can never be just connecting statements between observational antecedents and consequences. By the 1970s, it was clear that a conception of theories in science was emerging that emphasized the surplus meaning of theory above and beyond the mere redescription of empirical content.

End of the Received View

After World War II, severe doubts crept into the "received view," as the logical positivist version of science was often called. Norwood Hanson in his *Patterns of Discovery* (published in 1958) was among those who argued that the observations themselves are "theory laden." One does not naïvely observe the world as it is but always approaches the world with some preconceptions in place. Hanson argued that it is not a question of using or testing a theory but is the creation and discovery of what becomes an appropriate theory. In that sense, he claimed that he was more concerned with the way in which theoretical systems are built into observations such that they come to lead one to understand certain facts. Hanson did not claim that theories created facts de novo but that observations were always already colored by the theories or concepts that were used to frame the observations.

The question of theory and its relationship to data was revisited anew by Thomas Kuhn. In his influential book *The Structure of Scientific Revolutions* he increased the revisionist impulse in the understanding of science. Arguing that scientific advances run in cycles, Kuhn proposed that deeply embedded worldviews allowed science to proceed in a "normal" fashion until such time that the cracks in the established view led to a radical realignment, and a "scientific revolution" turns over the established "paradigm." Although Kuhn's work was later criticized, not least for its ambiguous use of the notion of paradigm, the overall impact was to steer philosophers and historians of science away from an emphasis on prescribing how science should proceed to describing how it might actually work in the context of human institutional and social activities. Contemporary research in science studies has continued this tradition by emphasizing the social nature of scientific progress.

Theories and Models

If theories are not precise statements of law, or systematic organizers of fact, then their role must be found elsewhere. Some philosophers of science, who were influenced by the work of Frederick Suppe, argued that theories were set-theoretic structures. This semantic conception of theories treats theories as abstract structures that stand in mapping relations to phenomena. In addition, on this view, scientists are busy constructing models that are idealized, partial simulations of the world or that probe real-world systems. According to Suppe, theories and models consist of mathematical spaces or structures standing in mapping relations to other systems. The consequence of this claim is that the structure of a scientific model can be examined as a semantic conception. These discussions have tended to focus in recent years on the problem of testing theories in such a way that the test is not tautological.

The Ascendancy of Functionalism

In the social sciences, however, where few models are expressed in precise mathematical terms, the relationship between theory and data or, more generally, theory and observation, continues to be a feature of ongoing debate. Theories come in different types and no one has determined the point at which the honorific label of theory is applied to a hunch or hypothesis. Traditions vary among social sciences, and what might be considered a theory might be anything from a counter-intuitive proposal (for example, several features of evolutionary psychology) to a redescription of experimental outcomes. Certain neoclassical economic theories tend to favor computational solutions to problems. However, early in the 20th century, the social sciences created functionalism as a way of accounting for processes or properties whose activity was of interest even if their actual ontological status was uncertain. That is, even if one did not know precisely what a phenomenon consisted in, one might be able to explain how it functioned.

In recent decades, the predominance of functionalism in the social sciences has been firmly established. Functional accounts normally do not commit themselves to what there is but to what is occurring in the processes under investigation. For example, without even giving an account of just what memory *is*, theories of memory have long been expressed in terms of the functions of memory (short-term memory, long-term memory, episodic memory, semantic memory, etc.). Furthermore, the development of the cognitive sciences created another meaning of function and further cemented the tradition as one of the most dominant in

the social sciences. For the cognitive scientist, functionalism was a thesis about the instantiation of a computer program on a physical platform, regardless of the nature of that platform. The mind could be likened to a computational function. A sense of this meaning of functionalism still permeates cognitive psychology and cognitive neuroscience.

Willard Quine Empiricism

The use of the term *theory* then has become rather unrestricted. It is often a placeholder for a variety of unknowns that serves to keep us from leaping to firm conclusions while otherwise formalizing hunches and guesses. There might be some “empirical evidence” for the case at hand, but the theory supported by that evidence is, of course, always underdetermined. This means only that no empirical results bring finality to theoretical frames; this problem was originally articulated by philosopher Willard Quine in his well-known article “Two Dogmas of Empiricism” (the dogma of the distinction between analytic and synthetic truths and the dogma of reductionism). Although the debate that followed its publication was lengthy and detailed, the outcome was a gradual historical reevaluation of the sciences. Most important, however, was the support it would provide for the work of the historians and sociologists of science who demonstrated that the distinction between *theory* and *fact* is a rather dubious and unhelpful one in evaluating science, its results, its methods, and its products.

Reflexivity

What characterizes most social science research is the reflexive nature of human activities. That is, to understand the human activities, the investigating scientist must of necessity be an apposite member of the community of participants under investigation. Otherwise, such phenomena as widely divergent as depression, abuse, socialization, fondness, racism, sexual attraction, and so on will be unintelligible to the investigator and, hence, will not likely capture all the relevant features of the phenomenon in question. One could argue that one needs to be a member of a community of scientists to do any kind of research; although the atomic number of, say, Fe (iron)—26—will not change according to cultural customs, depression might, in fact, do so. The latter is an example of a phenomenon that is the outcome of the shared practices of a particular community regardless of its neuroscientific precursors. Furthermore, as Joseph Margolis has argued, the combined intrapsychological powers alone of the aggregated members of a community cannot account for the

features at hand; it is not just a process that occurs “inside the head.” Instead, the phenomenon is the outcome of a communal set of activities; to be depressed is by definition to be depressed in a particular culture.

Other philosophers of the social sciences, such as Rom Harré, have argued that what characterizes the social sciences is a concern with the activities of ordinary life in their most varied and rich circumstances. These activities are best captured by the Wittgensteinian distinction of “following a rule” versus “acting in accord with a rule.” The former is done when conforming to a set of prescribed rules, such as those that must be followed when learning some new, complex skill. The latter is done when one speaks a natural language as a child, and thus, one has never observed the grammatical rules that are nevertheless followed, or when driving a car effortlessly after many years of practice even though one learned to do so by initially following a concrete set of rules. The distinction here is between habitual activity, which is highly overlearned, and the kind of activity that involves conforming to norms and conventions one might barely be able to articulate. A theory that takes the latter into account must have features unlike a neuroscientific account of human activity because norms and conventions are by definition communal phenomena.

In psychology, however, there are many who do not believe that special theoretical concessions need be made for these kinds of distinctions and that eventually all psychological phenomenon will be captured by some overarching neuroscientific or evolutionary framework. Despite the popularity of this reductive claim, these theories are a considerable explanatory distance from the activities of ordinary life. For an account of these kinds of activities, goes the counterargument, attention needs to be paid to the microdetails of life itself either through talk (as in various discourse analytic positions) or other forms of ethnography. Proponents of overarching theories, in contrast, argue that their positions will provide an ultimate explanation of the foundations of such activities.

Broadened Conceptions of Theory

Events outside the social sciences have also led to new and unusual forms of theory in recent years, such that the term has come to be used in an ever wider sense. Under the influence of formalism, historicism, Marxism, structuralism, feminism, queer theory, ethnic studies, postcolonialism, culture studies, and more, the idea of a theory came to represent something of a challenge to orthodoxy. In part motivated by the crisis in epistemology that was a consequence of postmodernism and the denial of the possibility of certain knowledge,

theory in the humanities resisted so-called universalizing impulses. Critical theory has been inserted into the humanities since the 1960s in a way that has led to new emphases on theoretical scholarship. Having suffered through a period of excess in the late 20th century, some of these orientations have settled into academic subdisciplines, whereas others have passed altogether. One important consequence has been the general suspicion of grand theories espoused traditionally in the social sciences. Hence, from Sigmund Freud to Talcott Parsons, the overarching theoretical frame has been treated with wariness and viewed as carrying within it other interests (for example, the phallogocentric nature of Freud's theory) that are not explicitly accounted for in the theory itself.

The consequences of these developments for the social sciences have been less disruptive to the research enterprise than they have been for the humanities. Nonetheless, the effects can be observed in the further institutionalization of theoretical traditions in such disciplines as sociology and psychology, where new divisions and societies devoted to the study of theory have come into their own in recent decades (e.g., the International Society for Theoretical Psychology) as well as new journals (e.g., *Theory & Psychology*). In addition, the greater influence of qualitative methods or microsociological research has changed the way theory is organized in the academy. The question of theory is not so much a question of finding the best “fit” for the data as it is providing an adequate account of a phenomenon that reflexively takes up the position of the researcher as well as the participants into its final articulation.

Theory is no longer the prerogative of narrowly determined empirical research enterprises that extract hypotheses from an overarching theory and then carefully test these along a neo-positivist model. In all areas of the social sciences, theory includes models and hypotheses, as well as systematically developed frameworks or just initial articulations of what is the phenomenon of interest. What constitutes theory is now largely a matter of convention as well as locally or disciplinarily determined rules for empirical adequacy.

THEORY OF ATTITUDE MEASUREMENT

There are two challenges a researcher faces when measuring an individual's attitude. First, an individual's attitude toward an object cannot be observed directly but must be inferred from observed behavior, such as responses to a questionnaire. And second, there is no inherent scale associated with the observed behavior. Louis Thurstone's ground-breaking article in 1929, "The Theory of Attitude Measurement," presented a method of scaling attitude to meet these challenges. His method presented a way to define a continuum/scale in which to place stimuli and respondents that would be on the interval level. The purpose of this entry is to describe the Thurstonian scaling method of similar reactions/attributes described by Louis Leon Thurstone, in which the scale values for each statement represent the actual distance or separation between each statement with respect to the degree of favorableness toward the object.

Method of Similar Attributes/Reactions

Attitude can be defined as a tendency to react favorably, neutrally, or unfavorably toward a particular class of stimuli, such as a custom, institutional practice, or national group. Thurstone's approach scales that tendency. Suppose a researcher has I statements regarding the attitude toward a particular object (e.g., capital punishment). The first step in the method of similar attributes is to rank order the statements from least favorable to most favorable regarding the object of interest. The method of equal-appearing intervals (as described by Thurstone) might be used to rank order the statements. Next, the coefficient of similarity (denoted ϕ) is computed between all pairs of statements using raw data collected from a sample of participants who were asked to endorse statements he or she agrees with. The ϕ coefficient represents the degree to which the endorsement of two statements reflects the same

attitude. For any statement i and statement j , the ϕ coefficient of similarity is computed as follows:

$$\phi_{ij} = \frac{n_{ij}}{\sqrt{p_i p_j n_i n_j}}, \quad (1)$$

where n_{ij} represents the number of participants who endorsed both statements i and j ; n_i and n_j represent the number of participants who endorsed statement i and statement j , respectively; and p_i and p_j represent the reliability of statement i and statement j , respectively. The reliability of a statement represents the probability a participant will endorse the particular statement given he or she has that opinion. In computing the reliability, the fact that the statements have been rank-ordered such that any two adjacent statements will reflect practically the same attitude is exploited. Therefore, the reliability of statement i , where statement j is adjacent to statement i , is computed as follows:

$$p_i = \frac{n_{ij}}{n_j}. \quad (2)$$

Essentially, the reliability of an item represents the proportion of participants who endorsed an adjacent statement that represents the same attitude.

To illustrate the procedure, Table 1 reports hypothetical raw data corresponding to five statements that were selected from a scale consisting of 50 statements administered to 1,000 participants (note that five statements have been selected for illustrative purposes only—i.e., a scale should contain many more items). The diagonal elements in Table 1, which are bolded, report the number of participants who endorsed each statement. The off-diagonal elements indicate the number of participants who endorsed both respective statements. The reliability of each statement is reported in the last row labeled p_i and is based on Equation 2, which was applied to the complete scale of 50 statements. The statements in Table 1 have been ordered from least favorable (s_1) to most favorable (s_5) based on the method of equal-appearing intervals, which was applied to all 50 statements.

Table 2 reports the coefficient of similarity (ϕ) based on the data from Table 1. The ϕ coefficient represents the degree to which any two statements are similar. The ϕ coefficient typically ranges from 0.00 to 1.00, where relatively large values of ϕ indicate that the two statements are similar and thus are close together on the continuum; small values of ϕ indicate that the two statements are dissimilar and thus are far from each other on the continuum. It is assumed that the ϕ coefficient has a maximum of 1.00 when the scale separation is zero

Table 1 Number of Participants Who Endorsed a Pair of Statements

	Statement				
	s_1	s_2	s_3	s_4	s_5
s_1	221	120	90	44	15
s_2	120	294	214	146	55
s_3	90	214	350	215	101
s_4	44	146	215	423	274
s_5	15	55	101	274	515
p_i	0.80	0.73	0.64	0.81	0.43

Table 2 ϕ Coefficient Indicating Similarity for All Pairs of Statements

	Statement				
	s_1	s_2	s_3	s_4	s_5
s_1	1.00	0.62	0.45	0.18	0.08
s_2	0.62	1.00	0.98	0.54	0.25
s_3	0.45	0.98	1.00	0.78	0.45
s_4	0.18	0.54	0.78	1.00	0.99
s_5	0.08	0.25	0.45	0.99	1.00

(e.g., when a statement is compared with itself or is the same as another statement).

The ϕ coefficients are converted to scale values to measure the separation between any pair of statements. The scale separation between any pair of statements can be obtained by finding the standard normal score associated with the ordinate (i.e., height of the standard normal distribution) defined by the ϕ coefficient. Thurstone suggested using a probability table in which the maximum ordinate is 1.00 (however, the maximum ordinate provided by most software packages is .40—dividing the ordinates by .40 will convert them such that the maximum equals 1.00). Table 3 reports the scale separation values for all pairs of statements.

When the ϕ coefficient is near 1.00, the scale separation will be close to zero, which indicates that the two statements are similar, whereas for small values of ϕ , the scale separation will be large. For example, for $\phi = 0.98$ (e.g., statements 2 and 3), the scale separation ($S_3 - S_2$) is 0.19, whereas for $\phi = 0.54$ (statements 2 and 4), the scale separation ($S_4 - S_2$) is 1.11. The sign of the scale separation value is determined by the end of the scale that is arbitrarily defined to be positive. For example, if the statement that has been rank-ordered first, which

indicates that it represents the least favorable regarding the object, is defined as zero, then the scale separation values associated with this statement will be negative (indicating that the scale value is less than all of the other statements). Last, Thurstone recommended ignoring scale separation values greater than or equal to 2 because of unreliability.

The final scale value for each statement is based on the average scale separations between adjacent statements defined by the rank ordering. The average scale separation for adjacent statements i and j might be expressed as follows:

$$\text{Ave}(S_i - S_j) = \frac{1}{I} \left[\sum_{k=1}^I (S_i - S_k) - \sum_{k=1}^I (S_j - S_k) \right], \quad (3)$$

where $(S_i - S_k)$ represents the scale separation values for statements i and k reported in the body of Table 3. For example, the average scale separation for statements 3 and 4 is

$$\text{Ave}(S_4 - S_3) = \frac{1}{5} [(3.54) - (-0.51)] = 0.81. \quad (4)$$

Table 4 reports the final scale values for the five statements. The final scale value is determined by first arbitrarily setting the scale value for statement 1 (i.e.,

Table 3 Separation Values ($S_{\text{column}} - S_{\text{row}}$) for All Pairs of Statements

	Statement				
	s_1	s_2	s_3	s_4	s_5
s_1	0.00	0.97	1.26	1.85	2.24
s_2	-0.97	0.00	0.19	1.11	1.66
s_3	-1.26	-0.19	0.00	0.70	1.26
s_4	-1.85	-1.11	-0.70	0.00	0.12
s_5	2.24	-1.66	-1.26	-0.12	0.00

Table 4 Final Scale Values for the Five Statements

Statement	Average Scale Separation	Final Scale Value
s_1	0.000	0.000
s_2	0.938	0.938
s_3	0.296	1.234
s_4	0.810	2.044
s_5	0.338	2.381

the statement that represents the least favorable attitude) to be zero and then aggregating the average scale separation values across the statements. For example, the final scale value for statement 3 equals the statement 2 final value plus the average scale separation between statements 3 and 2 (i.e., $1.234 = 0.938 + 0.296$).

The final scale values define the continuum and allow researchers to determine where a participant scores in comparison to the stimuli.

THINK-ALOUD METHODS

Think-aloud methods ask participants to verbalize their thoughts while performing a task. Such methods provide a basis for investigating the mental processes underlying complex task performance and can provide rich data on such cognitive processes. Since the inception of scientific psychology, think-aloud methods have contributed substantially to the understanding of problem solving and learning. This entry first describes the history of think-aloud approaches and then discusses the protocol analysis. Last, this entry addresses some limitations of think-aloud methods.

History

Early pioneers of scientific psychology, such as William James, Wilhelm Wundt, Alfred Binet, and Edward Titchener, used introspective reports of subjective experiences to provide insight into human consciousness, learning, and problem solving. However, the lack of reproducibility of findings from the analysis of introspective reports resulted in its marginalization and scientific psychology's emphasis turned from consciousness to observable behavior.

However, it should be noted that James Watson, whose seminal paper "Psychology as the Behaviorist Views It" provided the impetus to remove introspection from scientific study, advocated the use of think-aloud methods to understand cognitive processes. Gestalt psychologists also used think-aloud approaches to better understand cognitive processing during problem solving. Furthermore, Jean Piaget's seminal studies of the development of cognitive abilities relied on children's verbal descriptions of their responses to various experimental tasks. Contrary to the analytic introspection research that required participants be trained in self-observation or provide immediate retrospective reports of thoughts, participants were now being asked to simply "think aloud" their thoughts *as they emerged* while performing a task.

Psychology's embrace of information-processing approaches to understanding behavior in the 1950s onward resulted in the re-emergence of think-aloud methods as a valued research tool. The method gained popularity through Allen Newell and Herbert A. Simon's use of think-aloud data to inform their work on computational processes in problem solving. Contemporary use of the think-aloud method is informed by K. Anders Ericsson and Simon's protocol analysis of verbal reports.

Protocol Analysis

In a think-aloud study, participants are asked to verbalize thoughts that emerge as a task is being completed. The method aims to elicit the information required for task performance and consequently, the verbalizations should reflect the thoughts being attended to at the time. Participants should not provide an explanation of such thoughts, because to do so, they have to draw on additional thoughts and explanations that are not related to the task at hand and might alter the structure of the thought processes under study. Successful elicitation of the focal thoughts requires participants to attend uninterrupted to the completion of the task presented.

As people often feel that they have to explain or justify their thoughts in a social interaction, many strategies are used to minimize such possibilities. Participants often complete simple warm-up tasks to practice attending completely to a given task while verbalizing their thoughts only. It is also recommended that the researcher sits behind the participant to remove the social interactive element of the procedure. The researcher monitors the verbalizations and reminds the participant to speak if there has been a period of silence.

Concurrent Versus Retrospective Verbal Reports

A distinction is made between concurrent verbalization (thoughts are verbalized that emerge as the task is being completed) and retrospective verbalization (after completion of the task, the participant is asked about the thoughts that occurred at an earlier point in time). Retrospective verbalization aims to avoid the potential problem of task performance disrupting thoughts, but it is problematic as people might not accurately remember the thoughts that arose in completing the task. Post hoc rationalization of the cognitive processes might occur unintentionally. Hence, concurrent verbal reports are believed to be more accurate, and where appropriate, both concurrent and retrospective reports should be collected.

Analysis

Protocol analysis requires the verbal data to be classified into meaningful categories. The verbal responses are recorded verbatim, typically using a tape recorder, and transcribed. The data are reliably coded (e.g., using multiple raters and assessing interrater reliability of coding) into meaningful categories; such content analysis might be theory-driven or empirically driven depending on the nature of the study. For example, the think-aloud method can be used to develop a model of the cognitive processes underpinning problem solving or to test the validity of model derived from psychological theory. The verbalizations are often disjointed without any obvious relation between thoughts, and such incoherency and incompleteness is inherent in think-aloud data. The verbal protocols can be subjected to inferential categorical analysis (e.g., chi-square test) or simply descriptive analysis (e.g., frequencies).

Applications

Protocol analysis has been widely used to examine thinking in basic cognitive science and in many applied areas. Think-aloud methods have elucidated expert versus novice task performance across a variety of domains (e.g., chess). For example, in addition to having more knowledge, verbal protocol analysis has revealed that experts are better able to retrieve relevant information. In addition, protocol analysis has been applied to diverse topics, including cognitive processes in reading and writing, completing IQ tests, person perception, and scale development.

Limitations

A frequent criticism of the think-aloud method is that the act of concurrent verbalization might change task performance and the cognitive processes studied. However, Ericsson and Simon argue that concurrent verbalizations do not change the course or structure of thought processes. As the method relies on the verbalization of thoughts accessible in working memory, automatic processes cannot be accessed. Participants might only verbalize some working memory information used in task completion and hence provide an incomplete representation of the salient thoughts. Furthermore, the demand characteristics (e.g., social desirability) of the research might influence the nature of verbalizations made.

THOUGHT EXPERIMENTS

A thought experiment is an experiment that aims to persuade by reflection on its design rather than by its execution. After reviewing the origin of thought experiments and the empiricist-rationalist debate over their effectiveness, this entry concentrates on Ernst Mach's influential account.

History

Actual thought experiments predate the term *thought experiment*, which was first used by Georg Christoph Lichtenberg in 1793 and only acquired wide currency after Mach's 1897 essay "Gedanken experiment." Two thousand years before the term was invented, poets imported thought experiments into metaphysical verses about the nature of the universe. In his epic *De Rerum Natura*, the Roman poet Titus Lucretius supports the infinity of space by having the reader imagine that space has a boundary. If a man threw a spear at the edge of space, either the spear passes through, and so there is no edge of space, or it bounces back, in which

case there is a barrier that lies beyond space and yet is in space.

Rationalists welcome thought experiments. This *a priori* method shows that we can learn about the world without experience! Explaining *how* this happens is a classic problem—one that Plato hoped to solve with his Theory of Forms. Contemporary philosophers, such as James Robert Brown, continue to work on an explanation within the Platonic framework.

Empiricist Criticism

Empiricists have trouble understanding how thought experiments could be any more informative than poetry. If everything is learned from experience, then no information about the world can be extracted from a *hypothetical* experiment.

Yet many attacks on Aristotle's theory of motion are launched from Galileo's armchair. Consider his critique of Aristotle's principle that heavier objects fall faster than lighter objects. Galileo supposes that a smaller object becomes attached to a heavier object during its descent. On the one hand, the composite object must slow down because the heavy component is retarded by the slower component. On the other hand, the composite object must accelerate because it is heavier than the heavy component.

Empiricist reactions to thought experiments fall along a spectrum. Pierre Duhem condemns thought experiments as illusory sources of support. They have no more place in science than Plato's numerological arguments for the existence of seven planets.

John Norton thinks the success of Albert Einstein's thought experiments shows that Duhem was too dismissive. According to Norton, thought experiments should be heeded exactly to the degree that they can be reduced to cogent arguments. After all, empiricists endorse changes of opinion that are based on surprising deductions and calculations (even if the premises and data were already known).

Mach's Empiricist Account of Thought Experiment

Einstein's early philosophical mentor, Mach, was more concessive than Norton. Mach believed that thought experiments tap into stored "instinctive knowledge."

The pictorial form of this knowledge is evident from how questions such as "How many corners are in the capital letter preceding G?" are answered. A mental image of the letter is formed and the corners counted. In a sense, the number of corners was not known (they had to be counted), and in a sense, it was known (all the information was available to quickly answer the

question). Information is stored in mental images in the way information is stored in crime scene photographs (which, if need be, can be consulted later for missed clues).

The second form of instinctive knowledge is inferential. Thanks to personal experience, mental associations mimic natural associations. But these echoes extend well beyond personal experience. Thanks to the generate-and-eliminate mechanism of natural selection, inferential dispositions reliably reflect information that stretches back across thousands of generations. For instance, when babies begin to walk, they also begin to associate darkness with danger. They fear the dark regardless of whether they suffer or witness mishaps. The fear intensifies as their mobility increases and only begins to wane when they become educable. The child's fear is a form of innate knowledge—best explained by Charles Darwin's biology, not Plato's metaphysics.

Each human being is a sample of the universe. Evolution favors the more representative microcosmoses, so wider patterns of nature resonate in everyone. Thought experiments amplify the signal (by suppressing noise through negative idealizations, such as stipulating away friction, and by positive idealizations, such as caricaturing magnitudes to make effects salient). For instance, consider someone with a round trip ticket from Los Angeles to New York. He knows that prevailing winds accelerate travel west to east but retard travel east to west. To determine whether the losses and gains cancel out, he can realistically assume the jet speed at 500 miles per hour and exaggerate the wind speed to 499 miles per hour. The Los Angeles to New York flight is fast, but the return flight takes more than a month. The surreal thought experiment helps the traveler answer his mundane question by underscoring the principle that opposite forces cancel out only when applied equally.

The Economy of Thought

Actual trial and error is slow, costly, and dangerous. Those who could test hypotheses "by thought" lived longer and more economically. Although these mental simulations are less reliable than actual experiments, they are reliable enough to have a legitimate role in science. Techniques that trade accuracy for speed are just as much a part of the scientific repertoire as randomized control trials. (This explains why experiments that are designed to expose weaknesses of thought experiments are commonly designed with the help of thought experiments.)

Planning an experiment is itself a process that leads to rational revisions of opinion. Once these accidental improvements in cognitive credentials are noticed, one

tries to achieve them deliberately. That is, experiments are crafted to rationally persuade just by reflection on their designs, rather than by execution. For instance, after Galileo established the law of equal heights (that a ball will roll up a U-shaped track until it recovers its original height), he asked what would happen if the ball were rolled along an infinite, frictionless plane in a vacuum. The answer suggested by thought experiment, that the ball would roll endlessly in a straight line, is an anticipation of Newton's first law of motion.

Galileo did not fully believe the outcome of his thought experiment. He continued to subscribe to Aristotle's idea that natural motion is circular. But because a straight line approximates the segment of a large circle (as large as the earth), Galileo regarded the thought experiment as giving a result that was close to the truth.

This discrepancy between the thought experimenter's expectation and the result eases some concern about circularity. If imagination perfectly reflected prior theoretical commitments, then thought experiments could not be used to *test* theories.

As in the case of executed experiments, thought experiments are often marred by biases and methodological shortcomings. Measures are taken to damp down these disturbances.

Mach's naturalistic account of thought experiments suggests that thought experiments should only be reliable in conditions similar to those in which intuitions evolved and developed. Thought experiments that rely on intuitions about how objects behave under the extremes of temperature, pressure, and gravity should be regarded with suspicion.

Yet many of Einstein's thought experiments do concern the behavior of objects that are moving at unprecedented speeds. There are other well-regarded thought experiments concerning phenomena to which hunter-gatherers were oblivious (ones involving microscopic scale, electricity, quantum phenomena). If these thought experiments are as successful as many physicists assume, then they are anomalies for Mach's account.

The same goes for thought experiments in ethics and aesthetics. Nature is indifferent to what *should* be the case and what *should* be admired.

These challenges are akin to those first posed to Darwin. Thought experiments will themselves play some role in answering these questions. Like other scientific methods, thought experiments must pull themselves up by their own bootstraps.

THREATS TO VALIDITY

From a research design standpoint, the simplest way to understand threats to validity is that a hypothesis might be tested in a manner other than what the researcher had intended—a situation not to be confused with the researcher's failure to obtain the result he or she had expected. Much is presupposed in this distinction. Research is not a linear extension of common sense or everyday observation but rather requires a prior theory or paradigm that yields an appropriate hypothesis, on the basis of which the researcher selects relevant variables that are then operationalized and manipulated in an environment of the researcher's creation and control. Under these circumstances, two matters of validity arise: first, the reliability of the outcomes vis-à-vis other experiments of similar design, and second, the generalizability of the outcomes to the population that the experiment purports to model. The statistician Ronald Fisher established this way of thinking about research design validity, which included the random assignment of subjects to groups of the researcher's choosing, given the variables that need to be operationalized to test the researcher's hypothesis.

In what follows, the peculiarities of Fisher's original approach are examined, followed by the philosophical foundations of the concept of validity that is presupposed in research design, culminating in a discussion of the different threats to validity associated with different research designs.

Peculiarities of Fisher's Original Approach to Research Design

Two features of Fisher's original context help to explain the initial clarity but long-term difficulties of his approach. These might be called "meta-threats" to validity, because they pertain to the selection of the paradigm of research design validity. First, Fisher

developed his paradigm in the context of an agricultural research station, and hence, the things subject to “random assignment” were seeds or soils, not human beings. Second, the station was (U.K.) state run and not for profit. Whereas the former pertains to the concerns originally raised by Donald Campbell and Julian Stanley and in the bulk of this entry, the latter point has received increasing attention—indeed, as part of a general challenge to the idea that statistical significance is a meaningful outcome of hypothesis testing. This latter difficulty is briefly discussed in the next paragraph, before resuming with the threats to research validity specifically related to human subjects.

In the context where Fisher designed experiments on the efficacy of genetic and environmental factors on agricultural output, matters of utility and cost did not figure prominently. A state interested in acquiring a comprehensive understanding of what is likely to make a difference to food production presumed that every hypothesis was equally worthy of study. Thus, “statistical significance” came to be defined as the likelihood of an experimental outcome, given a particular hypothesis, which is tested by seeing whether the outcome would have been the same even if the hypothesis were false (i.e., the null hypothesis). In contrast, someone more explicitly concerned with utility and cost might cast the idea of validity in hypothesis testing as a species of normal rational decision making. In that case, the validity would be defined as follows: Given the available evidence, the cost of accepting a hypothesis vis-à-vis potentially better hypotheses that might require additional testing. Indeed, as Stephen T. Ziliak and Deirdre N. McCloskey observe, this stance was taken by William Sealey Gosset, a student of Karl Pearson who was lab director at Guinness breweries in the early 20th century.

Philosophical Foundations of the Concept of Validity in Research Design

Validity is a curious English word to use for, broadly speaking, knowledge acquired by methodologically appropriate means. Etymologically, the word is related to *value*, not *truth*. In formal logic, a valid inference is one that preserves the truth of the premises in the conclusion: Truth matters to validity not in itself but only insofar as it is preserved from one logical moment to the next. From a false premise, any conclusion—true or false—validly follows. Validity merely captures the fact that content has not been lost in the translation from premise to conclusion. In the case of a false statement, because nothing true has been asserted, there is nothing to lose in translation. Thus, anything goes.

Although the logician’s way of understanding validity might make good sense when considering bare knowledge claims, more complex and concrete acts of research like experiments, ethnographies, simulations, and surveys demand a more robust sense of “normative force,” or what the Germans call *Geltung*. Etymologically, the model for *Geltung* is the state’s backing of banknotes that enables them to retain their face value as they change hands in transactions over a wide variety of goods and services. There is a promise to pay a fixed amount, should one decide to cash in one’s banknotes. By analogy, one could ask how a piece of research establishes its significance beyond the original research moment, so that it becomes a fixed contribution to knowledge, on the basis of which subsequent claims to knowledge can be evaluated and built. Campbell and Stanley would put the matter in terms of the grounds on which research can be used as a basis for policy. The starting point here is the recognition that any experiment or even ethnography, simply taken alone, is a statistically improbable act in the normal run of human events. This, then, raises the question of what, if any, standing it should have in explaining or directing human affairs.

Questions about the determination of research validity began with debates over the nature of *Geltung* roughly a century ago, relating to the Neo-Kantian view that the methodology of science is the main substantive project of epistemology. A brief recapitulation of the original philosophical context puts the matter in focus. Immanuel Kant’s theory of normative force (i.e., his general theory of what should be the case) presumed that David Hume was right to argue that “is does not imply ought”: The bare fact that something exists has no normative force *per se*. Normative force depends on whatever else it manages to empower. As Kant put it: “Ought implies can.” This point was driven home in several disciplines, most notably jurisprudence, where it informed the positivist model of a legal system as constituted by a sovereign whose will underwrites all legislation. Accordingly, the law’s legitimacy rests on both the means by which the sovereign will is enforced, specifically the sanctions entailed by nonconformity, and the basis on which one comes to believe in the efficacy of those means. Science differs from law in that the difference between these two sources of legitimacy is minimized as the scientist’s research design allows her first-hand knowledge of how the relevant claims acquire the normative force they have.

Neo-Kantian philosopher Heinrich Rickert, perhaps the most influential epistemologist prior to the rise of logical positivism, generalized this point to argue that the sciences (i.e., *Wissenschaften*) might be distinguished, not by the nature of their objects, but by the

nature of their validity conditions. Thus, a study of human beings might be “valid” (or not) in many different senses depending on the intensity of the normative force attached to the study itself and the extent of the study’s normative reach. Moreover, these two dimensions might trade off against each other, which is inscribed in the Neo-Kantian literature as the distinction between *idiographic* and *nomothetic* inquiry. Someone immersed in a particular native or historic culture (i.e., idiographic) more reliably knows that culture than someone who regards it as simply one of a kind (i.e., nomothetic), yet that superior knowledge is unlikely to be generalizable to other cultures.

The clearest contemporary legacy of this perspective is Jürgen Habermas’s four validity claims (*Geltungsansprüchen*) relevant to human action, which imply that research might be (in)valid in terms of the accuracy, appropriateness, sincerity, and/or comprehensiveness vis-à-vis its target reality. According to Habermas, the existence of relatively self-contained yet equally enlightening schools of sociology, each dedicated to establishing one of these validity claims, demonstrates that validity is not a univocal concept and that so-called threats to it might be best understood as an attempt to mix different validity claims in a single study. This point is implicitly recognized at the most fundamental level of research design, in which a study might provide an adequate model of either other studies of exactly the same kind or of a range of rather different studies performed in conditions more closely resembling the target reality one wishes to capture or affect. This is the basis of the distinction between “internal” and “external” validity. Valid research designs in the former sense are often called “reliable,” in the latter sense “representative,” but there is no general expectation that these two qualities will be positively correlated.

Types of Validity Threat in Research Design

The actual phrase *threats to validity* is a somewhat alarmist Cold War coinage from Campbell and Stanley. Campbell and Stanley had introduced the quasi-experimental design in response to demoralized education researchers who despaired of ever identifying a “crucial experiment” that could decide between rival hypotheses, each of which could claim some empirical support in explaining a common phenomenon. Campbell and Stanley concluded that such despair reflected an oversimplified view of the research situation, which demanded a more complex understanding of research design that enabled rivals to demonstrate the different senses and degrees in which all of their

claims might be true. But opening up the research situation in this fashion legitimized the loosening of the various controls associated with the experimental method, which in turn reinvented versions of the traditional problems of naturalistic observation. It was these problems that Campbell and Stanley attempted to address as threats to validity.

A survey of the 12 threats to validity enumerated in Campbell and Stanley reveals that most of them involve insensitivity to the complex sociology of the research situation. For example, research might be invalidated because the researcher fails to take into account the interaction effects between researcher and subject, the subject’s own response to the research situation over time, the subject’s belonging to categories that remain formally unacknowledged in the research situation but might be relevant to the research outcome, salient differences between sets of old and new subjects, as well as old and new research situations, when attempting to reproduce an outcome, and so on.

The quasi-experimental research design that Campbell and Stanley advocated as a strategy to avoid, mitigate, and/or compensate for such potential invalidations can be understood as a kind of “forensic sociology of science” that implicitly concedes that social life is not normally organized—either in terms of the constitution of individuals or the structures governing their interaction—to facilitate generalizable research. In effect, methodologically sound social research involves an uphill struggle against the society in which it is located and which it might subsequently improve with valid interventions. This rather heroic albeit influential premise has come under increasing pressure as insights from the sociology of science have been more explicitly brought to bear on research design. When presented as a reflexive application of the scientific method to itself, the resulting analysis can be skeptical.

Whatever practical problems are posed by the achievement of internal validity, the main theoretical problems are posed by the achievement of external validity. Here, it is useful to distinguish *ecological* and *functional* validity, the latter being external validity in the strict sense. This distinction, which was inspired by Campbell’s teacher Egon Brunswik, pertains to the respects in which one would expect or wish the target reality to resemble the original research event, typically an experiment. Ecological validity pertains to an interest in reproducing the causes and functional validity the effects. Few experiments meet the standard of ecological validity but many might achieve functional validity if they can simulate in the target environment the combination of factors that had produced the outcome in the original experiment. The key epistemological point made by dividing external validity in this

fashion is that experiments might provide valid guides to policy intervention without necessarily capturing anything historically valid about the underlying causal relations.

This point bears on Augustine Brannigan's skepticism concerning Stanley Milgram- and Phillip Zimbardo-style experiments that demonstrate the relative ease with which subjects will submit to authority and torture their fellows. Brannigan doubts that they provide the basis for inferring some deep, perhaps genetically based moral deficiency in *Homo sapiens*. Although his skepticism is probably warranted with respect to any questions of evolutionary psychology, it is equally probable that those experiments could provide—if they have not already—the basis for re-creating the outcomes in such nonresearch settings as the gathering of intelligence from potential enemies. This would provide a vivid example of an experiment manifesting functional validity yet lacking ecological validity.

This divided verdict on the external validity of experiments is also familiar from economics, especially thought experiments about what the ideal rational agent *Homo oeconomicus* would do under various hypothetical conditions. On this basis, Karl Menger, who brought the marginalist revolution in economics to the German-speaking world, sharply distinguished between the rationality of *H. oeconomicus* and the imperfect rationality of real economic agents. The phrases *normative* and *positive* economics were invoked to stress the gulf between these two states. Clearly, *H. oeconomicus* was not an ecologically valid construct. But additionally, and more importantly from a policy standpoint, Menger held that the interconnectedness of markets and the unique array of forces influencing each agent's decision making meant that even claims to functional validity could never be achieved, certainly not at the macroeconomic level. Such skepticism underwrites the continued aversion of the libertarian Austrian school of economics to the use of statistics as a basis for major policy interventions, as notably expressed by the opposition of Menger's disciple Friedrich Hayek to Keynesianism.

When compared with the methodological scruples displayed in these social science discussions of external validity, the natural sciences seem downright speculative. Take biological research done under the Neo-Darwinian paradigm. Whereas Charles Darwin himself was interested in reconstructing the Earth's unique natural history, Neo-Darwinists are mainly concerned with demonstrating evolution by natural selection as a universal process. Thus, since the 1900s the center of gravity of biological research has migrated from the field to the laboratory. In Neo-Kantian terms, this results in a tension between idiographic and nomothetic

modes of inquiry. However, Neo-Darwinian biologists rarely register the tension as such. Rather, they routinely treat contemporary laboratory experiments as models of causal processes that repeatedly happened to a variety of species in a variety of settings over millions, if not billions, of years. But if Milgram's or Zimbardo's experiments fail to model causal processes across human cultures and human history, there should perhaps be even less grounds for believing that Neo-Darwinian experiments succeed in their even more heroic generalizations across species and eons.

Whereas most threats to validity pertain to the generalization of a single research event, the phrase can be understood in both more macro and micro terms. Macro-threats to validity derive from what logicians call the fallacies of composition and division. In other words, properties of the parts might be invalidly projected as properties of the whole and vice versa. Economists following Menger's lead were especially sensitive to the fallacy of composition, because individuals who act on their own sense of self-interest routinely generate both positive and negative unintended consequences that constrain a society's subsequent range of action. Conversely, it is equally fallacious to infer that a society's overall strength or weakness is caused by some particular strength or weakness in each or most of its members. Thus, those who stress ideological change as a vehicle of social reform are often guilty of the fallacy of division. But at the ultimate microlevel—namely, inferences that a single individual makes from psychological states to epistemological judgments—a still underappreciated source of invalidity is the tendency to use the ease and/or vividness of one's response or recall as a basis for inferring its representativeness of a larger reality it purports to address.

THURSTONE SCALING

From the perspective of a person whose attitudes, behaviors, or knowledge are being assessed with a survey of some sort, an attitude scale might seem little more than a series of questions or statements (stimuli) to be answered. For a researcher, however, the instrument used to gather these data is the end product of a process involving considerable reflection on a psychological construct of interest and culminates in a grouping of items that provide material information about people's beliefs and opinions. The process of psychological scaling itself is the measurement and quantification of attitudes, attributes, or traits, and many approaches to this process are available to researchers that vary with respect to both theoretical underpinnings and how they are applied in practice. Among these is the Thurstone approach, which can be counted among the first formal techniques for attitude measurement.

First theorized by Louis L. Thurstone in the 1920s, Thurstone scaling locates stimuli on a psychological dimension of interest, and then, as individuals respond to the statements that make up a psychological instrument, those people are also located on the continuum of the construct being measured. In this way, Thurstone scaling is typically referenced as an example of the two-step process known as stimulus then person scaling.

At the outset, Thurstone's methodology began with the law of comparative judgment and led to the development of the methods of equal-appearing intervals and successive intervals (the latter was developed in

collaboration with Allen Edwards). In this entry, a general overview of Thurstone's methods is provided, and modern applications of the fundamentals of the Thurstone scaling approach are described as well.

Two-Step Scaling and the Thurstone Approach

As in any scaling exercise, the beginning step is to operationalize the construct of interest and several statements that help to define that attitude such as beliefs, feelings, and/or behaviors are written. These must be reviewed by judges (in this case, the participants in a scale development study) in the first part of the two-step approach to scaling. The goal of this step is not to obtain the actual opinions of the participants toward the construct of interest. Rather, what are needed here are their judgments about the favorableness of those statements on that construct, to identify how items differentially reflect specific levels of an attitude or trait. Typically, many more statements than are strictly necessary are written, as some winnowing of statements might occur in the scale development process to create the final measurement instrument from the assortment of scaled stimuli.

Next, taking the statement ratings across judges, the stimuli can then be sequenced on a subjective continuum from least to most favorable. Positions on this continuum should span the full range from strongly negative through neutral to strongly positive. Then, for the last piece of scale assembly, the statements to be included are deliberately sequenced in no particular order; that is to say, they are not sorted by their scale values.

Once the scale is assembled in this manner, the second step of scaling occurs through administration of the scale itself, as people's endorsements (or not) of the statements on the scale allow for positioning the respondents to the survey on the attitude continuum. The attitude score for a person is the mean (or median) scale score of the stimuli that the individual agreed with. An important point to be made here is that the actual *scaling* portion of Thurstone scaling in fact references three distinct approaches to the judges' task of rating the stimuli, as described below.

The Law of Comparative Judgment

This first approach to scaling the statements by way of judges' ratings is the law of comparative judgment, which more aptly describes a model rooted in the notion of comparisons between two stimuli at a time. This was originally conceptualized as involving physical entities (such as handwriting specimens), but was

subsequently generalized by Thurstone to psychological qualities.

In this method, each entity or stimulus is compared with each and every other item; hence, it is also referenced as pairwise comparisons. As a part of scale development, the comparative judgment technique depends on judges' determinations of which of each pair of stimulus statements belong above the other (e.g., more favorable toward the attribute being measured). The kinds of judgments made are described by Thurstone as any qualitative or quantitative attribute for which we can think "more" or "less" for each specimen.

Once the judges' ratings are made, the scaling task uses proportions to rank statements. Proportionally, the more often a statement is deemed to be more favorable than another determines the distance between the statements; thus, the scale emerges through the rating data based on the perceived differences among the entire collection of items, and it is obtained through the complete series of paired comparisons. Statistically, the scale value for each statement is obtained using these proportions and the standard errors of observations. An illustrative example of this computation is provided in Thurstone's writings on paired comparisons, particularly his 1927 article in which 266 students were asked to judge 19 crimes on a scale of seriousness. Rape, then homicide, was judged to be the most serious, whereas vagrancy was considered the least-serious offense.

Recognizing that a scale is an artificial construct created through the presentation of stimuli that are not fixed but might exhibit small fluctuations in their values from presentation to presentation, one assumption in Thurstone scaling is normality, in the sense that the distribution of judgments on the judgment dimension is normal for each stimulus and centered on the stimulus's scale value, not that the stimuli themselves are normally distributed. Indeed, Thurstone's *discriminal process* can be viewed as a conceptual analog of a random variable in current research methods.

It should be noted that comparative judgment in some applications can be cumbersome in practice depending on the pool of stimulus items that must be reviewed in this pairwise approach, because with n statements, the number of pairs is computed as $[n(n-1)]/2$. If a final scale of 20 to 25 items is needed, then the number of comparisons is considerable. A 25-item scale minimally requires 600 paired judgments from each judge, if exactly 25 stimuli are tried out; of course, sometimes scale developers expect a scale to undergo some refinement by way of item selection and will try out more stimuli than they might use in practice. Thus, if the comparative judgments technique is used, it translates into more statements

and more judgments. Across all judges, the proportion that a given statement is judged more favorable than its mate in each comparison allows the scale developer to position items on the scale.

Method of Equal-Appearing Intervals

The scaling task for this Thurstone scaling method is considerably different from that in the comparative judgment approach. This method is a sorting task in which the judges are instructed to consider each stimulus independently and then assign a value to each stimulus on a scale of 1 to 11, with one end of the scale set to "less favorable" and the other end anchoring "more favorable." Again, the judgment of interest is not the judges' own agreement/disagreement with the stimuli, but rather it is the extent to which each stimulus indicates that the future respondent possesses a large or small quantity of the quality being measured. For example, a rating of 1 for an item to be used on an instrument measuring misogyny might indicate that the person has a low amount of negative feelings toward women, whereas an 11 would correspond to a high level of misogynistic attitude.

By arranging the stimuli in this way, each judge creates 11 "piles" or intervals, and it typically results in intervals that to each judge appear to be more or less equal in width. There is some question whether judges are instructed that the intervals are equal or not, as Thurstone's first writings on this method are silent on the issue but in later works Thurstone is clear that it was an explicit instruction. Whether overtly said or not, the assumption underlying this approach is that the intervals are equal, which permits the scale developer to set the width of each interval to 1 and to assign a sequential value to each interval, from 1 to 11. Obtaining the median score of the judges' ratings for each stimulus then completes the scaling task.

Method of Successive Intervals

Successive intervals scaling was subsequently developed as a response to the imperfect assumption underlying the equal-appearing intervals approach; as it turned out in practice, the scale intervals were not equal, with more stimuli located at the ends of the continuum and fewer in the middle. This scaling method follows much of the same path as equal-appearing intervals, in that the rating/sorting task is the same. However, instead of adhering to an advance belief that the intervals are equal to one another these intervals can be empirically estimated by using Thurstone's earlier assumption about the normality of the judgments for each stimulus. This method was first described by

Milton Saffir, and later by Allen Edwards and Thurstone, among others.

As with equal-appearing intervals, the successive intervals approach begins with the simple proportions of interval judgments for each item. Next, the cumulative proportions of judgments for all items are provided. These cumulative proportions can then be represented by z score values via the use of a lookup table to create a matrix of z scores. The z scores in these cells are in effect boundaries of the intervals, and by subtracting the values in adjacent cells, it is possible to estimate interval widths. Whereas the equal-appearing intervals method sets this value as 1, in reality, these widths can vary considerably.

When these data are taken with the data for all items in the stimulus pool for a given instrument, by working in columns, the mean interval width can be computed for each interval, thus defining a scale for the intervals. To obtain the scale values for individual items, the scale must first be centered. A simple way to do this is to compute the mean of interval widths for each row and then use the row means (one for each stimulus) to work down and obtain a mean of the row means. That value can then be set as the zero point for the scale; then, by subtracting the row mean from the mean of row means, the location for each item on the scale can also be determined. Other extrapolation methods for computing interval widths and stimulus locations were detailed by Edwards in the 1950s.

Item Selection

In discussing Thurstone's scaling methods, an important consideration in scale development that warrants mention is item selection. Given the nature of the sorting task in both the equal-appearing and successive intervals approaches and that it involves judges' ratings for different stimuli, the stimuli that are preferred for inclusion on the final version of the instrument are those with a high level of agreement among judges. Greater dispersion among the judgments might be an indicator that the stimulus is ambiguous to the judges (and potentially the respondents as well). Thurstone and Ernest Chave in collaboration suggested that the interquartile range could be used as an indicator of the level of dispersion.

A second consideration in this regard is to ensure that the items included on a scale appropriately differentiate between respondents with low and high amounts of the quality of interest. If a stimulus does not discriminate between respondents in this way, then it does not contribute unique measurement information about respondents to help locate them on the continuum of the attribute being assessed. For scale developers, item

discrimination in the Thurstone sense can be evaluated by looking at the probability of agreement with the stimulus items conditional on attitude scores across the scale. This operative characteristic curve can be plotted graphically and reviewed.

Modern Applications

The Thurstone scaling approaches detailed here have been in use since the 1920s, and in that time, these methods have helped shape the practice of modern psychometrics significantly. Beginning with his 1925 paper "A Method of Scaling Psychological and Educational Tests," Thurstone's thinking about attitude measurement was also applied to the realm of educational assessment, considering test items that can be graded as right or wrong, and for which separate norms are to be constructed for successive age or grade groups.

Thurstone's *absolute method* for scaling items permitted scale developers to create scales that were independent of data, specifically in that the scale is independent of the unit selected for the raw scores and the shape of the distribution of the raw scores. His 1925 paper illustrated how the method could be used for scaling tests across successive age groups (a practice now commonly referred to as vertical equating). This approach assumes that a normal distribution of the construct being measured within an age/grade group, and each item can be placed on the scale such that the probability of correct responses is equal to the probability of incorrect responses (in effect, as described by Wendy Yen, the p value for each item is transformed to a z value using the inverse cumulative normal function). Thurstone's methods were employed a great deal by many educational testing agencies in the second half of the 20th century.

These theoretical developments that occurred throughout the 1920s to conceptualize persons and items on the same scale with regard to an underlying psychological construct (often referred to as a latent trait in the item response theory [IRT] context) helped to pave the way for modern psychometrics, and this is particularly apparent in the connections that can be found between Thurstone's work and IRT. The relationship between the Thurstone approach to vertical scaling and scaling using a three-parameter IRT model is strong, particularly with respect to the normality and equal interval assumptions found in Thurstone scaling. Thurstone's philosophy of measurement is also considered to have contributed to the foundation of the Rasch IRT tradition for assessment.

Empirical analyses comparing the distribution of performance across grade levels as produced by Thurstone and IRT scaling have also been carried out. In

this research, one quality of Thurstone's scaling that was specifically studied was the finding that variability of performance tended to increase with age under Thurstone's method, in contrast to IRT, where decreasingly variability was often observed. The results indicated that the two approaches yielded reasonable consistency in growth trends. Other researchers who examined Thurstone scaling in relation to one and three-parameter IRT models also found increased variability as grade levels increased.

Conclusion

Thurstone scaling represents a family of approaches to quantifying psychological qualities, and the idea that "attitudes can be measured," as Thurstone wrote in 1928, was a significant part of a movement that transformed not only psychology but also educational assessment. The principles underlying his scaling theory emerged at a time when the idea of objective mental measurement itself was being formalized by Thurstone and others, and thus his contributions in this regard to modern psychometrics are undeniable.

In the intervening years since these methods were first established, Thurstone himself and others have identified some modifications and limitations to them. For example, as noted previously, the scope of the task in the paired comparisons method is one obstacle to its use when the number of stimuli might be large. The main underlying assumption of equal-appearing intervals has been found to not be supported through research, and therefore the results obtained through that method might not be as robust as they might have appeared. Last, whereas Thurstone approaches account for random variation through the idea of the discriminial process, some questions have been raised about the potential for systematic variation to emerge through the judges' ratings. Those ratings themselves might be systematically biased by the judges' own attitudes, and the possibility exists that those biases could impact the scaling in a way that might not be accounted for by Thurstonian logic.

Ultimately, as an approach to scaling, Thurstone's work serves as one strategy among many that offers scale developers with a process for formally quantifying information that was once not thought possible. The balance of sophistication and elegance in his original conceptualizations is considerable, and Thurstone scaling methods are valued for their substantial contribution to psychometrics.

TIME-LAG STUDY

A time-lag study examines the responses of different participants of similar age at different points in time. Time-lag is one of the three methods used to study developmental and generational change. The other two methods are a cross-sectional study (which examines participants of different ages at one point in time) and a longitudinal study (which examines the same participants as they age). This entry first examines the types of differences these methods assess; then, it describes the possible confounds and the procedures to follow to perform a time-lag study. Last, this entry briefly discusses the future of time-lag studies.

Differences

These methods assess three types of differences: age differences (a result of development), generational

differences (a result of generational succession), and time period (a result of historical events that affect all generations equally). Longitudinal studies, which follow a group of people of the same age over time, can determine age and time period differences (but not generation, as the participants are all the same generation). Cross-sectional studies collect data at only one time; thus, any differences could be a result of age or generation (but not time period, as the time period is the same). Time-lag studies examine people of the same age at different points in time; thus, differences could be a result of the generation or time period (but not age, as age is the same). Sequential designs are the best way to separate age, time, and cohort effects. For example, a time-lag study might study several age groups over time. However, a change across all ages, usually interpreted as a time effect, could still be a cohort effect if the cohort change has been continuing for many years. For this reason, some authors have concluded that it is impossible to completely separate age, cohort, and time effects even with sequential designs. Most researchers agree that it is most important to separate age and cohort effects, as time period is a less important effect.

Thus, time-lag studies are the best method for examining generational (or birth cohort) differences. Most research and theorizing suggest that historical events and cultural trends have the most impact on the attitudes of children and adolescents; thus, generational effects are stronger than time period effects. For example, the large changes in sexual attitudes and behavior found in a time-lag study headed by Brooke Wells are primarily driven by generational change, as people tend not to change their views on sexuality much once they are past young adulthood.

Time-lag studies illustrate how historical changes in culture affect individuals. Recent research and theory in psychology have recognized that environments vary between countries and regions, producing differences in personality, emotion, perception, and behavior. Environments vary over time and generations in a similar way (for example, the United States in the 1950s was a different environment than the United States in the 2000s). The time-lag method makes it possible to study generational change scientifically, separating the effects of age and generation (as a cross-sectional study, with data collected at the same time, cannot do).

Some time-lag studies examine only two or three data points. Other studies, such as *Monitoring the Future*, *The American Freshman*, and the *General Social Survey*, collect data from participants every year for many years. For example, *Monitoring the Future* data show that 24% of high-school seniors in 1976 anticipated receiving a graduate degree, which jumped

to 50% by 2000. Time-lag methods can be used for health measures as well; one time-lag study found that tooth loss among older people was primarily explained by cohort rather than age or time.

A method called cross-temporal meta-analysis modifies the time-lag method by gathering mean responses on psychological scales from journal articles and unpublished dissertations using many data points (always more than 10, and usually 50 or more). These studies examine data separately by age group (e.g., college students and middle school students), analyzing whether the means differ by the year of data collection. For example, one study examined whether scores on the Narcissistic Personality Inventory had changed over time. The analysis showed that college students' NPI scores were significantly higher in 2006 than they were in 1979. This was a time-lag study because the participants were the same age (college students) but completed the scale at different points in time (sometime between 1979 and 2006).

Confounds

Like any research study, a time-lag study must consider possible confounds. If the time of data collection and location are correlated, location (and the accompanying differences in the population) rather than time might cause any differences or suppress differences. Confounds by location are more problematic if there are only a few data points, introducing the possibility of location and year being perfectly confounded—that is, all the earlier data point(s) were collected at one location, and the later data point(s) at another location. For example, Jerry Burger's partial replication of Milgram's obedience experiment collected data on an ethnically diverse sample of men and women from California in 2006, which was different from Stanley Milgram's nearly all White sample of men only from New Haven, Connecticut, in the early 1960s. Thus, the differences, or in this case lack thereof, might have been caused by sample differences in gender, ethnicity, or location. Another study found that college students' narcissism scores were flat in 8 samples from University of California campuses; however, the first 2 samples (in 1982 and 1996) were from one campus, and the later samples (2002–2007) were from another. Thus the change in location might have obscured any change. When the 2002–2007 samples from one campus were examined, they showed an increase in narcissism scores similar to that found in a nationwide analysis.

Changes in the population sampled can also cause problems. More women have attended college over time, so an increase in the mean score of anxiety

measures for college students could have been caused by more women in the samples, as women score higher on measures of anxiety. In a time-lag analysis of anxiety scores, men's and women's data were analyzed separately and still showed the effect, so in this case, there was a cohort effect apart from the confound.

Procedures

There are three primary ways to do a time-lag study. The first requires patience: One can collect data from a sample (preferably of the same age or with many people from every age group) and then wait to collect more data—either every year or after the desired interval. Researchers will sometimes compare recent data with data they have collected earlier in their careers. This strategy has the advantage of openness of research question: One can ask the questions desired. Second, researchers can draw from one of the large time-lag studies such as the General Social Survey. The advantage is that the data have already been collected back in time; the disadvantage is one must make do with the questions in the survey. Another advantage is that many of these large projects attempted to obtain nationally representative samples.

The third choice is to conduct a cross-temporal meta-analysis, gathering mean scores on psychological scales. This type of study can be conducted at one time, but gives a historical view through other researchers' reports. There is some restriction on the characteristics to be examined; the scale(s) must have been used by many researchers, and the mean scores must have been reported by many of them, over a good span of time (at least 10 years, and preferably 20 or more). To do a cross-temporal meta-analysis, the first step is to choose a scale measuring the desired concept and search the Web of Science citation index or a similar database to determine whether enough studies have been published that cite the main source for the scale (at least 100 is a good rule of thumb). One then obtains the full text of these articles (and of dissertations using Digital Dissertations) and records the mean score, standard deviation, year of data collection, n , and characteristics of the sample (gender, ethnicity, location, etc.). Analyses are performed split by age group (e.g., middle school, high school, and college students), as a time-lag study must use respondents of the same age. A regression is then performed with year as the independent variable, mean as the dependent variable, and n of each sample as the WLS weight (WLS stands for Weighted Least Squares, but most statistical programs list it simply as WLS). If the regression is significant, then an additional step must be taken to calculate the effect size: Multiply the unstandardized B by the number of years examined (e.g., 20 for 1985–2005) and divide by the mean standard deviation from the samples.

This technique avoids the ecological fallacy (also known as alerting correlations), which occurs when an effect size relies on the standard deviation of a group of means (which is smaller) rather than the standard deviation of a group of individuals (which is larger). Because this method uses the standard deviation given in the samples—and thus the standard deviation of a group of individuals—it avoids the ecological fallacy.

Time-lag studies can also examine how traits and attitudes differ along with specific aspects of an historical period. For example, to determine whether children's anxiety is correlated with the overall divorce rate, social statistics (e.g., the divorce rate) are used in place of the year of data collection in an analysis. These analyses cannot prove causation, but they can show what social trends occur at the same time as shifts in personality traits and attitudes. Analyses can also use the responses of other time-lag studies; for example, materialism measured by the American Freshman survey is correlated across time with symptoms of depression and anxiety as measured by the Minnesota Multiphasic Personality Inventory.

Future Directions

Although more research is emerging on generational change, a great deal remains to be done. Exactly how cultural change occurs is a fascinating and mostly unanswered question. The studies that attempt to address cultural and generational change in the future will most likely rely on the time-lag method.

TIME-SERIES STUDY

Time-series analysis (TSA) is a statistical methodology appropriate for longitudinal research designs that involve single subjects or research units that are measured repeatedly at regular intervals over time. TSA can be viewed as the exemplar of all longitudinal designs. TSA can provide an understanding of the underlying naturalistic process and the pattern of change over time, or it can evaluate the effects of either a planned or unplanned intervention. The advances in information systems technology are making time-series designs an increasingly feasible method for studying important psychological phenomena.

Modern TSA and related research methods represent a sophisticated leap forward in the ability to analyze longitudinal data. Early time-series designs, especially within psychology, relied heavily on graphical analysis to describe and interpret the results. Although graphical methods are useful and provide important ancillary information, the ability to bring a sophisticated statistical methodology to bear has revolutionized the area of single-subject research.

TSA was developed more extensively in areas such as engineering and economics before it came into widespread use within social science research. The prevalent methodology that has developed and been adapted in psychology is the class of models known as Autoregressive Integrated Moving Average (ARIMA) models. TSA requires the use of high-speed computers; the estimation of the basic parameters cannot be performed by precomputer methods.

A major characteristic of time-series data is the dependency that results from repeated measurements over time on a single subject or unit. All longitudinal designs must take dependency into account. Dependency precludes the use of traditional statistical tests because they assume the independence of the error. ARIMA models have proven especially useful because they provide a basic methodology to model the dependency from the data series and allow valid statistical tests. This entry discusses several aspects of TSA, including its application in research, modeling procedures, weakness and confounders, and the use of telemetrics in TSA.

Research Applications

As the methodology for TSA has evolved, there has also been increasing interest among applied researchers. Many behavioral interventions occur in applied settings such as businesses, schools, clinics, and hospitals. More traditional between-subject research designs might not always be the most appropriate, or in some instances, these designs can be very difficult to implement in such settings. In some cases, data appropriate for TSA are generated on a regular basis in the applied setting, like the number of hospital admissions. In other cases, a complete understanding of the process that can explain the acquisition or cessation of an important behavior might require the intensive study of an individual during an extended period of time. Advances in information systems technology have facilitated the repeated assessment of individuals in natural settings. In addition, there has been increasing concern about

Figure 1 Smoking Behavior Measured on 124 Occasions: An Example of Time-Series Data for a Single Individual

the appropriateness of group methods based on the ergodic theorems. The ergodic theorems state that an analysis of the interindividual variation yields the same results as an analysis of intra-individual variation only if the trajectory of each subject obeys the same dynamic laws (i.e., the same autocorrelation structure), and each individual trajectory has the same statistical characteristics (i.e., equal mean level and temporal pattern).

Several important classes of research questions can be investigated using time-series data. The first class involves using ARIMA modeling to investigate the naturalistic process of change across time. Investigations of this type focus on the dependency parameters and attempt to identify the underlying nature of the series. Figure 1 illustrates time-series data for an individual smoker with no intervention attempted. The data are the number of cigarettes smoked during an 8-hour period for a single individual (two periods per day).

A second important class of research questions involves the analysis of the effects of an intervention that is applied to an individual subject or unit. Such an investigation is commonly referred to as an *interrupted time-series analysis*. The *interruption* refers to the intervention that is applied at some fixed point in a process. Repeated measurements are taken before and after the intervention to evaluate the effects of the intervention. Such investigations can be very useful in trying to understand causality within the process and as a result of the intervention.

A third class of research questions involves the pattern of change over time. These patterns can be varied, and some questions that can be investigated in this context include the following: (a) Are the effects of intervention temporary or permanent, (b) does the intervention cause a change in the "slope" of the behavior process as well as the overall level, (c) does the intervention cause a change in any cycle that is present in the underlying behavior process, (d) does the intervention cause the variance to change, and (e) does the intervention cause a change in the nature of the dependency?

A fourth class of research questions involves forecasting future values of the series. This strategy is primarily used in economics.

Caveats

Several difficulties and weaknesses associated with standard TSA must be recognized. First, generalizability should not be inferred from a single study. The researcher needs to engage in systematic replication to demonstrate generalizability. Second, the traditional measures employed in cross-sectional studies in many content areas might not be appropriate for time-series designs.

For TSA, the best measures are those that can be repeated a large number of times on a single subject at intervals of short duration. Third, many equally spaced observations are required for accurate model identification, which is a necessary step for identifying basic processes.

ARIMA Modeling Procedures

TSA, within the ARIMA model framework, involves two important steps that can vary in importance depending on the goals of the study. The first step is *model identification*, in which the researcher tries to identify which underlying mathematical model is appropriate for the data. Model identification focuses on dependency parameters.

The ARIMA model represents a family of models characterized by three parameters (p , d , and q) that describe the basic properties of a specific time-series model. The value of the first parameter p denotes the order of the autoregressive component of the model. If an observation can be influenced only by the immediately preceding observation, then the model is of order one. If an observation can be influenced by the two immediately preceding observations, then the model is of order two, and so on. The value of the second parameter d refers to the order of differencing that is necessary to stabilize a nonstationary time series. A process is described as nonstationary when the values do not vary about a fixed mean level; rather, the series might first fluctuate about one level for some observations and fluctuate about a different level. The value of the third parameter q denotes the order of the moving average component of the model. Again, the order describes how many preceding observations must be taken into account. Higher order models (p or $q > 3$) are rare in the behavioral sciences.

Dependence is assessed by calculating the values of the autocorrelations among the data points in the series. In contrast to a correlation coefficient, which is used to estimate the relationship between two variables measured at the same time on multiple subjects, an autocorrelation estimates the relationships within one variable measured at regular intervals over time on only one subject.

The direction of dependency in a time series refers to whether an autocorrelation is positive or negative. The direction can be determined with a high degree of accuracy when there is strong dependency in the data and the direction has clear implications. When the sign of the autocorrelation is negative, a high level for the series on one occasion predicts a lower level for the series on the next occasion. When the sign is positive, a high level of the series on one occasion predicts a higher level on the next occasion.

Figure 2 Correlogram of the Autocorrelations and Partial Autocorrelations for the Smoking Data Example

The calculation and interpretation of the pattern of the related partial-autocorrelations calculated at each lag is employed as a second diagnostic step to aid in the identification of the specific ARIMA model. Partial-autocorrelations are mathematically complex and will not be formally defined here. Figure 2 illustrates the autocorrelations and partial-autocorrelations for the data from Figure 1.

Figure 3 illustrates four different types of models using computer-generated data for 60 observations before an intervention and 60 observations after the intervention. The first graph (a) represents an ideal interrupted time-series example initially at level = 5.0 with no error and an immediate change in level of 2.0 units at the time of intervention. The next three graphs represent an order 1 autoregressive model [ARIMA (1, 0, 0)]. The second graph (b) adds random error with a variance of 1.00. There is no autocorrelation in this model. The third graph (c) is the same change in level and error variance as (b) but with a large *negative* autocorrelation (-0.80). The fourth graph (d) is a model with the same change in level and error variance but with a large *positive* autocorrelation ($+0.80$). The impact of dependency can be easily observed. The negative dependency results in an exaggerated “saw tooth” graph with increased apparent variability. The positive dependency results in a smoother graph with apparent decreased variability. The inclusion of an intervention effect (the change in level) illustrates how difficult it is to determine whether an intervention had an effect by visual inspection alone.

Interrupted Time-Series Analysis

Often, the goal of research with single subjects or units is to determine the efficacy of a specific intervention. This can be accomplished by employing various techniques that fall under the nomenclature of interrupted time-series analysis. A simple example of an interrupted TSA is a design that involves repeated and equally spaced observations on a single subject or unit followed by an intervention. The intervention would then be followed by additional repeated and equally spaced observations of the subject or unit. The intervention could be an experimental manipulation, or it could be a naturally occurring event. To determine whether the intervention had an effect, preprocessing of the data series to remove the effects of dependence is needed. The actual statistical analysis used in an interrupted TSA employs a general linear model analysis using a generalized least-squares estimator.

If the intervention effect is found to be statistically significant, then a related question concerns an evaluation of the nature of the effect. One great advantage of TSA is the ability to assess the pattern of the change over time, which can involve both a change in the mean level of a measured dependent variable and/or a change in the slope over time of the dependent variable.

The most common methodology for interrupted TSA is the Box-Jenkins procedure, which is a two-step process. The first step is determining which ARIMA model fits the data, and the second step is the analysis of the effects of the interruption. Model identification

Figure 3 Computer-Generated Data for ARIMA (1, 0, 0) Models for Level = 5.0 and Change in Level = 2.0 for Four Time Series Illustrating Different Degrees of Dependency

is necessary to determine the specific transformation matrix to be used to remove the dependency from the data series.

The general linear model (GLM) is an approach to data analysis that includes many familiar statistical procedures as special cases. In algebraic terms this can be expressed as

$$\mathbf{Z} = \mathbf{X}\mathbf{b} + \mathbf{a}. \quad (1)$$

In a multiple regression analysis, the $\mathbf{X}$ matrix contains the numeric observations for each of the p predictor variables for the N subjects, the $\mathbf{Z}$ vector contains the criterion scores for the N subjects, the $\mathbf{b}$ vector contains the regression weights, and the $\mathbf{a}$ vector contains the error of prediction and represents the difference between the actual score on the criterion and the predicted scores on the criterion. In an analysis of variance, the $\mathbf{X}$ matrix would consist of indicator variables, such as the numeric values “1” or “0,” which indicate group membership, and the $\mathbf{Z}$ vector contains the dependent variable observations.

For both of these examples, the estimates of the parameters are

$$\mathbf{b} = (\mathbf{X}'\mathbf{X})^{-1}\mathbf{X}'\mathbf{Z}. \quad (2)$$

For TSA, the parameter estimates include a lower diagonal transformation matrix. The exact nature of the transformation matrix is determined by the model identification step. The parameter estimates are now

$$\mathbf{b} = (\mathbf{X}'\mathbf{T}'\mathbf{T}\mathbf{X})^{-1}\mathbf{X}'\mathbf{T}'\mathbf{T}\mathbf{Z}. \quad (3)$$

For example, an ARIMA (1, 0, 0) model with five observations would have the following transformation matrix:

$$\mathbf{T} = \begin{bmatrix} 1 & 0 & 0 & 0 & 0 \\ \phi_1 & 1 & 0 & 0 & 0 \\ 0 & \phi_1 & 1 & 0 & 0 \\ 0 & 0 & \phi_1 & 1 & 0 \\ 0 & 0 & 0 & \phi_1 & 1 \end{bmatrix}, \quad (4)$$

which indicates that only the previous observation is necessary to explain the dependency in the data. The GLM can be viewed as a special case of the more general time-series model.

For an interrupted TSA, there are typically four parameters of interest, which include the level of the series (L), the slope of the series (S), the change in level (DL), and the change in slope (DS). The slope parameters represent one of the other unique

characteristics of a longitudinal design, the pattern of change over time.

Figure 4 illustrates eight different outcomes for a simple one-intervention design. By inspecting the different patterns of change over time, it can be observed

Figure 4 Examples of Eight Different Patterns of Intervention Effects

that selecting different points in time for the single assessment would result in different conclusions for four of the examples (c, f, g, and h). For instance, ignoring the slope in (c) would lead the researcher to conclude incorrectly that the intervention was effective. The evolutionary effect (h) is a good example of where the intervention results in a temporary negative effect, perhaps while a response pattern is unlearned, followed by a positive effect. An early assessment would conclude that the treatment had a negative effect; a somewhat later assessment would find no treatment effect, whereas an even later assessment would find a positive treatment effect.

Although it is the most prevalent time-series methodology, the Box–Jenkins approach to intervention analysis suffers from several difficulties. First, gathering the number of data points required for accurate model identification is often prohibitive for research in applied settings. Second, even with the required number of data points, correct model identification is problematic. Third, the method is complex, making applications by the mathematically unsophisticated researcher difficult. Three alternative approaches are described in the next section, all of which attempt to avoid the problematic model identification step.

Dean Keith Simonton proposed a procedure that uses an estimate of the variance-covariance matrix based on pooling the observations across all subjects observed. This approach requires a basic assumption, namely that all series are assumed to be an ARIMA (1, 0, 0) model. While this assumption seems to be theoretically indefensible, empirical investigations indicate that this procedure works well in a wide variety of cases. James Algina and Hariharan Swaminathan have proposed an alternative in which the sample variance-covariance matrix is employed as an estimator for $T'T$ in the modified least squares solution. This approach, however, requires the assumption that the number of subjects is greater than the number of observations per subject, a condition unlikely to be met in most applied research settings. Wayne Velicer and Roderick McDonald have proposed the use of a *general* transformation matrix with the numerical values of the elements of T being estimated for each problem. The rationale is that all transformation matrices T have an identical form and use a lower triangular matrix with equal subdiagonals. Weight vectors with five nonzero weights were found to be accurate for most cases. More weights can be employed where indicated by appropriate diagnostics.

Generalizability Issues

One issue involved in TSA is generalizability, that is, determining how the results from a single individual or

unit can be generalized to a larger population. Although generalizability might not always be the primary goal for time-series studies, it can be explored fruitfully using the following methods.

One approach is *systematic replication*, which relies on logical inference rather than formal statistical inference. A weakness of this approach is that the judgment of the reviewer plays a critical role in the conclusions reached.

Two quantitative approaches have been developed that combine multiple replications of a time-series study. A *pooled time-series analysis* involves the direct combination of the data from different time-series studies. In this section, only one approach is described, an extension of the general transformation approach. This method uses a patterned transformation matrix, where a single vector represents observations of all the units. This vector contains the set of subvectors for the individual units combined in the form of a single vector. A properly parameterized design matrix permits comparisons among different units. The basic form of the design matrix should be based on the analyses of the individual units and/or a priori knowledge.

An alternative procedure to combining data from several individuals or units is *meta-analysis*. Procedures for performing a meta-analysis have been well developed for traditional experimental designs. However, meta-analysis procedures have not been widely applied to single-subject designs. A problem is developing definitions of effect size that are appropriate for time-series data.

Multivariate Time-Series Analysis

A time-series analysis on a single dependent measure involves many procedures common to multivariate statistics because the following two vectors of unknowns must be estimated simultaneously: (1) the vector of parameters and (2) the vector of dependency coefficients. However, when assessing a single unit or subject on multiple occasions, two or more variables can be observed on each occasion. The term *multivariate time series* is used here to denote the observation of more than one variable at each point in time. The variables might be viewed conceptually as including both dependent and independent variables, or multiple dependent variables. If some of the observed variables are independent variables, then the appropriate analysis is the time-series equivalent of an analysis of covariance. In time-series designs, there are two unique problems. First, the investigator must determine the appropriate lag between the covariate(s) and the dependent variables. Second, there might be dependency present in the covariate(s), requiring a transformation before

performing the analysis. One application is to control the effects of seasonality in the data (see below).

If the variables can be viewed as a set of dependent variables (i.e., multiple indicators of one or more constructs that form the outcome space of interest), then the appropriate analysis would be the time-series equivalent of a multivariate analysis, sometimes described as dynamic factor analysis. This method involves merging the longitudinal data approaches employed in TSA with the use of latent variables or factors to organize a set of observed variables. The recently developed dynamic factor analysis permits serial dependency in the data. Dynamic factor analysis might prove especially useful to behavioral researchers interested in questions of growth or change over time, as well as the underlying processes, because complex serial relationships among variables can be explored using this methodology. One limitation to implementing a dynamic factor analysis in practice is the number of observations required to provide an adequate sample estimate of the population covariance matrices. Other issues include determining the correct number of factors to extract and determining the correct lags between the variables in the final model. However, the use of multiple indicators to measure one or more latent variables represents a promising means of extending the focus of TSA from univariate to multivariate outcome spaces.

Cyclic Data

The presence of cyclic or seasonal data is another potential confounding variable in time-series data. Daily data gathered on individuals often have a weekly or monthly cycle. The following three alternative procedures have been proposed to deal with cyclic data: (a) *deseasonalization*, which assumes that the cyclic nature of the data is well known and the data can be adjusted for seasonal effects before it is reported, based on a priori information, prior to any TSA; (b) *statistical control*, which identifies a variable that is sensitive to the same seasonal effects as the dependent measure but cannot be affected by the intervention and thus used as a covariate; and (c) *combined models*, which involve two models, one that demonstrates the dependency and a second that demonstrates the seasonal component.

Missing Data

The problem of missing data is almost unavoidable in TSA, and it presents several unique challenges. Life events will result in missing data even for the most conscientious researchers. Roderick Little and Donald Rubin provide the most thorough theoretical and

mathematical coverage of handling missing data. In an extensive simulation study, Wayne Velicer and Suzanne Colby compared the following four different techniques of handling missing data in an ARIMA (1, 0, 0) model: (a) deletion of missing observations from the analysis, (b) substitution of the mean of the series, (c) substitution of the mean of the two adjacent observations, and (d) maximum likelihood estimation. Computer-generated time-series data were generated for 50 different conditions. The maximum likelihood procedure for handling missing data outperformed all others. Although this result was expected, the degree of accuracy was very impressive. The three ad hoc methods all produced inaccurate estimates for some parameters.

Time as a Critical Variable

Another critical but often overlooked aspect of longitudinal designs is the importance of choosing an appropriate unit of time. TSA assumes that the observations are taken in equally spaced intervals. Unfortunately, very little information is available in the behavioral sciences to guide the choice of interval size. Sometimes the interval is predetermined, such as when existing data are employed. Other times, the choice of interval is determined by the convenience of the experimenter or the subject. As less obtrusive methods of data collection become available, and thus denser sampling of dependent variables are made possible, the choice of interval will be able to better reflect the needs of the research question.

The interval employed could strongly influence the accuracy of the conclusions that can be drawn. For example, in Figure 1, the choice of two 8-hour intervals (parts of the day when the subject was awake) strongly influenced the results. A negative autocorrelation of $-.70$ would become a positive autocorrelation of $.49$ if the observations had occurred once a day and $.24$ if assessed every 48 hours. In general, longer intervals can be expected to produce lower levels of dependency in the data.

If the focus is on the functional relationship between two variables, then the time interval can also be critical. If a change in X produces a change in Y with a 48-hour lag, then observations taken at weekly intervals might erroneously conclude that the variables are not related, whereas observations taken at 24-hour daily intervals would detect the relationship. Until there are adequate theoretical models and accumulated empirical findings for the variables of interest, shorter intervals will be preferable to longer intervals because it is always possible to collapse multiple observations. It is also important that any statements about the presence or degree of a relation between variables based on

autocorrelations and cross-lagged correlations always reference the interval employed.

Telemetrics

Recent advances in *telemetrics* (for a review see work by Matthew Goodwin, Wayne Velicer, and Stephen Intille)—a class of wireless information systems technology that can collect and transmit a wide variety of behavioral and environmental data remotely—permit an unprecedented amount of longitudinal data to be gathered for time-series studies. Telemetrics include “wearable computers” that weave on-body sensors into articles of clothing, “ubiquitous computers” that embed sensors and transmitters seamlessly into the environment, and handheld devices such as mobile phones and personal digital assistants that can record cognitive and affective states. With this technology, the input or signal is repeatedly assessed, quantified, and combined with timing data, resulting in a single data stream for researchers to explore.

Conclusion

Time-series analysis and telemetric monitoring have tremendous potential for enhancing behavioral science research. TSA is one of the many computational procedures that have been developed specifically for the analysis of longitudinal data since the 1970s. In fact, TSA can be viewed as the prototypic longitudinal method. The combination of computational advances and new sources of data has increased the number of potential applications. We are now reaching the point in the behavioral sciences where the data analysis method will be matched to the research problem rather than the research problems being determined by the available methods of data analysis.

Toulmin Method

The British philosopher and logician Stephen Toulmin (1922–2009) first proposed his method of argumentation in 1958 in a book called *The Uses of Argument*. Toulmin created this method as a way to understand arguments that can be used in real-world situations. His goal was to get away from the classical model of arguments based around syllogisms. It is important to note that Toulmin was not interested in arguments as they apply to scientific claims specifically. His book (and the article that inspired it) dealt mostly with legal arguments. It wasn't until the 1970s that people started applying the method to general communication theory. Even the updated version of *The Uses of Argument* (2003) does not address argumentation in the sciences. Nevertheless, the Toulmin method is useful in describing how people make scientific claims and support them with evidence, warrants, and qualifiers. This entry discusses how the Toulmin method applies to scientific research and the components of the method.

Background Information

In logic, a syllogism is a three-statement argument. The conclusion or final statement is based on the two previous and related statements. For example, (1) Socrates was a man. (2) All men are fallible. (3) Socrates was

fallible. Although there are many different types of syllogisms, the basic three-line structure is common to them all.

Toulmin was unsatisfied with the absolute nature of syllogisms as they did not reflect the real world, where arguments were often more convoluted and required more than three lines. He took the essential three parts of a syllogism and added three supporting components. The three basic elements of a syllogism relate directly to the parts of an argument called the claim, fact, and warrant. In the example used earlier, the claim is that Socrates was fallible. The fact, what we would call evidence, is that Socrates was a man. And the warrant connects the two with the idea that all men are fallible. However, real-world arguments are often more complicated.

In casual arguments, the warrant is often implied, such as in the following example. Claim: You should wash the fruit you buy at the grocery store before you eat it. Fact: Pesticides and bacteria have been found on produce at most grocery stores. The warrant (that pesticides and bacteria can make you sick) can be unstated. Good arguments take into account exceptions. In life, there are very few absolutes. We usually need qualifiers to let people know when a claim is not always true. The Toulmin method also includes backing to support the warrant and rebuttals or potential objections to the claim.

Primary Components of the Toulmin Method

In general, an argument is a sequence of statements that present evidence to support a claim or rather a statement about the natural world based on scientific observation intended to persuade another person. In addition, argument involves reasoning (using logical thinking to evaluate and explain how the evidence and methodology support or refute the claim), followed by why the claim should be accepted based on the evidence (justification). The first three parts of Toulmin's method are the primary components. They come from the syllogistic model discussed earlier. The primary components include a claim, ground (fact, evidence, and data), and warrant.

Claim

The claim is the assertion that is being made, which must be established as true. It is what the authors of a scientific paper hope to convince the audience to agree with or believe.

Ground (Fact, Evidence, and Data)

The ground is the information that is used to support and explain the claim. Modern applications of the

method use the term *evidence*, although fact and data could also be used here. In science, facts are considered to be observable, measurable, or verifiable information that is unchanging and generally accepted by the scientific community. Because claims can also be supported by information not classified as fact—information such as data gathered through new observation or experimentation; accepted theories, laws, and principles; and expert opinions—*evidence* may be a more appropriate term. This is a rather common substitution in modern applications of the method, reflecting the general change in the usage of the words *fact* and *data*. The ground (fact, evidence, and data) explains why the claim is valid.

Most of Toulmin's work was in real-world arguments and supported by a single piece of evidence. For example, "Harry was born in Bermuda (evidence); therefore, Harry is a British subject (claim)." However, most scientific arguments are not supported by just a single piece of evidence. Instead, a successful claim depends on a large amount of supporting evidence. As such, an individual claim may have many associated evidence statements or grounds.

Warrant

A warrant is a piece of essential information that connects your evidence to your claim. Warrants are often left unsaid. It is often necessary to make the warrant explicit, especially when dealing with beliefs that not everyone may share or which may be unfamiliar with the audience. Using the previous example of the need to wash fruit, the claim would be that you should wash the fruit you buy at the grocery store before you eat it. The ground is that pesticides and bacteria have been found on produce at most grocery stores, while the warrant is that pesticides and bacteria can make you sick.

If someone doesn't know that bacteria can make you sick or doesn't believe that pesticides are harmful to humans, this warrant must be made explicit in order to make the argument compelling. In most arguments made in a scientific paper, the warrant—and the accompanying backing—is where the bulk of the researched information would come in. The warrant relies on existing knowledge, which needs to be presented as factual. Most citations to other researchers' work in a paper will relate to the warrant, as the argument requires that the warrant connect the evidence presented to the claim.

Secondary Components

The final three parts of Toulmin's method are the secondary components. They supplement and support the primary components and are not present in all arguments. They include backing, rebuttal, and qualifier.

Backing

Similar to how the evidence supports the claim, the backing supports the warrant. The backing is what tells the audience that the warrant is rational. In the case of the produce example earlier, the backing would include information on the health effects of pesticides as well as the risks involved in ingesting bacteria from produce. Note that a warrant may essentially be a claim itself.

One may choose to combine the warrant and backing into a single component called *chain of reasoning*. This terminology makes the purpose of the warrant, connecting the evidence to the claim, more explicit. It also reinforces reasoning and critical thinking as the overall task of the activity. Because a claim is supported by a single evidence statement in Toulmin's method, there is a warrant associated with each piece of evidence. To simplify the concept, a more holistic application is presented in the chain of reasoning. Rather than having a warrant and backing for each evidence statement, one could describe generally what kinds of warrants are present in the chain of reasoning. Is the evidence supported mostly by (1) the authority of experts, (2) the application of scientific theory, or (3) the use of logical arguments such as analogies or cause and effect?

Rebuttal

Rebuttals are potential objections to the claim. As any debater knows, it is often helpful to demonstrate that you have considered oppositions to your own assertion, which shows that you are aware of the limitations and nuance in your position. Rebuttals make a claim more complete. For example, a claim with a rebuttal might be, "You should wash the fruit you buy at the grocery store before you eat it but not with soap or detergent." As acknowledged by this rebuttal, soap and detergent are not approved washing methods, as residues from soap or detergent could be ingested if absorbed on the produce.

In an academic paper, scientific researchers are expected to offer their own thoughts about limitations to their claim and ask new questions for further research. However, when people are exposed to scientific claims in the media, these rebuttals are left out. In these cases, the audience is left with additional questions or concerns that were not present in the claim. The rebuttal stage is often presented separately from the claim and evidence rather than as an integral part of the claim.

Additionally, Toulmin's method was predicated on the idea that the evidence was true and correct (remember, he called it *fact*). In scientific arguments, very often, the evidence is invalid, unreliable, or biased. Therefore, rebuttals are often split into two related ideas. Rebuttal could specifically refer to an assertion that the evidence

is incorrect and does not support the claim. There could also be a counterargument to refer to the assertion that the evidence may be correct but that it is being misapplied and does not support the given claim. One could be given sample rebuttals and counterarguments and asked whether they are significant enough to cause one to reconsider the claim. It is a combination of the strength of the evidence, the chain of reasoning, and the rebuttals or counterarguments that one will use to decide whether they will accept the claim, reject the claim, or withhold judgment for later.

Qualifier

Qualifiers allow you to add specificity to your claim, making it more stable and less susceptible to rebuttals. Most of the time, qualifiers limit the claim using words such as *mostly*, *may*, *often*, *some*, and the like. Some people refer to these as *weasel words*. Rarely, qualifiers strengthen a claim with words like *always* or *never*. Qualifiers often take the rebuttal into account by acknowledging the limitations that the rebuttal makes explicit. For example, a claim with a qualifier might be, "You should wash most fruit you buy at the grocery store before you eat it." This qualifier, using the word *most*, makes the claim more stable and less susceptible to rebuttals.

TRANSPARENCY

Transparency refers to the accuracy and extensiveness of the information provided to readers about the research process and the presentation of its results in a

scientific publication. It is a key element both for qualitative and quantitative research design.

This entry first explains how the relationship between transparency and scientific ethos has been addressed by positivism and hermeneutics, the two main paradigms in the social sciences. Second, it highlights the uneven development of the debate about transparency in different disciplines. Finally, this entry considers the issue of transparency from the perspective of scientific publications.

Transparency and the Scientific Ethos

The transparency of a research design concerns the open or conditioned accessibility to all of its phases: problem definition, selection of indicators, sampling procedures, inclusion criteria, time, space and quality of data collection, coding procedures, methods and tools of analysis, and presentation of results. Transparency also regards the sources of funding for a given research and the topic selection processes implemented by publishers. A transparent research design helps other scientists to replicate one empirical work. Thus, there is a strong link between transparency on one hand and reproducibility, verifiability, and falsifiability on the other hand. Transparency is a precondition of open science and communist ethos in the terms offered by Robert K. Merton in his 1973 work *The Sociology of Science*. In this text, the American sociologist lists four institutional imperatives that ideally characterize modern science: communism, universalism, disinterestedness, and organized skepticism. Communism is defined as the common and shared ownership of any scientific good.

However, while the ethical valorization of transparency is largely shared, the link between transparency and reproducibility is more controversial. Positivist social scientists take this link for granted. Indeed, positivism advocates the continuity between social sciences and natural sciences as logical and experimental disciplines. Given this continuity, it is considered possible for a social scientist to obtain the same results by replicating *ceteris paribus* a given experiment, all the conditions of which are transparently known.

The hermeneutic paradigm, however, conceives man as a meaning-making being. This distinguishes the social sciences, whose data nature is interpretative, from the natural sciences, which instead deal with objective data. Given the subjective and interpretative character of the relationship between researcher and research participants, in the hermeneutical approach, transparency is not conceived as a guarantee of replicability but rather as related to the rigor of data collection and of interpretative procedures.

Certainly, there are more varieties of positivism and more varieties of hermeneutic approaches. Moreover, there are more intermediate positions and critical theories between the two epistemological poles. This distinction is therefore to be understood in an ideal-typical sense.

Transparency in Various Disciplines

The debate on transparency has had an uneven development among the social sciences. In economics, the discussion on transparency is quite advanced and has produced both institutional arrangements and publishing policies. As institutional arrangements are concerned, a brilliant example is represented by the Berkeley Initiative for Transparency in Social Sciences (BITSS), an interdisciplinary team whose directors and staff are mainly economists and quantitative data analysts. The BITSS project, according to its website, is aimed to “improve the credibility of science by advancing transparency, reproducibility, rigor, and ethics in research.” Its mission is threefold: generating evidence on problems and solutions in science through meta-research, increasing access to open science education, and strengthening the scientific environment. A concrete outcome of BITSS has been the publication of MetaArxiv, an interdisciplinary archive of preprints aimed at improving access to information and meta-analysis in various disciplines. In addition, since the beginning of the 2000s, the American Economic Association adopted an extensive policy regarding the availability of data and materials for published works.

In other social sciences, such as sociology and psychology, the commitment to transparency is considered as an ethical and individual matter to be conciliated with the protection of research participants. The American Sociological Association code of ethics, available on the website of the association, states, “Once findings are publicly disseminated, sociologists permit their open assessment and verification by other responsible researchers, with appropriate safeguards to protect the confidentiality of research participants.”

This recommendation takes into account the increasingly significant development of qualitative sociological research and also the engagement of sociologists with sensitive topics such as criminality and deviance. In those cases, the commitment to transparency clashes with the data protection, the privacy, and anonymity of research participants. A recent example is enlightening. In 2014, the publication of Alice Goffman’s *On the Run* sparked a wide-ranging debate concerning the validity and reliability of ethnographic data. The research explored the discriminatory practices of American

police against young African Americans living in Philadelphia. In the book, Goffman reported a series of criminal events she had witnessed during the 6 years she had spent on the fieldwork. Some critics considered some reported episodes as unrealistic or invented, while others questioned Goffman's role as a covered researcher in a criminal context. Regardless of their merits, those allegations concern exactly the conflictual relationship between transparency and data protection in research designs such as ethnography.

Publishing and Transparency

A final aspect concerns the relationship between transparency and scientific publishing. Transparency issues can arise in several moments, such as the definition of the thematic agenda of a given journal or book series, the process of peer-reviewing, the complete or partial presentation of results, and the verification of the validity of the contributions proposed in preprints. All of these moments can result in what has been called a *publication bias*, that is, the tendency of an author or a publisher to shape the results of a research in order to meet the standards of the scientific community.

In 1979, psychologist Robert Rosenthal used the expression *file drawer problem* to refer to the tendency of researchers to exclude from their work results that did not confirm their hypothesis. A publication bias is also found when publishers select only those contributions whose results best confirm publicly legitimized beliefs about a given reality and exclude others falling out of the interests shared by the scientific community. To reduce these kinds of biases, many scientific journals have been providing extensive documents concerning their selection and review policies.

However, improving the transparency of scientific publishing comes up against increasing institutional pressure on the individual productivity of researchers. This can result in a multiplication of scientific journals and a decreased quality in the reviewing process. Transparency, therefore, continues to be an important factor in the future of scientific publishing and, more generally, to the assessment of scientific works.

TREATMENTS

The word *treatment* appears many times in the typical text on statistics and/or research design. It appears frequently in the indices of such texts. It is rarely defined. It is defined here, and how the term is used by researchers is shown.

Treatments, Treatment Effects, Independent Variables, and Experimental Research

Researchers are most likely to use the word *treatment* when referring to experimental research, especially when the data from that research were analyzed via analysis of variance (ANOVA). In experimental research, the researcher manipulates the independent or treatment variable(s) and then observes whether the treatment groups differ on one or more dependent or outcome variables.

Multiple-Case Research

In multiple-case research, the scores of two or more groups of cases (which might be the same research units or might be different research units) are compared to determine whether a treatment effect exists.

Two-Treatment Research

Consider a research study designed to determine the effects of damage to a particular nucleus in the brain. The researcher randomly assigns 20 rats to each of two groups. The rats in the one group have an electrode placed at the location of the nucleus of interest, and then electrical current is applied to damage that nucleus. The experimental treatment here involves everything done to these rats as part of the

research—how they are housed, fed, and prepared for surgery; the placement of the electrode in the brain; the electrolytic damage to the nucleus; and so on. The other group of rats receives a different treatment—sham surgery. They are treated exactly the same as the lesioned group, with the exception that the electrical current is not applied to the electrode that is placed within the brain. Sometimes such a group is called a control group. For this group, the (control) treatment is how they are housed, fed, and prepared for surgery; the placement of the electrode in the brain; and so on, but no electrolytic damage is done to the nucleus. It is important that the two groups be equated on all aspects of their treatment with the exception of the one (or more) aspect(s) of interest to the researcher. Accordingly, when the two groups of rats are compared on some outcome variable(s) of interest, any significant differences found can be attributed to the treatment variable.

For this example, the treatment variable is “type of surgery,” and it has two values, “lesion surgery” and “sham surgery.” After the animals have recovered from the surgery, they are tested on one or more outcome variables and then the groups are compared on the outcome variable(s). If the outcome variable is categorical (for example, does the rat approach or flee when a strange conspecific is presented), then the data might lend itself to a contingency table analysis (typically done with chi-square), which, if statistically significant, will lead to the conclusion that the treatment variable does affect the outcome variable. If the data are continuous and normally distributed, then a *t* test or ANOVA would typically be employed to determine whether the treatment variable affected the outcome variable. If the outcome variable is continuous but not normally distributed, then one would typically employ one of the several available techniques that do not require normality.

As noted earlier, the term *treatment* is most likely to be used when the data were analyzed with an ANOVA. For the research just described, suppose that the outcome (dependent) variable was the number of trials it took the rat to learn some new task and that the data were normally distributed. The ANOVA would partition the sums of squares (precursor to variance) for the outcome variable into two sources. One source is the treatment sum of squares, which is also known as the between-groups sum of squares or the model sum of squares. The other source is the within-group, error, or residual sum of squares. Each of these sums of squares is divided by its degrees of freedom to obtain a mean square. The treatment mean square estimates the variance as a result of the treatment and error, whereas

the error mean square estimates the variance caused by error alone. The ratio of the treatment mean square to the error mean square is the *F* statistic, which is used to obtain the conditional probability of getting sample groups that differ from one another by at least as much as those obtained if the groups did not differ in the populations from which they were sampled. In other words, the *F* and the *p* values obtained in an ANOVA evaluate the null hypothesis that there is no treatment effect.

ANOVA and Nonexperimental Research

The ANOVA might also be employed to analyze data from nonexperimental research. For example, female and male clients of a medical clinic are asked how satisfied they are with the services received at the clinic. The satisfaction scores are normally distributed. ANOVA is used to compare the two groups, which consist of men and women. The between-groups sum of squares here would not appropriately be called a treatment sum of squares, because the researcher did not (presumably) treat the two groups differently. Most researchers would not refer to the gender variable as a treatment variable, although some might refer to it as an independent variable, which can be confusing. With nonexperimental research like this, some researchers believe that if they conduct an ANOVA and call gender the “independent variable,” then significant results allow them to make a causal inference, but if they perform a (mathematically equivalent) correlation/regression analysis, then they cannot make a causal inference.

In some cases, it might be appropriate to employ the term *treatment* even with nonexperimental data. Suppose that patients at the clinic with a particular medical condition are treated with either one drug or another. They are not randomly assigned to groups. Which drug is prescribed depends in part on the preference of their physician and in large part on the formulary used by the provider of their medical insurance. To compare the two groups on posttreatment severity of symptoms, again, assuming normality of the outcome variable, ANOVA could be employed. Because the two groups were treated differently (with respect to which medication they received), it would be reasonable to call the between-groups sum of squares a treatment sum of squares and to call the difference between the groups a treatment effect. An interpretation of the results in this case would, however, need to be tempered by recognition that the two groups might well have been nonequivalent prior to being treated with one or the other drug.

More Than Two Treatments and More Than Two Treatment Variables

An experiment might involve more than two treatments. For example, one could add to the lesion surgery versus sham surgery experiment a third group of rats that received no surgery (sham or lesion) at all. In this case the treatment variable has three levels—no surgery, sham surgery, and lesion surgery.

An experiment might involve more than two treatment variables. For example, one could add to the lesion research a second treatment variable, the dose of an experimental drug administered to the rats after the surgery. To investigate the effects of an experimental drug that is hypothesized to help animals recover from a brain lesion, rats might be assigned randomly to the following three treatment groups: one receiving only a placebo injection, a second receiving an injection with a low dose of the experimental drug, and a third receiving an injection with a high dose of the drug. Such a layout is referred to as a factorial design. In this case, it is a 3×3 factorial design. One factor or treatment is the type of surgery with three levels (none, sham, or lesion), and the other is the dose of the drug (none, low, or high). The factorial combination of the two trichotomous independent variables produces $3 \times 3 = 9$ treatment combinations (often called “cells”): No surgery and no drug; no surgery and low dose of drug; . . . lesion surgery and high dose of drug. The factorial analysis would test four treatment effects, as follows: the effect of the combination of the type of surgery and the dose of drug, the effect of the type of surgery ignoring the dose of the drug, the effect of the dose of the drug ignoring surgery, and the interaction between the type of surgery and the dose of drug.

A factorial experiment might include both an experimental factor and a nonexperimental factor. One example is the randomized blocks design. The experimental units (subjects or cases) are matched up into blocks of k (where k is the number of levels of the treatment variable) such that within each block, the subjects are identical or similar on the matching variable(s). In some cases, the subjects within a block are identical in all aspects; that is, they are the same person, animal, or other thing. In this case, the treatment variable is referred to as within subjects or repeated measures, and each subject is exposed to each of the k treatments. The ANOVA used with such a design is sometimes called a treatment block ANOVA. The blocking variable is treated as a second factor in a factorial design. The analysis partitions the total variance into three sources: treatment, blocks, and treatment $\times$ blocks. The treatment $\times$ blocks mean square is employed as the error term for the F used to test the

effect of the treatment variable. This analysis removes, from what otherwise would be error variance, the effects of the variable(s) on which subjects were matched when creating the blocks. This reduction in error variance should increase power, the probability that the analysis will detect as significant the effect of the treatment variable (assuming it has an effect). This increase in power depends on whether the researcher chose matching variables on which the subjects differ and that are well correlated with the dependent variable.

Single-Case Research

The term *treatment* is also employed in single-case research. One common design used in single-case research is the A-B-A withdrawal design. In this design, “B” stands for the experimental treatment and “A” for the control treatment. For example, a researcher might be interested in the effects of a particular behavioral contingency management program for a child with a developmental disability. In phase A₁ (baseline) of the design, the target behavior(s) [dependent variable(s)], such as frequency of various behaviors, are measured until relatively stable across time. During phase B, the experimental treatment (the behavioral contingencies and the intervention) is introduced, and it is observed whether the dependent variable(s) change. Phase A₂ involves withdrawal of the experimental treatment and continued observation of the dependent variable(s). The treatment might be implemented a second time (ABAB) or an alternation of baseline and treatment might occur several times. If the treatment effect is observed every time, the treatment is introduced and the behaviors return to baseline every time the treatment is removed. Then, the researcher can be relatively confident that the change in behavior accompanying the treatment is caused by the treatment rather than by factors such as maturation, history, and other threats to internal validity.

TREND ANALYSIS

Trend analysis is the assessment of linear and curvilinear associations among variables. Linear trends are straight-line associations commonly evaluated in ordinary least squares (OLS) regression. Curvilinear trends include U- or inverted U-shape associations known as quadratic or parabolic trends, as well as sideways S-shape associations known as cubic trends. Other types of trends are available but rarely pursued because justifications for their use are often questionable. After describing some applied examples and the background of trend analysis, this entry discusses how trend analysis is applied in research.

Examples and Background

Applied examples of trend analysis within the research literature are prevalent. For example, Debra Murphy and William Marelich report linear trend declines in depression during an 18-month period for both resilient and nonresilient children whose mothers are HIV positive. Jessica Kahn and colleagues investigated patterns of adolescents' physical activity, noting a quadratic trend as physical activity peaks at the age of 13 then declines (an inverted U-shape). Adele Hayes and her associates found that the effects of exposure-based cognitive therapy (EBCT) on depression during the course of therapy could best be summarized as a cubic trend, with depression initially declining after treatment, followed by an increase or depression spike, then another decline in depression (a sideways S-shape).

Trend analysis and assessment of curvilinear associations emerged because of the limitations in assuming variable relationships are linear. In the latter two examples noted earlier, assessing a linear trend alone would not have been sufficient to explain the variable associations. To illustrate, say an investigation was performed examining the association between task performance and arousal level. Using the Yerkes-Dodson law as the theoretical framework, performance and arousal

should have an inverted U-shape; moderate levels of arousal should lead to optimal performance, whereas low and high levels of arousal should show arrested performance. A bivariate scatter plot of hypothetical task performance and arousal data reveals the expected curvilinear association. However, a bivariate OLS regression between these two variables would not capture this inverted U-shape association because only the linear trend is being assessed, and the multiple R value would be close to zero. The variables are related to each other but in a curvilinear fashion. To reveal this relationship, a quadratic trend should be assessed to summarize the inverted U-shape association between the two variables.

Trend Analysis in Application

Trend analysis is commonly performed in OLS multiple regression and analysis of variance (ANOVA) applications. It is also used in statistical applications designed to assess associations such as structural equation modeling and multilevel modeling. Trend analysis is performed when there is a hypothesized linear and/or curvilinear association between two or more variables, with one of the variables acting as a criterion or dependent variable and the others acting as predictors. In addition, the predictors must be scale measured to allow the shape of the association to have meaning. For example, a predictor might be a continuous score on a measured psychological scale, such as a score on the depression inventory. Or, the predictor might be a discrete measure such as group membership, with each group representing participants receiving different doses of a drug or possibly each group representing additive intensity levels of an independent variable. As long as the discrete variable is scale measured, it might be used for trend analysis.

Trend analysis cannot be used if the predictor is nominal because the resulting linear and curvilinear associations will have little meaning because of the arbitrary order of the discrete values. For example, a bivariate scatter plot between a nominal predictor variable such as color preference (e.g., 1 = white, 2 = blue, and 3 = red) and a scale measured criterion such as depression might show a curvilinear association, but such an association would be artificial because the values assigned for color preference are arbitrary. The values assigned to each color could have easily been 1 = blue, 2 = red, and 3 = white. Dummy coding a nominal variable such as color preference would assist in correctly evaluating the linear association of each color on depression, but investigations into higher order trends cannot be made because each dummy coded variable has only two levels. Therefore, an assessment

beyond linear trends for nominal level predictors (assuming dummy coding is applied) cannot be made.

The two ways to apply trend analysis include powered polynomials and orthogonal polynomials. The term *polynomial* is a label for a mathematic expression applied to one or more variables. For trend analysis, polynomials are created by multiplying the predictor variables by specific values. Regardless of whether powered polynomials or orthogonal polynomials are adopted, both will produce the desired trends. As a rough rule of thumb, powered polynomials are used when the predictor variables are scale measured and continuous. When the predictor variables are scale measured and discrete, and represent a small number of scaled categories or groups, then orthogonal polynomials are often used.

As with most quantitative methods, trend analysis is performed with Occam's razor in mind. The linear trend must always be assessed first, followed by the higher order trends (i.e., quadratic, cubic, etc.). Fitting the more complex trends first can be problematic, especially when the terms are not orthogonal because the linear trend is evident in the higher order trends. Even if the trends are orthogonal, accounting for the simplest trend first retains the simplest explanation for the variable associations.

Powered Polynomials

Powered polynomials refer to taking a predictor variable to a particular power to form the trends. The original variable (x) acts as the linear trend. The quadratic trend is formed by squaring the predictor (x^2). The cubic trend is formed by cubing the predictor (x^3). Additional trends are created in a similar manner using higher order powers. The powered polynomial approach is used when predictor variables are scale continuous, but it might also be used when the predictor variables are scale discrete.

Prior to creating powered polynomials, it is recommended that the predictor variable is mean centered. Mean centering the predictor prior to creating the powered polynomials will reduce problems associated with multicollinearity between the linear and quadratic trend. Because a predictor variable is being squared, the new variable will have a large correlation with the original predictor (e.g., greater than .98 for the original predictor and the newly formed quadratic trend). In some instances, such multicollinearity might cause computational problems. After mean centering, the correlation will be zero. However, centering will only relieve multicollinearity between the linear and quadratic trends. It will not relieve multicollinearity between the linear and other higher order trends.

Mean-centering is completed by taking each score on the predictor and subtracting it from the mean value of the predictor. This will produce a distribution with a mean of zero and will retain the original variable's standard deviation. An alternative is to center the variable through standardization. This will also produce a mean of zero but will change the standard deviation to a value of one. Either approach is acceptable. Once the predictor is centered, the powered polynomial is produced using the centered predictor. The centered predictor acts as the linear trend, whereas the square of the centered predictor is the quadratic trend. Centering the data will not alter the overall assessment of variance accounted for in the criterion or significance of the trends being assessed. It will, however, have an effect on the final parameter estimates and their significance. If the OLS regression parameters and their significance are of import to the research, then centering the predictor is required.

After the powered polynomials are created, OLS multiple regression might be used to evaluate the different trends. This is done using a hierarchical approach, entering first the linear trend followed by the quadratic trend. If a cubic trend is of interest, then it is entered after the linear and quadratic trends. The hierarchical approach is used assuming the trend lines based on powered polynomials are correlated. Each trend (linear, quadratic, etc.) is entered into the regression model one by one, and it is evaluated at each step through the change in the model multiple R -square value. As this process unfolds, trend analysis can determine (a) whether the linear trend accounts for a significant amount of variance in the criterion and (b) whether the quadratic trend accounts for a significant amount of variance in the criterion, above and beyond that of the linear effect. These analyses continue as higher order trends are added to the model. For each of the steps in the hierarchical analysis, the change in the model multiple R -square value and its significance are examined. In addition, assuming the powered polynomial for the higher order trends were created from a centered predictor, the subsequent regression parameter estimates and their significance values might be used for subsequent regression applications.

Orthogonal Polynomials

Orthogonal polynomials for trend analysis are created by taking a scale discrete predictor variable and multiplying the category or group means by a set of contrast weights. The resulting products are used to assess the trends. Orthogonal polynomials are commonly used in ANOVA applications and are specific contrasts constructed to produce the trends of interest.

They might also be used in OLS regression or similar applications.

The orthogonal polynomials might be derived by the researcher or found in the appendices of most advanced statistical textbooks. In addition, statistical programs such as SPSS®, an IBM company, have options that produce orthogonal polynomial results (IBM® SPSS® Statistics was formerly called PASW® Statistics). Unlike powered polynomials, the predictors do not need to be centered. However, one limitation for orthogonal polynomials is that the number of individuals within each category of the predictor should be equal. If the numbers within each scaled category or group are unequal, then the resulting trends will not be orthogonal, and additional steps must be taken to ensure the accuracy of the results.

When using orthogonal polynomials, the first step is to identify the number of scaled categories or groups in the predictor variable. The number of trends that can be fit is equal to the number of categories in the predictor variable minus one ($k - 1$; k being the number of categories or groups) and follows the typical trend sequence (linear, quadratic, cubic, etc.). If the predictor has three categories, then only the linear and quadratic trends might be fit. If there are four categories, then three orthogonal polynomials might be fit.

The easiest way to derive the orthogonal polynomials for trend analysis is to refer to an advanced statistics textbook, which has an appendix of orthogonal polynomial mean contrasts. For a three-category predictor variable, a standard textbook appendix would show two orthogonal polynomial contrasts: $\{-1 \ 0 \ 1\}$ for the linear trend, and $\{1 \ -2 \ 1\}$ for the quadratic trend. Look closely at these mean contrast values. The contrast applied to the means for a linear trend follows a linear trajectory, whereas the contrast for a quadratic trend is a U-shape. If the predictor variable had four levels, then the three orthogonal polynomial contrasts are $\{-3 \ -1 \ 1 \ 3\}$ for the linear trend, $\{1 \ -1 \ -1 \ 1\}$ for the quadratic, and $\{-1 \ 3 \ -3 \ 1\}$ for the cubic trend. Assuming equal category or group sizes, these mean contrasts are independent of each other. Ways to proof the independence of the contrasts might be found in most advanced textbooks.

Once the orthogonal polynomials have been applied, they might be used in the typical manner for assessing contrasts. Assuming equal category or group sizes, the orthogonal polynomials will be independent, and their effects might be evaluated simultaneously if ANOVA is the statistical application of choice. However, if unequal category sizes are evident, then the resulting trends will not be independent, and a hierarchical approach should be adopted. Interpreting trend analysis results using orthogonal polynomials is done in the same

fashion as with powered polynomials. The linear trend takes precedent, followed by the quadratic and higher order polynomials.

TRIANGULATION

The term *triangulation* refers to the practice of using multiple sources of data or multiple approaches to analyzing data to enhance the credibility of a research study. Originating in navigational and surveying contexts, triangulation aligns multiple perspectives and leads to a more comprehensive understanding of the phenomenon of interest. Researchers differ in the emphasis placed on the purposes of triangulation; some investigators view it as critical to establishing corroborating evidence, and others focus on its potential to provide multiple lines of sight and multiple contexts to enrich the understanding of a research question. Particularly associated with qualitative research methods, triangulation typically involves examining data from interviews, focus groups, written archives, or other sources. Triangulation is often used in studies that combine both quantitative and qualitative approaches, and it is sometimes referred to as mixed methods or multi-method research.

Types

Norman Denzin identified four types of triangulation. First, *data triangulation* involves using multiple sources of data in an investigation. In a research study examining hospital staff morale, for example, interviews with medical personnel might be compared

and cross-checked with staff surveys and records of focus groups consisting of hospital employees. Second, *investigator triangulation* involves employing several evaluators to engage in observations or analyze participant responses. Using multiple investigators allows for the auditing of data consistency and reduces the potential bias inherent in employing only one investigator or analyst. For example, a group of researchers analyzing responses to open-ended survey questions might be less likely to draw erroneous conclusions than a single investigator, whose expectations might color interpretations of the data. A related practice known as *member checking* involves having study participants review transcripts and the findings derived by investigators to verify the accuracy of their recorded responses and comment on the conclusions drawn. Third, in *theory triangulation*, multiple theoretical perspectives are considered either in conducting the research or in interpreting the data. Employing a multidisciplinary team is one approach that brings different theoretical perspectives to bear on the research question. Last, *methodological triangulation*, which is the most commonly used form of triangulation, engages multiple methods to study a single problem. Typically employed to compare data collected through qualitative methods with quantitative data, methodological triangulation can establish the degree of compatibility between information obtained through different strategies. Qualitative and quantitative methods might be employed simultaneously (e.g., distributing a questionnaire and conducting a case study) or might be used in a sequential fashion (e.g., a pilot study serves as the foundation for a randomized controlled trial conducted at a later date). Methodological triangulation might take the form of within-methods triangulation, where multiple quantitative or qualitative approaches are employed, or between-methods triangulation, where both quantitative and qualitative approaches are used. Within-methods triangulation, on the one hand, has been criticized as a weaker strategy, as it only employs one method (either qualitative or quantitative) and does not compensate for the limitations of the particular paradigm. Between-methods triangulation, on the other hand, offers the possibility that the biases inherent in one approach will be mitigated by the inclusion of other sources of data, methods, and investigators.

Studies that employ triangulation typically yield one of three outcomes: convergence, inconsistency, or contradiction. The particular outcome of the study challenges the researcher to bring together theory, research, and practice in the construction of a comprehensive explanation of the results.

Debates Regarding the Purposes and Contributions of Triangulation

Researchers have disagreed regarding the purposes and potential contributions of triangulation. These differences emerge out of the paradigms underlying investigators' approaches to research. Researchers influenced by the positivist or postpositivist philosophies have viewed triangulation primarily as a means of overcoming the limitations inherent in using only one approach to research. They have viewed the benefits of employing multiple data sources as a means of verifying the findings of different methods, asserting that if data from two or more sources converge on the same information, the likelihood of error is reduced. This viewpoint is closely akin to the traditional criteria of reliability and validity in quantitative approaches. If a researcher finds that data from multiple sources corroborate in support of the same conclusion, then the researcher can be more confident in its validity.

In contrast, researchers influenced by a constructivist philosophy consider the benefits of triangulation to lie not in its potential to verify information but in its capacity to provide multiple viewpoints on the phenomenon of interest and to amplify the perspectives of participants who have been ignored or overlooked in traditional scientific inquiry. To constructivists, triangulation offers the opportunity to deepen the understanding of the research question and to explore multiple realities. Rather than viewing participant checking as validation or verification, for example, constructivists conceptualize it as obtaining additional data to expand the understanding of the research problem. To constructivists, triangulation is less concerned with attending to converging data than attending to obtaining multiple perspectives.

Some constructivists caution that researchers should avoid drawing links between qualitative research and quantitative methods as it might be construed as an effort to legitimize qualitative research to traditional quantitative audiences. They argue that by framing triangulation as a means of establishing validity or reliability, constructivists take an apologetic stance in trying to fit their methods into a traditional paradigm that postpositivists will appreciate and accept. This practice perpetuates the belief that qualitative research is not as rigorous or legitimate as "real science."

Benefits

The benefits of triangulation vary depending on the perspective of the researcher. Postpositivists assert that triangulation enables researchers to minimize the biases inherent in using a single research approach. Studies

that employ several methods and yield multiple types of data provide the opportunity for comparing and cross-checking findings. Because every type of data has strengths and limitations, using a combination of techniques helps compensate for the weaknesses found in one approach. Observations, for example, are limited in that the observer might focus attention on one particular aspect of the situation, while overlooking other, more significant events. The presence of the observing researcher might impact the participants in undetected ways. Likewise, it is difficult to determine whether the behaviors observed are typical of the participants or represent a limited snapshot of an uncommon action. Interviews might yield data that are affected by the interviewer's unique style of communication, by the personal recall or interpretation of responses, or by the interviewees' assumptions about, or reactions to, the interviewer. Archived documents tend to be limited by the specificity of the information contained in written records, biases of the document writer, or distortion of information. Because of the inherent limitations of these and other research approaches, investigators can enhance the credibility of findings by building in the use of multiple sources of data through triangulation. This strategy enables the researcher to capitalize on the strengths of each approach and reduce the impact of the weaknesses inherent in a single approach.

Constructivist researchers, in contrast, assert triangulation is beneficial in that it allows the airing of multiple perspectives on the problem and prompts the researcher to consider multiple realities. They argue that traditional approaches to scientific inquiry have largely overlooked individuals who have had less power and influence. Triangulation invites members of these groups to have a voice in determining reality and in contributing to the expansion and proliferation of knowledge.

Limitations

Although triangulation offers many benefits to the study of complex phenomena, several limitations have been identified. From a postpositivist perspective, triangulation does not always reduce bias. A researcher might triangulate using data collected through different methods (e.g., self-reports, diaries, and political speeches), but if that data come from a common source, such as a single person, then bias remains. Even if findings are corroborated from two different sources, a researcher cannot guarantee that both sources do not yield data that are flawed. A researcher's conclusions based on this information inevitably will be impacted. Thus, using triangulation to strengthen a study's validity is not always an effective strategy.

In studies that use methodological triangulation, it is not uncommon to obtain conflicting data. Investigators disagree regarding how to interpret discrepant findings. Constructivists argue that one should not necessarily expect triangulation to lead a researcher to a single truth, as there are multiple constructions of truth. Triangulation, they assert, should be viewed as a tool to enrich the process of inquiry and to allow multiple perspectives to emerge. Others note that discrepancies indicate different methodologies have captured different information. The skilled researcher is then challenged to make sense of the differences.

Some researchers have cautioned that different research methodologies should not be combined without a clear rationale. Data derived from different approaches cannot necessarily be compared and viewed as equivalent in their ability to address a research question. For example, data collected from journal entries might differ dramatically from data collected in interviews, because one approach elicits private thoughts, whereas the other taps communication within a social context. When using methods triangulation, researchers should be able to articulate a clear rationale for combining different methods.

Triangulation can be expensive and time consuming. Most research projects are limited by financial and time constraints. Therefore, using multiple investigators, measures, theoretical perspectives, and methods will depend on the resources allocated for the study. The potential benefits of triangulation must be weighed against the practicalities of budget and time frame.

An additional consideration in using triangulation involves the experience level of the primary investigator and the research team. Because studies employing triangulation can be complex, it is critical that the researchers involved are experienced and knowledgeable regarding the strategies used and the data obtained. Novice researchers will struggle to interpret divergent results. Experienced qualitative researchers, regardless of their philosophical bent, generally agree that inconsistencies are common in studies using triangulation. Rather than unraveling the credibility of the findings, divergent results often direct the researcher to a deeper appreciation for the multidimensionality of the research question and point to new avenues of inquiry.

TRIMMED MEAN

Trimmed means are means of distributions that have been adjusted by removing a percentage of very high and very low scores. They are used to address the problems caused when there are outliers in the data. There are at least three fundamental concerns when using the mean to summarize data and compare groups. The first is that hypothesis testing methods based on the mean are known to have relatively poor power under general conditions. One of the earliest indications of why power can be poor stems from a seminal paper by John Wilder Tukey published in 1960. Roughly, the sample variance can be greatly inflated by even one unusually large or small value (called an outlier), which in turn can result in low power when using means versus other measures of central tendency that might be used. A second concern is that control over the probability of a Type I error (when the true hypothesis is wrongly rejected) can be poor. It was once thought that Type I error probabilities could be controlled reasonably well under nonnormality, but it is now known why practical problems were missed and that serious concerns can arise, even with large sample sizes. A third concern is that when dealing with skewed distributions, the mean can poorly reflect the typical response.

There are two general strategies for dealing with the problem of poor power, with advantages and disadvantages associated with both. The first is to check for outliers, discard any that are found, and use the remaining data to compute a measure of location. The second strategy is to discard a fixed proportion of the largest and smallest observations and average the rest.

This latter strategy is called a trimmed mean, which includes the median as a special case, and unlike the first strategy, empirical checks on whether there are outliers are not made.

A 10% trimmed mean is computed by removing the smallest 10% and the largest 10% of the observations and averaging the values that remain. To compute a 20% trimmed mean, remove the smallest 20%, the largest 20%, and compute the usual sample mean using the data that remain. The sample mean and the usual median are special cases that represent two extremes: no trimming and the maximum amount.

A basic issue is deciding how much to trim. In terms of achieving a low standard error relative to other measures of central tendency that might be used, 20% trimming is a reasonably good choice for general use, except when sample sizes are small, in which case it has been suggested that 25% trimming be used instead. This recommendation stems in part from the goal of having a relatively small standard error when sampling from a normal distribution. The median, for example, has a relatively high standard error under normality, which in turn can mean relatively low power when testing hypotheses. This recommendation is counterintuitive based on standard training, but a simple explanation can be found in the books listed under Further Readings.

Moreover, theory and simulations indicate that as the amount of trimming increases, certain known problems with means, when testing hypotheses, diminish. This is not to say that 20% is always optimal; it is not, but it is a reasonable choice for general use. However, if too much trimming is used, with the extreme case being the median, then power can be relatively poor under normality. And when comparing medians, special methods are required for dealing with tied values.

After observations are trimmed, special methods for testing hypotheses must be used (and the same is true when discarding outliers). Moreover, appropriate estimates of standard errors must be performed in a manner that takes into account how extreme values are identified and removed. That is, applying standard methods for means to the data that remain after trimming violates the basic principles used to derive standard techniques. Some of these methods are relatively simple to apply, whereas others are based on bootstrap methods that take advantage of modern computing power. It is now known that trimmed means also help deal with problems associated with means when the goal is to control Type I errors or compute accurate confidence intervals. A rough explanation of why trimming helps is that the sampling distribution of the trimmed mean, or some appropriate test statistic, is less affected by nonnormality versus no trimming (the sample mean). This strategy has practical importance

because recent studies have found general conditions in which classic methods based on means perform poorly. For example, there are realistic conditions where the one-sample Student's *t*-test requires a sample size of 300 or more to get accurate results. The two-sample Student's *t*-test can perform poorly if the distributions differ in terms of skewness. Indeed, there are general conditions where the actual Type I error probability does not converge to the nominal level as the sample size gets large. And when comparing more than two groups, practical problems are exacerbated.

TRIPLE-BLIND STUDY

Triple-blind (i.e., triple-masking) studies are randomized experiments in which the treatment or intervention is unknown to (a) the research participant, (b) the individual(s) who administer the treatment or intervention, and (c) the individual(s) who assess the outcomes. The terms *blind* and *masking* are synonymous; both terms describe methods that help to ensure that individuals do not know which treatment or intervention is being administered. The purpose of triple-blinding procedures is to reduce assessment bias and to increase the accuracy and objectivity of clinical outcomes.

Examples

Conducting a triple-blind study is difficult. The following two examples highlight some challenges in conducting and evaluating triple-blind studies.

Example 1

The first example, from a study by Abraham Heller and colleagues, highlights the difficulties in conducting a triple-blind study in a clinical setting of psychiatric patients ($n = 15$). The authors report using a triple-blind design to compare the effectiveness of three medications, which include imipramine, desipramine, and placebo. Participants were accepted into the study if the examiner determined that the individual was severely depressed, after which the examiner rated the individual on the Hamilton Depression Scale, and the participant completed self-reports on the Zung Self-Rating of Depression and the Minnesota Multiphasic Personality Inventory (MMPI). These scales were repeated in 1 week, biweekly during the hospitalization, and monthly for 3 months on an outpatient basis. The authors reported that a random triple-blind method was used to assign medication to patients. Reportedly, a secretary was given the responsibility of pairing each participant's name to a list of three randomly assigned letters. After randomization, participants were monitored first in an inpatient treatment psychiatric setting, followed by treatment in an outpatient day-care setting for 1–4 weeks, and finally treatment in a regular outpatient setting. After a 3-month follow-up period, the patient was administered another MMPI and the previous scales. The authors stated that to eliminate bias no one with direct contact with the patients knew which medication the patient took during the study.

Challenges

This study enrolled a small sample, and the methods used do not provide sufficient detail to determine whether the clinical findings truly support use of one medication over another. For example, a secretary paired each patient's name with a letter, but it is not clear who actually administered the medications, or if the person giving the medication was truly blinded to which medication was administered. Furthermore, it is unclear how the list of letters was randomly assigned nor what methods were used to ensure that each patient did not know which medication they received. Because the side-effect profile of the three medications discussed earlier is substantially different (particularly for the placebo compared with the antidepressants), it is unlikely that the patients did not know which medication they received. It is also unclear what methods

were used to ensure that the individuals that conducted the outcomes assessment did not know the clinical outcomes. There is no clear description of how the individuals who performed the outcomes were blinded to the clinical outcomes.

Example 2

A second example, from a study by Seung-Jung Park and colleagues, highlights the challenges in conducting a triple-blind study using multiple clinical sites. The study seems to be a much more rigorously conducted triple-blind study compared with the Heller study discussed earlier, given the methods described to ensure a triple-blind. The study examined in symptomatic patients ($n = 177$) whether a coronary stent coated with an antiproliferative agent paclitaxel prevented restenosis (e.g., whether this agent prevented hyperplasia and reoccurrences of coronary artery occlusion). The study involved three medical centers and compared stents coated with one of two doses of paclitaxel compared to a stent that was uncoated (i.e., placebo). Randomization was conducted using blocks of participants (i.e., each block used a 1:1:1 ratio to assign participants to 1 of the 3 interventions), and each block of participants was stratified according to stent diameter. Reportedly, stents were ordered in a randomized sequence, angiography was used to determine vessel diameter, and the appropriate diameter stent was selected. The authors state that patients, investigators, and core-analysis laboratories were all unaware to what groups the patients were assigned.

Challenges

Although the authors used block randomization, it is unclear what procedures were used to stratify based on diameter. Also, it is unclear what methods were used to ensure the correct dosing of the paclitaxel. The authors are vague regarding who was in the core-analysis team and to what extent the core-analysis team was truly independent from the independent clinical-events committee and the data safety monitoring committee. Furthermore, it is not known what procedures were in place to ensure blinding of results across the three clinical sites.

Conclusion

Although the triple-blind study offers clear advantages of control from various sources of bias, these designs are logistically difficult to conduct. Prior to initiating a triple-blind study, a conscientious effort needs to be made to identify the necessary parties who will conduct

the study. There should be clear guidelines in place regarding which individuals and monitoring boards will be blinded and how investigators will maintain the triple blind. In evaluating any study that reports using a triple blind, a critical eye is needed to determine whether triple-blind procedures were rigorously enforced.

TRUE EXPERIMENTAL DESIGN

The exact definition of true experimental designs has been debated. The term *true experiment* is sometimes used to refer to any randomized experiment. In other instances, the term *true experiment* is used to describe all studies with at least one independent variable that is experimentally manipulated and with at least one dependent or outcome variable. Furthermore, the word *true* has been interpreted to mean there are a limited number of correct experimental methods. Regardless of the exact definition, the distinguishing feature of true experimental designs is that the units of study—be they individuals, animals, time periods, areas, clinics, or institutions (i.e., whoever or whatever is assigned to an experimental condition is the unit)—are randomly assigned to different treatment conditions.

Because of the various meanings and the use of the term *true experiment*, others have preferred to use the term *randomized experiment* as a clearer, more concise description of the experimental design. A randomized experiment is any experiment in which units are randomly assigned to receive one or more treatments or

one or more alternative control conditions. Randomized assignment refers to any procedure for assigning units to either treatment or control conditions based on chance, with the potential for every unit to be assigned to one of the treatment conditions at a greater than zero probability. In the following sections, how random assignment facilitates causal inference is discussed, and common designs that use random assignment are presented.

Random Assignment and Causality

For randomized experiments, the use of random assignment is important because it facilitates causal inference. For example, randomization ensures that the experimental units' treatment condition is not confounded by an alternative cause or systematically introduced difference between conditions. Randomization, therefore, reduces potential threats to experimental validity by dispersing these threats randomly across experimental groups to minimize group differences before treatment begins. Randomization allows the researcher to know how groups were assigned and has the advantage that the selection process can be modeled accurately. Random assignment also allows for the computation of valid estimates of error variance that are orthogonal to treatment conditions. Each advantage captures different aspects of the benefits of randomization. Random assignment is the only design feature that accomplishes all the above in the same experiment, and it does so reliably while minimizing threats to internal validity.

Designs Using Random Assignment

This section presents various randomized experimental designs. The following designs are among the most commonly used in field and treatment research and are basic designs from which more complex designs can be built. With each design, key features include control and manipulation over the timing, intensity, and duration of experimental variables. The basic design of a randomized experiment requires a minimum of two conditions, with random assignment of experimental units to treatment conditions, followed by posttest assessment of units. Herein, the letter "R" indicates that the group on a given line is formed by random assignment. Although random assignment R is placed at the beginning of each line, in practice, randomization often occurs before or after pretests. "X" is the treatment and "O" is the observation. The basic design can be depicted as

R	X	O
R		O

The diagram presented above depicts a two-group experiment in which one group receives the experimental treatment X followed by observation O, and the second group acts as a comparison to be observed without experimental manipulation. This second group is one example of a control condition. An important issue with this design is the selection of the control condition. In all randomized experiments, the researcher must consider what factors need to be controlled in the design of the study. Depending on what hypothesis needs to be tested, the number and type of treatment and control groups might vary. Examples of control groups include no-treatment controls, dose-response controls, wait-list controls, expectancy controls, or attention-only controls.

The Basic Randomized Design Comparing Two Treatments

One variation of the randomized design uses two treatments, one of which is a gold standard treatment of known efficacy. This design can be used to test what is the effect of the new treatment compared with the effect of the standard treatment. This design often works well when the standard treatment has already been shown to be effective when compared with no-treatment controls (see basic design, presented previously):

R	X _A	O
R	X _B	O

The Basic Randomized Design Comparing Two Treatments and a Control

A second variation of the randomized design is used when it is unknown whether experimental units after treatments A and B are likely to be different (e.g., because of the treatment being equally effective or equally ineffective) at posttest. In this case, a control group is added to the basic randomized design, as follows:

R	X _A	O
R	X _B	O
R		O

The Pretest-Posttest Control Group Design

Often, it is advantageous to add a pretest to the basic randomized design, as follows:

R	O	X	O
R	O		O

Or, random assignment can occur after the pretest, as follows:

O	R	X	O
O	R		O

The two designs presented earlier are frequently used for randomized field experiments because they offer two major advantages. First, they can help to minimize threats to internal validity resulting from attrition. Second, they can be used with specific statistics to increase power to reject the null hypothesis.

In some instances, however, it makes sense not to use a pretest. Examples include when pretesting is expected to produce an unwanted change in the experimental units before the treatment occurs, when pretesting cannot be obtained, and when the pretest condition is known to be constant.

The Alternative-Treatment Design with Pretest

Pretests are also recommended when comparing different treatments. If the researcher has reason to believe there might be no difference in outcomes between two alternative treatments, this design allows for the determination of whether both groups improved or whether neither did. Another advantage of this design is its utility when the researcher faces the challenge that it is unethical to withhold treatment to a group of patients, but it is unknown which treatment is more effective. Alternatively, this design can be used when there is a gold-standard treatment against which all other treatments can be compared.

R	O	X _A	O
R	O	X _B	O

Multiple Treatments and Controls With Pretest

Randomized experiments with pretests can also include a control group and multiple treatment groups. This design can be expanded to include more than two treatments and more than one control condition. For example, the Treatment of Depression Collaborative Research Program studied 250 depressed adults who were randomized to receive one of three active treatments: cognitive behavior therapy, interpersonal therapy, antidepressant therapy (imipramine) with clinical management, or placebo medication with clinical management (i.e., control condition).

R	O	X _A	O
R	O	X _B	O
R	O	X _C	O
R	O		O

This design can also be used to manipulate experimentally independent variables that are likely to have differing measurable effects on experimental variables

at different doses or with increasing levels (i.e., parametric or dose-response studies). For example, in a study conducted in Cali, Columbia, adults were administered educational, nutritional, and medical treatment in four “doses” of total time receiving the following treatments: 990 hours, 2,070 hours, 3,130 hours, and 4,170 hours. The results showed significant effects at higher doses, with minimal effects at the lowest dosage.

Factorial Designs

Factorial designs use two or more independent variables (i.e., factors), which have at least two levels, and are combined such that all logical combinations of factors can be tested. The simplest version of this design is called a two-by-two factorial design, which is depicted as follows:

R	X _{A₁B₁}	O
R	X _{A₁B₂}	O
R	X _{A₂B₁}	O
R	X _{A₂B₂}	O

Factorial designs have several advantages. They can allow for smaller sample sizes than might be needed when using other designs, because each participant can receive the treatment conditions simultaneously. Second, factorial designs can be used to test whether a combination of treatments is more effective than one treatment or no treatment. Third, experiments that use a factorial design can be used to test for interactions (i.e., when the effects of treatment vary over levels of another variable).

Although factorial designs have clear advantages and are commonly used in laboratory research, they also have disadvantages because of the difficulty of implementing this design in many situations. For example, factorial designs require rigorous control over the combinations of treatments administered to each experimental unit, but maintaining control over multiple factors and multiple levels can pose special challenges.

Longitudinal Designs

Longitudinal designs use multiple observations that occur before, during, and after treatment, with the number and timing of observations determined by the specific hypotheses. Longitudinal designs have several advantages. They can determine change over time with the use of growth-curve models of individual differences in response to treatment. Longitudinal designs can also increase statistical power when five or more

waves of observations are used, even when sample sizes are small.

R	O...O	X	O	O...O
R	O...O		O	O...O

Unfortunately, longitudinal designs have many disadvantages. Importantly, attrition might increase with longer follow-up periods and require rigorous follow-up procedures. For longitudinal randomized treatment studies, it is often unethical to withhold treatment for long periods of time using no-treatment or wait-list control groups.

Crossover Designs

Crossover designs are generally used with participants who are randomized to receive two or more treatments, after which they receive a posttest. After the posttest, the participants are assigned to the other treatment they did not receive previously and then they receive a second posttest, in the following design:

R	O	X _A	O	X _B	O
R	O	X _B	O	X _A	O

The crossover design is used to counterbalance and assess order effects. The crossover design is also used to obtain more information on causality than would be possible with only the first posttests. In either case, crossover designs are most useful when the treatments do not produce carryover effects. (Carryover effects occur when one treatment has residual effects such that the effects of the first treatment continue after beginning a second treatment.)

Solomon Four-Group Design

The Solomon four-group design is often used to control for effects of pretesting. This design uses two experimental groups and two control groups. After randomization, for each respective group, one receives a pretest and the other does not. This design allows for examination of the effects of the pretest to determine whether the pretest itself is an active treatment or intervention.

R	O	X ₁	O
R	-	X ₁	O
R	O	X ₂	O
R	-	X ₂	O

Conclusion

The *true experimental design* is a synonym for randomized experiments. Randomized experiments are useful because they facilitate causal inference and reduce

threats to internal validity. A variety of experimental designs can be used, depending on what research hypotheses are to be tested. However, randomized experiments are often complex, expensive, and difficult to do. Therefore, they should be conducted only after preliminary study results support very specific testable hypotheses.

TRUE POSITIVE

True positive, as it pertains to null hypothesis significance testing (also known as hypothesis testing), is correctly rejecting the null hypothesis when it is in fact false. In other words, it is correctly finding a

Table 1 Statistical Decision Table: The Four Potential Results with Any Null Hypothesis Significance Test

correlation or a difference between groups. Research design is founded on the principles of hypothesis testing and in short, the pursuit of discovering true positives is a goal. In this entry, the definition of the true positive is developed in the context of null hypothesis significance testing, how it relates to power analysis is described, and an example is provided.

Definition

Null hypothesis significance testing examines the probability of two outcomes (the null and alternative hypothesis). Because these two hypotheses are mutually exclusive and exhaustive, there are four potential results. Two of these results are correct decisions. Two potential results are incorrect decisions. A true positive is one of the potential correct decisions. It is finding a difference between groups (e.g., males and females) or a relationship (e.g., the association between height and weight) that truly exists and does not represent a chance fluctuation. Table 1 outlines the four possible

conditions and states the research question in terms of group differences. The same table can be made for predictive or correlational relationships.

It is desirable to find a difference between the groups (or an association between the variables) when it truly exists. In other words, the goal of a research project is to detect the true state of affairs. If men and women are different with respect to height, then the researcher wants to be able to reproduce this difference. The concept of a true positive (and the concepts of Type I error, Type II error, and true negative) is a theoretical abstraction. The true state of affairs can never really be known (because of random error, measurement error, etc.). Thus, it is not possible to determine whether an error has been made or whether a true positive or true negative exists. The use of statistical significance testing attempts to limit the likelihood of making an error and to increase the chance that the correct decision is made.

The word *positive* in this case does not reference *good*. The positive with respect to the true positive is more akin to the presence (versus the absence) of a condition or relationship (e.g., having chicken pox). Therefore, a true positive indicates that condition, association, or difference exists.

In Relation to Power Analysis

Another concept that is related to the idea of true positive is the concept of statistical power. Statistical power analysis is the sensitivity of a research design to detect a true positive. In other words, it is the ability of the research study to find a difference or reject the null hypothesis when it is in fact false. Statistical power and alpha level (the likelihood of a false negative or a Type I error) are impacted by the design of the research study and influence each other. Statistical power is determined by the effect size, directional nature of the test, and the alpha level. The alpha level is set a priori (prior to running the research study) by the researcher.

Example

To illustrate the concept of the true positive, the case of Naomi's potential pregnancy is provided. Naomi wants to determine whether she is pregnant. She takes a pregnancy test (pregnancy was chosen because the reality of the situation will eventually be known in contrast to real research situations). After following the directions correctly, Naomi gets a positive pregnancy test (indicating that she is pregnant). As the weeks follow, Naomi begins to show more signs of the pregnancy (i.e., weight gain, hearing the baby's heart beat, and feeling the baby move) and eventually gives

birth. In short, Naomi's pregnancy test result was a true positive. The test said she was pregnant and she really was.

In contrast, Naomi's pregnancy test could have said that she was pregnant and she really was not (i.e., false positive or false report). In this case, she could start preparing for the pregnancy only to later find out that the test was wrong. The test could have also said that she was not pregnant. In that case, if she had really been pregnant, it would have been a false negative. As with any error, there are repercussions for the false information. Naomi could have thought she was not pregnant and decided to drink alcohol or participate in other activities that are considered dangerous for pregnant women. If the test said that Naomi was not pregnant and in reality, she was not, then it was a correct result.

TRUE SCORE

True score, which is the primary element of true score theory, is the individual's score on a measure if there was no error. Some classic theories of measurement believe that a true score can be estimated through repeated testing. The concept of true score is important to research design as it emphasizes that there is some error involved in any type of measurement (e.g., height, weight, self-esteem, IQ, and heart rate). In this entry,

the definition of a true score is developed and explored with respect to reliability, measurement error, and classic extensions. Finally, some alternatives to true score theory are briefly presented.

Definition

True score can also be defined with respect to the idea of an observed score. In short, the observed score is the true score plus some error. Symbolically, the equation is

$$X_o = X_t + E,$$

where X_o is the observed score or the participant's score on a measure (e.g., the participant's score on Prochaska's smoking decisional balance inventory) and X_t is the participants true score or what is really of interest. In addition, E represents the error term that can be comprised of measurement error (i.e., systematic error) and some random error (i.e., unsystematic error). For example, real body weight (i.e., the true score of our weight) is never really known as it fluctuates with time of day, gravitational pull, retention of water, clothing choice, and many other variables. The number viewed on a scale would be considered an observed score (the true weight plus some error). The observed weight on the scale is based on the real weight with the addition of the calibration of the instrument used to measure weight plus the other variables that might interfere with the scales ability to properly measure weight. Conceptually, the formula would be

$$\text{Observed score} = \text{true score} + (\text{measurement error} + \text{random error})$$

Or

$$\text{Weight on the scale} = \text{real weight} + \text{calibration of scale} + \text{time of day, etc.}$$

Although weight can be measured on a scale, it is important to remember that it is estimated. Without knowing the amount of error or the true score, the observed weight is actually meaningless. The obtained weight (or measurement on a myriad of other psychological measures or tests) could be greatly flawed (i.e., have a large amount of error) or very precise (i.e., have a little amount of error). Without multiple measurements on the individual or test subject or replication studies, it is difficult to know how much error is in the measurement.

Assumptions of True Score Theory

Because of the theoretical nature of the true score, X_t , it is not possible to know its value. Although it cannot be directly measured, there are some basic assumptions (according to true score theory and classic measurement theory) concerning the true score. As mentioned earlier, the first assumption is that all observed variables contain some error. If there was no error, then the true score would equal the observed score X_o . Another assumption is that the true score and the error score are independent. In other words, the correlation between the true score and the error score is zero (signifying that the movement in the error score has no impact on the value of the true score). The error score E is considered completely random. For example, if a baby weighs 12 pounds (her true score) and is weighed multiple times, then the amount the baby's weight fluctuates (thereby showing the differential error values) does not impact the baby's real weight.

Beyond the error of measurement and the lack of relationship between the true score and the error score, it is also assumed the mean of the error scores will be equal to zero. Some error scores will be above the true score and some error scores will be below the true score. It is assumed that the pattern of the error scores (over repeated testing) will represent the normal curve and thus have a mean of zero. Another assumption is that the expected value of X_o is X_t . In other words, the observed variable is to be a good estimate of the true score. This assumption could be difficult in the case of someone who is unfamiliar with the language used in a measure. For example, if the participant's primary language is not English and the measure is constructed in English, then he or she might miss the true meaning of the items and therefore provide answers that do not reflect his or her true ability or disposition. In true score theory, it is also assumed that the error terms across tests will not be correlated. For example, if participants are completing a battery of measures (e.g., emotional intelligence, alcohol use, or self-efficacy), the error terms on each of these measures will not be related. This assumption is difficult to obtain if the participant's mood (or fatigue or other variable) impacts his or her ability to complete the measure. True score theory presupposes that the error on one measure or test will not be related to the true score on another test (i.e., the correlation between E_1 and X_{t2} is zero). These assumptions provide the basis for reliability testing.

Reliability Testing

As mentioned earlier, replication is necessary to estimate a true score. There are two types of replication.

The first type of replication is test-retest. It involves assessing the participants or research subjects multiple times using the same measure (stability over time), for example, giving participants a measure of emotional intelligence today and giving them the same measure of emotional intelligence next week. Because it is assumed that the true score is stable (or trait-like), the scores of the participants could be correlated. The correlation would indicate the stability or reliability of the measure over time. Another type of replication is measuring emotional intelligence across different participants.

Several tests for the reliability of measures were developed based on the concepts of true score theory. G. Frederic Kuder and Marion Richardson's KR-20 and KR-21 were used to provide statistical estimates of reliability. The most popular method of estimating reliability is Lee Cronbach's coefficient alpha (which is quantified on a scale of 0 to 1, with higher scores indicating more internal consistency). It is a measure of the internal consistency of a series of items using the observed scores of the participants. In short, it is the variance of the observed variable that is ascribed to the stable true scores. The variation in the observed scores caused by error (as error decreases reliability increases) is discussed in the next section.

Error

If it were possible to know the true score, then it could be subtracted from the observed score to obtain the error score. In essence, the error score represents the observed score's deviation from the true score. As mentioned earlier, it can be composed of two components (systematic and unsystematic error). Although some classic theories only address unsystematic error (also known as random error), this section develops both concepts with respect to true score theory.

The two types of error affect the observed variable in different ways. Systematic error affects all of the measurements equally (i.e., a constant is added to all scores). An example of a systematic error is in the case of two professors team teaching the same class in the same manner. If professor A consistently grades the students 10 points higher than professor B, then there is a systematic error in the grades of the students. Another example of a systematic error would be if professor A graded the left-handed students easier than the right-handed students (in other words, there was a bias against right-handed students). Unsystematic (or random) errors complicate the relationship between the true score and the observed score.

Another concept important to error and true scores is the standard error of measurement. Similar to the concept of standard deviation when the word *standard*

indicates a mathematical average, standard error of measurement is an average of the error terms about the true score. In short, it is an estimate of how different the observed scores are from the true score on average. The standard error of measurement is commonly used to develop confidence intervals for the observed scores. The confidence interval surrounds the true score. In other words, a 95% confidence interval indicates that there is a 95% confidence that the participant's true score falls within the range of the confidence interval (e.g., 95% confident that the participant's IQ falls between 70 and 130 on a standard measure of intelligence).

Extensions of True Score Theory

Measurement error is a key term in true score theory. If the standard error of measurements are equivalent across two tests, the true scores are equivalent ($X_{t1} = X_{t2}$), and the tests do not violate the aforementioned assumptions, then the two tests are considered parallel forms. Parallel forms are in many educational testing situations (e.g., GREs, SATs, ACTs, and LSATs). Another extension of true score theory is the concept of tau equivalent tests. In essence, tau equivalent tests are tests that the true scores differ by a constant ($X_{t1} = X_{t2} + c$). Tau equivalent tests are not necessarily parallel tests.

Alternatives to True Score Theory

Beyond the extensions of the true score theory, theorists have suggested some alternative theories or models. One alternative is domain sampling. It was developed in rebuttal of the rigid dichotomy of true and error scores. The underlying idea of domain sampling is that a constellation of behaviors can represent a trait or domain. For example, exercise is a broad domain in which many people choose different behaviors (e.g., running, walking, swimming, tennis, rowing, and biking). To measure the trait or domain, a series of items or questions measures different aspects of the domain. Within the concept of domain sampling, the idea of parallel tests that was previously mentioned is an extension or a special case. Another special case of domain sampling is factorial domain-sampling. In this case, within a domain, there can be several factors (or subcategories). For example, within the previous example of exercise, factors could be weight-bearing exercises (e.g., running and walking) versus non-weight-bearing exercises (rowing and biking). Another alternative to true score theory is the binomial model. In this model, it is assumed that the error scores have a binomial distribution around the true scores. Contemporary alternatives include latent variable modeling (supposing that there is an underlying trait to a series of items) and

multitrait multimethod (using multiple venues to access an estimation of a trait). A discussion of these methods is beyond the current entry. A final alternative is generalizability theory. It uses a universe score (similar to the true score in that it is an expected value for the observed score across all valid observations) and clearly outlines the dimensions in which a test can be used.

TUKEY'S HONESTLY SIGNIFICANT DIFFERENCE

The Tukey's honestly significant difference test (Tukey's HSD) is used to test differences among sample means for significance. The Tukey's HSD tests all pairwise differences while controlling the probability of making one or more Type I errors. The Tukey's HSD test is one of several tests designed for this purpose and fully controls this Type I error rate. Other tests such as the Newman-Keuls lead to an inflated Type I error rate in some situations. This entry describes how to conduct and interpret the Tukey's HSD test.

Philosophy

It is rare for any two experimental treatments to have identical effects. For example, it is implausible that two drug treatments could produce the same relief from

Table 1 The Six Comparisons Among Four Treatment Conditions

depression if measured to 100 decimal places. As a result, the role of inferential statistics in these situations is not to reject the null hypothesis of no difference, because that hypothesis is false on its face. Instead, it is to determine whether a confident statement can be made about the direction of the difference. Depending on the results of the inferential test, a researcher might be able to state with confidence the direction of the difference, might have a hint about the direction, or might have little or no information about the direction. Clearly, an all-or-nothing decision rule in which one either rejects or fails to reject the null hypothesis is not consistent with this approach. Instead, the probability value obtained in the inferential test is used to aid in the assessment of the confidence one should have in the direction of the difference.

Because some treatments of inferential statistics take the more traditional approach of testing whether a difference is exactly zero, it is important to show the correspondence between the approach taken here and the traditional approach. In the traditional approach, a Type I error is defined as rejecting a true null hypothesis. Here, a Type I error is defined as making a confident claim about the direction of the difference when there is either no difference or when the difference is in the opposite direction of the claimed difference. The Type I error rate in this context depends on the size of the true difference between means: If there is a large difference between the means, then the probability of getting the direction wrong is smaller than when there is a small difference between means. In computing the Type I error rate, the conservative approach is to assume that the true difference is zero. Although this might not often represent reality, it is the best way to ensure that the Type I error rate is controlled and is adopted here.

The Problem of Multiple Comparisons

If a researcher compared the means of four treatment conditions, there would be six pairwise comparisons. These comparisons are shown in Table 1.

It is important to distinguish between the following two error probabilities: 1) the probability that any single comparison results in a Type I error and 2) the probability that one or more comparisons result in a Type I error. The former probability is referred to as the per-comparison error rate; the latter probability is referred to as the family-wise error rate.

Because there are six comparisons in this example, the researcher has six chances to make a Type I error. Naturally, the more chances one has of making a Type I error, the higher the probability that at least one Type I error will be made. The probability is highest when the comparisons are independent. When independent, the probability of at least one Type I error can be computed using the following formula:

$$p_f = 1 - (1 - p_c)^c$$

where p_f is the family-wise error rate and is the probability of making one or more Type I errors, p_c is the per-comparison error rate and is the probability of making a Type I error in a single comparison, and c is the number of comparisons. For example, if the probability of making a Type I error with a single comparison were .05 and six comparisons were made, then the probability of one or more Type I errors would be

$$p_f = 1 - (1 - 0.05)^6 = 0.265.$$

This formula overstates the family-wise error rate because comparisons of pairs of means are not independent. In this example, consider whether a finding that Mean 1 is greater than Mean 2 would have any bearing on the comparison of Mean 1 and Mean 3. It turns out that if Mean 1 is larger than Mean 2, then it is likely that Mean 1 is larger than Mean 3. This can be observed from Table 2, which lists all possible orders of means. Of the six orders, Mean 1 is higher than Mean 2 in three orders (orders 1, 2, and 5). The critical question is, What happens when only these three orders are considered? Looking only at these three orders, it can be observed that Mean 1 is larger than Mean 2 in two of the three orders (orders 1 and 2). Therefore, the probability that Mean 1 will be greater than Mean 3 given that Mean 1 is greater than Mean 2 is .67. Clearly, the comparison of Mean 1 with Mean 2 is not independent of the comparison of Mean 1 with Mean 3.

Because these comparisons are not independent, the calculation that $p_f = .265$ overstates p_f . Although the details of how to calculate p_f for this example are beyond the scope of this entry, p_f is about .12. Therefore, although p_f is considerably below the value of

Table 2 Demonstration of Nonindependence of Comparisons

Order	Largest	Middle	Smallest	Mean 1 > Mean 2?	
				Mean 1 > Mean 3?	Mean 2 > Mean 3?
1	1	2	3	Yes	Yes
2	1	3	2	Yes	Yes
3	2	1	3	No	
4	2	3	1	No	
5	3	1	2	Yes	No
6	3	2	1	No	

.265 that is based on the assumption that the comparisons are independent, it is still considerably above the per-comparison rate of .05.

The degree to which the family-wise error rate is higher than the per-comparison rate depends on the number of comparisons, which, in turn, depends on the number of conditions in the experiment. The number of comparisons can be computed from the following formula, where c is the number of comparisons and k is the number of conditions:

$$c = \frac{k(k-1)}{2}$$

As shown in Table 3, the number of comparisons increases rapidly with the number of conditions.

The family-wise error rate for 10 conditions is about 0.80 and the rate for 20 conditions is about 0.90. It is obvious that the family-wise error rate can be extremely high if steps are not taken to control it.

One might be tempted simply to compute a t test between the largest and smallest means and, because only one test is computed, interpret it in the usual way. However, such a test would be greatly biased because the to-be-compared means would have been chosen after the data were examined. As a result, this procedure is tantamount to testing all pairwise differences and thus would result in the same inflated family-wise error rate as testing all pairwise comparisons.

Statistical Basis

The Tukey's HSD test controls the family-wise Type I error rate. The basic approach is to compute the difference between the largest and smallest means and determine the probability of obtaining a difference that is big or bigger if all the population means were equal. Because the range is defined as the difference between largest and smallest values, the probability in question is the probability of finding means with a range as large or larger than the range of means in the sample data.

Table 3 Number of Comparisons as a Function of Number of Conditions

Conditions	Comparisons
2	1
3	3
4	6
5	10
10	45
20	190

The significance test is based on the studentized range distribution. The studentized range distribution is similar to the Student's t -distribution but differs in that it takes into account the number of means being compared. The formula for a t test comparing two independent means is given below:

$$t = \frac{\bar{x}_1 - \bar{x}_2}{\sqrt{\frac{2MSE}{n}}}$$

where $\bar{x}_1$ is the sample mean for group 1, $\bar{x}_2$ is the sample mean for group 2, n is the sample size for each group, and MSE is the estimated population variance computed by averaging the sample variances in the two groups. The probability value for the t is computed based on the degrees of freedom which is equal to $N-2$, where N is the total number of observations.

The Tukey's HSD tests the difference between each pair of means using the value of the studentized t (t_s) computed using the following formula:

$$t = \frac{\bar{x}_i - \bar{x}_j}{\sqrt{\frac{MSE}{n}}}$$

where $\bar{x}_i$ is the mean of group i , $\bar{x}_j$ is the mean of group j , and MSE is the estimated population variance computed by averaging the sample variances of all the groups. The probability value for t_s is computed based on two parameters: the degrees of freedom (df) and the number of conditions in the experiment (k). The degrees of freedom is equal to $N - k$, where N is the total number of observations. Probability values for the studentized range distribution are calculated by some but not all statistical packages. An online calculator for the studentized range is available at http://onlinestatbook.com/analysis/lab/studentized_range_dist.html.

There are two differences between the formulas for t and t_s : the formula for t compares the means of the

two conditions in an experiment and therefore there is only one value of t . The t_s formula compares $\bar{x}_i$ and $\bar{x}_j$ for all combinations of i and j except for the trivial cases in which i equals j . Therefore, if there are three conditions, the values of i and j are 1, 2; 1, 3; and 2, 3 for the three comparisons among the means. These represent comparisons of Mean 1 with Mean 2, Mean 1 with Mean 3, and Mean 2 with Mean 3, respectively. Second, notice there is a "2" in the denominator for t but not for t_s . This difference is more or less a historical accident and has no practical consequence because the definition of the studentized range assumes the computation does not involve a "2" in the denominator. The studentized range could have been defined in such a way that the formula for t_s did include this "2."

The t -distribution is equal to the studentized range distribution when $k = 2$ except for whether there is a "2" denominator. Because the calculation of probabilities takes this difference into account, the p values are always the same. For example, for a difference between means of 12, a sample size (per group) of 10, and an MSE of 100, the values of t and t_s are 2.68 and 3.79, respectively. The p value for a t of 2.68 and a t_s of 3.79 are both equal to .0137.

Assumptions

The Tukey's HSD test assumes that (a) all observations are sampled randomly and independently, (b) the k populations are distributed normally, and (c) the k populations all have the same variance. This last assumption is called the assumption of homogeneity of variance.

Displaying the Results

There are a variety of ways the results of the Tukey's HSD test can be displayed. A common approach is to use underlining to indicate which means are significantly different from each other and which means are not. In the example shown below, means that are not significantly different share a line.

Because there is a line between Conditions 1 and 2, these conditions are not significantly different. Similarly, there is a line between Conditions 2 and 3, which indicates these conditions are not significantly

Condition			
1	2	3	4

Figure 1 Commonly Used Method to Indicate Which Means Are Significantly Different

Table 4 Probability Values and 95% Confidence Intervals

	1	2	3	4
1	X	-0.88 to 3.55	2.28 to 5.72	7.95 to 12.38
2	.358	X	-0.05 to 4.38	6.62 to 11.05
3	.001	.057	X	4.45 to 8.88
4	<.001	<.001	<.001	X

different. As there is no line between Conditions 1 and 3, Conditions 1 and 4, Conditions 2 and 4, and Conditions 3 and 4, these four differences are all significant. This approach is not recommended, however, because it follows the all-or-none rejection of the null hypothesis philosophy.

A better method for displaying the results is to give the probability values and confidence intervals for each comparison in a matrix as shown in Table 4.

The upper triangle contains the 95% confidence intervals for each difference between means. For example, the entry "-0.88 to 3.55" in the first row, second column is the 95% confidence interval for $\bar{x}_2 - \bar{x}_1$. The interval has a lower limit of -0.88 and an upper limit of 3.55. Because both positive and negative values are included in the interval, a confident statement about the direction of the difference cannot be made. The lower triangle contains the probability values. The value in the second row and first column is .358. This is the two-tailed probability for the comparison of Means 1 and 2. Consistent with the confidence interval (as it always will be), this result does not allow a confident conclusion about direction.

Worked Example

Table 5 shows the raw data from a hypothetical experiment in which there are four conditions and six observations in each condition. The data for a given condition is in the column labeled by the number of the condition.

Table 5 Example Data

	Condition			
	1	2	3	4
1				
3		4	8	12
2		5	6	13
4		4	6	12
5		5	5	15
4		4	8	16
3		7	9	14

Table 6 Means and Variances as a Function of Condition

	Condition			
	1	2	3	4
Mean	3.500	4.8333	7.000	13.667
Variance	1.100	1.3667	2.400	2.6667

Table 7 Tests for the Comparisons Among Conditions

Condition <i>i</i>	Condition <i>j</i>	Difference	t_s
4	1	10.167	18.15
4	2	8.833	15.77
4	3	6.667	11.90
3	1	3.500	6.25
3	2	2.167	3.87
2	1	1.333	2.38

The first step in computing the Tukey's HSD is to compute the means and variances for each condition. These are shown in Table 6.

The next step is to compute the *MSE*. Recall that the *MSE* is the mean of the variances. For these data, *MSE* = 1.883. The denominator of the formula for t_s can be computed as follows:

$$\sqrt{\frac{MSE}{n}} = \sqrt{\frac{1.883}{6}} = 0.560$$

To compute t_s for a comparison, the difference between means is divided by the denominator of 0.560. The values of t_s are shown in Table 7.

The probability values can be computed from the calculator referenced in the "Statistical Basis" section. Note that the probability values shown in the "Displaying the Results" section are based on these data.

If a studentized range calculator is not available, the critical values for significance testing can be found in a table of the studentized range distribution. Typically, the rows show the degrees of freedom, the columns show the number of conditions, and each entry contains a critical value. As discussed, it is better to report probability values than whether a difference is significant. Therefore, tables of the studentized range should be used only as a last resort.

Unequal Sample Sizes

The formula given previously for t_s has n , the sample size for each group, in the denominator. Therefore, a

different formula is required when the sample sizes are not equal. A good solution is to use what is called the Tukey-Kramer Method. The formula for unequal n s is

$$t_s = \frac{\bar{x}_i - \bar{x}_j}{\sqrt{\frac{MSE}{n_b}}},$$

where n_b is the harmonic mean of n_i and n_j and is computed as follows:

$$n_b = \frac{2}{\frac{1}{n_i} + \frac{1}{n_j}}.$$

Therefore, if $n_i = 12$ and $n_j = 16$ then

$$n_b = \frac{2}{\frac{1}{12} + \frac{1}{16}} = 13.71.$$

Notice that the harmonic mean is slightly lower than the arithmetic mean of 14.

When the sample sizes are not equal, *MSE* is computed somewhat differently so as to take into account the fact that some sample variances are based on more observations than others. For each group, the sum of squares error is computed using the numerator for the formula for the variance. That is, for group i , the sum of squares error (*SSE*) is

$$SSE_i = \sum (X - \bar{x}_i)^2.$$

The *SSE* is then the sum of the *SSE*s for the separate groups. Finally, *MSE* is computed by dividing *SSE* by the degrees of freedom error (*dfe*). The degrees of freedom error is equal to $N - k$.

Violations of Assumptions

The Tukey's HSD is relatively robust to violations of the normality assumption and, in general, provides conservative probability values. However, a violation of the assumption of homogeneity of variance can seriously inflate the Type I error rate. There are a variety of approaches to handling heterogeneity of variance including Dunnett's T3 test, Dunnett's C test, and the Games-Howell test. The calculations of these tests and their associated probability values is complex and beyond the scope of this entry. Researchers should use the Tukey's HSD cautiously when there is evidence of heterogeneity of variance.

Is the Tukey's HSD Test a Post Hoc Test?

Some statistics texts and software packages classify the Tukey's HSD test as a post hoc test and/or as a test performed following a significant analysis of variance. Classifying the Tukey's HSD as post hoc means that the decision to use this test was made after having analyzed or viewed the data. Although this might be true in some instances, there is no reason a researcher cannot (or should not) plan a priori to compare all pairs of means using the Tukey's HSD. It is therefore a misnomer to classify the Tukey's HSD as post hoc.

The Tukey's HSD test is often presented as a follow-up to a significant analysis of variance (ANOVA). The thinking is that if the ANOVA is significant, then the omnibus null hypothesis that all population means are equal can be rejected. The Tukey's HSD is used as a follow-up to determine which means are significantly different from other means. Although this sequential testing scheme is valid, it is not necessary. The Tukey's HSD when used alone controls the family-wise Type I error rate. There is, therefore, no requirement that the Tukey's HSD be conducted following a significant analysis of variance.

Because ANOVA and the Tukey's HSD have different statistical bases, they occasionally lead to different results. That is, it is possible for the ANOVA to fail to be significant while one or more of the Tukey's HSD comparisons is significant. It is also possible for the ANOVA to be significant and none of the Tukey's HSD comparisons to be significant.

It is instructive to consider the costs and benefits of these two procedures when they lead to different results. First, consider the case in which the ANOVA is not significant and a Tukey's HSD comparison is. In this case, the sequential procedure would not lead to any confident conclusion, whereas the Tukey's HSD alone would lead to a confident conclusion about the direction of at least one difference between means. In the case in which the ANOVA is significant and none of the Tukey's HSD comparisons are significant, the sequential procedure would allow the rejection of the omnibus null hypothesis, whereas the Tukey's HSD alone would not result in any confident conclusions. Thus, the potential loss of the sequential procedure is to miss out on a conclusion about a particular pair of means, whereas the potential loss of the Tukey's HSD alone is to miss out on rejecting the omnibus null hypothesis. The former loss would seem more serious than the latter so the recommended procedure is to do the Tukey's HSD alone.

Two-Mode Data

A two-mode network, also known as an *affiliation network*, depicts relationships that connect entities of two distinct types. Examples are memberships of individuals in groups or participation in events by individuals. This entry describes typical uses of two-mode network data, sources from which they can be drawn, and some common approaches to studying them.

Two-mode network data include two different sets of nodes, one for each type of entity. Following convention, this entry uses the terms *actors* and *events* to distinguish between these node sets. All direct relationships in a two-mode network connect nodes that differ in type: neither actors nor events may be directly tied to one another. Ordinarily, however, they are indirectly linked—for example, when two individuals (actors) are co-members of a given group (event) or when two events have participants (actors) in common. In two-mode data, relationships usually are binary—either present or absent—although it is possible to add weights that reflect variations in relationship strength. Information about attributes of actors and/or events may supplement the relational data.

Some studies accord equal attention to the actors and the events. A high school social structure, for instance, could be represented by two-mode data on the participation of students (actors) in extracurricular activities (events). It might highlight patterns in how students affiliate with activities as well as in where both students and activities stand relative to one another.

Other applications place emphasis on entities of one type, say actors. Here, the indirect relations between actors mediated by their shared affiliations with events are of principal concern; these provide proxy measures of relationships within a one-mode *projection* network that links the actors. In this situation, the events serve to

connect the actors but are otherwise subordinated. A study of patterns in scientific collaboration may, for example, be based on a two-mode network reporting which scientists (actors) authored publications (events)—concentrating mainly on relationships among the scientists as reflected in their coauthorships, with little or no attention to particular publications.

Representations of Two-Mode Network Data

A two-mode network may be described as a set of subsets that include entities of one type, say actors; the subsets represent the other type (events). For example, consider the student members of five extracurricular

groups in a small school; the groups are subsets of the 10 students:

- I (Service Club): {Casey, Kelly, Morgan, Riley, Taylor}
- II (World Cultures): {Blake, Parker, Taylor}
- III (Concert Band): {Drew, Noel}
- IV (Student Council): {Blake, Casey, Kelly, Noel, Parker}
- V (Ballroom Dancing): {Avery, Drew, Morgan, Noel}

Two-mode data are often presented in the form of an *incidence matrix*, in which rows index actors and columns events. With the usual binary data, entries of 1 indicate that an actor (e.g., student) is affiliated with an event (e.g., extracurricular group), while 0s indicate nonaffiliation. Table 1 displays the incidence matrix representation of the school data.

Table 1 Incidence Matrix for a Two-Mode Network

Student	Extracurricular Group				
	Service Club	World Cultures	Concert Band	Student Council	Ballroom Dancing
Avery	0	0	0	0	1
Blake	0	1	0	1	0
Casey	1	0	0	1	0
Drew	0	0	1	0	1
Kelly	1	0	0	1	0
Morgan	1	0	0	0	1
Noel	0	0	1	1	1
Parker	0	1	0	1	0
Riley	1	0	0	0	0
Taylor	1	1	0	0	0

Figure 1 Visualization of Incidence Matrix in Table 1

Visualizations of two-mode network data include points for all actors and events and lines that symbolize their affiliations. Such displays distinguish actors and events using symbols with different shapes and/or colors. In the graph for the school data shown in Figure 1, black squares represent activities, while gray circles represent students.

Sources of Two-Mode Network Data

Any social science research method may be used to assemble data on a two-mode network. A survey might collect information about the school network by asking students about their involvement in activities; alternatively, one might code student participation in extracurricular groups from pictures or lists in a high school yearbook.

Archives and administrative data often record information about those involved in activities or groups, providing a rich, unobtrusive, and often economical source of two-mode network data. Data listing the individuals (actors) who serve on corporate boards of directors (events) are an especially well-known case, on which much research about intercorporate networks rests. Records maintained by law enforcement agencies that report the persons (actors) arrested or charged with specific episodes of criminal activity (events) yield insight into patterns of collaboration in otherwise difficult-to-observe counternormative activities. Financial records indicating which physicians (actors) sought payment for treating particular patients with a medical condition (events) are used to infer patterns of interphysician communication and collaboration. Bibliographic data bases provide a means of linking authors, articles, and/or journals via coauthorship or citation relationships.

Electronic record-keeping systems also contain data from which two-mode networks can be constructed, often by indicating whether two actors were in the same place at approximately the same time. Examples include records of when individuals (actors) swiped in to gain access to buildings or meeting rooms (events) or the times at which they contributed to and/or retrieved information from a knowledge repository.

Projections: One-Mode Networks Derived From Two-Mode Data

Two-mode network data contain no information about the direct dyadic relationships between two entities of the same type (say actors). Two actors may be indirectly related, however, by the way of shared affiliations with events. Many studies use such indirect relationships as indicators of interactor ties, in lieu of

direct measurements of the latter. For instance, two authors are deemed to have a collaborative relationship if they coauthor a published work or two persons are regarded as conspirators if they are arrested for the same crime.

This rests on the rationale that shared affiliations of two actors are associated with the prospect that a direct relationship exists between them. Co-participation in events might offer opportunities for contact that lead actors to form relationships or it might reflect an already-existing tie that leads the actors to do things together. Inferring a direct linkage from shared affiliations is highly plausible in some applications: For example, on one hand, if two scientists coauthor an article, it is reasonable to assume that they know and work with one another. On the other hand, if two students are both members of a large club or are both in the same building at the same time, it is less certain that they are directly linked. Some regard shared affiliations as an opportunity structure or *backcloth* on which dyadic relationships may be built.

One-mode networks based on indirect relationships in two-mode networks are known as *projections*. For binary two-mode data, a one-mode projection for actors usually gives the number of events with which each pair of actors is co-affiliated. A count of the shared affiliations c_{ij} for two actors i and j in the one-mode projection can be calculated from an incidence matrix representation of two-mode data as $c_{ij} = \sum_{m=1}^M x_{im}x_{jm}$ where x_{im} indicates whether actor i is affiliated (1) or not (0) with event m in the two-mode data, and M is the number of events. A *dual* projection for events gives the number of actors co-affiliated with each pair of events. Some studies use different formulas to construct one-mode projections (e.g., by assigning less weight to a shared affiliation with a large event than with a small one).

One-mode projection matrices derived from the two-mode school network of Table 1 appear in Table 2. Entries in the upper panel show how many activities each pair of students shares; for example, Kelly and Casey are members of both the student council and the service club. The lower panel presents the numbers of students who co-participate in each pair of activities; for example, the service club has two members who are also on the student council, but none who are in the concert band. Entries linking actors to themselves give their number of memberships—Noel is involved in three activities and Riley in one; likewise, the World Cultures club has three members.

Analysts often dichotomize the entries in projections prior to analyzing them as one-mode networks, as many network-analytic techniques require binary data. For the student-student projection in Table 2, one might

Table 2 Projection Matrices for a Two-Mode Network

<i>Number of shared group memberships for pairs of students:</i>										
<i>Student</i>	<i>Avery</i>	<i>Blake</i>	<i>Casey</i>	<i>Drew</i>	<i>Kelly</i>	<i>Morgan</i>	<i>Noel</i>	<i>Parker</i>	<i>Riley</i>	<i>Taylor</i>
Avery	1	0	0	1	0	1	1	0	0	0
Blake	0	2	1	0	1	0	1	2	0	1
Casey	0	1	2	0	2	1	1	1	1	1
Drew	1	0	0	2	0	1	2	0	0	0
Kelly	0	1	2	0	2	1	1	1	1	1
Morgan	1	0	1	1	1	2	1	0	1	1
Noel	1	1	1	2	1	1	3	1	0	0
Parker	0	2	1	0	1	0	1	2	0	1
Riley	0	0	1	0	1	1	0	0	1	1
Taylor	0	1	1	0	1	1	0	1	1	2

<i>Number of shared members for pairs of activities:</i>					
<i>Activity</i>	<i>Service Club</i>	<i>World Cultures</i>	<i>Concert Band</i>	<i>Student Council</i>	<i>Ballroom Dancing</i>
Service Club	5	1	0	2	1
World Cultures	1	3	0	2	0
Concert Band	0	0	2	1	2
Student Council	2	2	1	5	1
Ballroom Dancing	1	0	2	1	4

take any positive number of co-memberships to indicate that two students are related to one another; a more stringent standard would require two shared activities for making that attribution. Some analysts use statistical methods to identify a binary *backbone* of a projection network; this consists of those pairs of actors who have significantly greater-than-expected numbers of shared affiliations, given each actor's number of memberships and each event's number of participants.

Analytic Strategies for Two-Mode Network Data

Counterparts to most methods used to analyze one-mode networks exist for two-mode networks. Visualization of two-mode data (e.g., Figure 1) is possible. Measures (like centrality) of the positions of both actors and events within the two-mode network—as

well as either one-mode projection—can be obtained. Subgroups of actors and/or events that are densely interrelated, or that are related in similar ways to other elements of the network, may be identified. Summary statistics about the network structure—including density, diameter, or average path length, among others—may be calculated. Stochastic models assessing the importance of structural tendencies that underlie a given two-mode incidence matrix can be estimated.

Analysts may use methods like these to study the two-mode network itself, thereby giving simultaneous attention to both actors and events. Alternatively, one may analyze a one-mode projection derived from two-mode data. The latter strategy often aligns with research questions posed by studies in which interest centers on one of the two types of entity (actors or events). It can entail some information loss, however, because a given one-mode projection may correspond to more than one

two-mode network. Some analysts argue that studying both the actor-by-actor and event-by-event projections can avert this.

TWO-TAILED TEST

A two-tailed test is a statistical procedure used to compare the null hypothesis (that a population parameter is equal to a particular value) against the alternative hypothesis (that the population parameter is *different* from this value). Evidence regarding the null hypothesis is obtained from a test statistic, and the test is said to be “two tailed” because its alternative hypothesis does not specify whether the parameter is greater than or less than the value specified by the null hypothesis. Hence, both large and small values of the test statistic, that is, values on both tails of its distribution, provide evidence against the null hypothesis. This type of test is relevant for situations in which researchers wish to test a null hypothesis, but they do not have a prior belief about the direction of the alternative, a situation that is likely to happen in practice. The term *two-tailed test* is usually reserved for the particular case of one-dimensional hypotheses, even though it might be used more generally.

Two-Sided Hypothesis Testing

In hypothesis testing, the hypotheses are always statements about a population parameter that partitions the set of possible values that the parameters might take. For example, letting μ be the parameter for which the hypothesis test is performed, a null hypothesis, which is referred to as H_0 , might be defined as

$$H_0 : \mu = \mu_0,$$

and its two-sided alternative hypothesis, which is referred to as H_1 , is defined as

$$H_1 : \mu \neq \mu_0.$$

The alternative hypothesis H_1 does not make a statement about whether μ is greater than μ_0 or less than μ_0 , which makes this a two-sided test. The difference between a one-sided test and a two-sided test lies solely in the specification of the alternative hypothesis. As a consequence, whereas a one-sided test specifies in its alternative hypothesis that the parameter is either greater than or less than the value specified in the null hypothesis (H_1 is either $\mu > \mu_0$ or $\mu < \mu_0$), in a two-sided test, the direction of the alternative hypothesis is left unspecified.

Evidence for or against the null hypothesis is obtained by means of a test statistic, which is a function of the available data. Just as in the one-sided case, in a two-sided hypothesis test the decision of whether to reject the null hypothesis H_0 is based on a test statistic $W(X) = W(X_1, X_2, \dots, X_N)$ which is a function of a (random) sample $X_1, X_2, \dots, X_N$ of size N from the population under study. The test specifies a rejection rule that indicates in what situations H_0 should be rejected. In a two-sided test, rejection occurs for both large and small values of $W(X)$, whereas in a one-sided test, rejection occurs either for large or small values of the test statistic (but not both) as dictated by the alternative hypothesis. Formally, a two-sided rejection rule is defined as:

$$\text{Reject } H_0 \text{ if } W(X) < c_1 \text{ or } W(X) > c_2.$$

$$\text{Do not reject } H_0 \text{ if } c_1 \leq W(X) \leq c_2.$$

To establish the values of the critical values c_1 and c_2 , it is common practice to follow the Neyman–Pearson approach and first choose a significance level α . The significance level α of the test is an upper bound to the probability of mistakenly rejecting H_0 when H_0 is true (probability of Type I error). Once the

significance level has been fixed, the constants c_1 and c_2 are chosen so that the probability of rejecting H_0 when H_0 is true is (at most) equal to the significance level. In other words, c_1 and c_2 are chosen so that

$$\Pr_{H_0}[W(X) < c_1] + \Pr_{H_0}[W(X) > c_2] \leq \alpha,$$

where $\Pr_{H_0}(z)$ indicates the probability of z computed assuming that the null hypothesis H_0 is true.

This still might leave the constants c_1 and c_2 undetermined, because there might be infinitely many ways in which the sum of these two terms can be made equal to α . Thus, the researcher must usually make a decision regarding how to divide the probability α between the two terms, that is, between the two tails of the distribution of $W(X)$ under H_0 . If the researcher has no prior information regarding the direction of the alternative, then it seems appropriate to divide this total probability symmetrically between the two tails. That is, the condition $\Pr_{H_0}[W(X) < c_1] = \Pr_{H_0}[W(X) > c_2]$ is imposed, and therefore

$$\Pr_{H_0}[W(X) < c_1] = \Pr_{H_0}[W(X) > c_2] \leq \frac{\alpha}{2}.$$

If the researcher has prior information regarding the population parameter that might affect the alternative hypothesis, then this total probability might be divided asymmetrically between the two tails. However, an asymmetric allocation of α between both tails is not used very often, because in cases when information regarding the direction of the effect under study is available, researchers usually choose a one-sided alternative.

The two-sided rejection rule is easier to construct when the distribution of $W(X)$ under the null hypothesis is symmetric, because in this case, the critical values c_1 and c_2 are equal in absolute value. In this case, there is only one unknown constant that needs to be established based on the underlying distribution of the test statistic.

Comparison With One-Sided Test

The difference in the specification of the alternative hypothesis between a one-tailed test and a two-tailed test has important conceptual consequences. As illustrated in the example that follows, using a two-sided test is generally conservative in the sense that it is more difficult to reject the null hypothesis with this test than with the correct one-sided test for a given significance level. This occurs because a more extreme value of the test statistic will be necessary to reject the null hypothesis at the same α significance level with a two-sided

test than with a one-sided test, because in the former, the total probability of rejecting H_0 when it is true (Type I error) is split between both tails of the distribution of $W(X)$.

For example, when the null hypothesis H_0 is tested using both an α -level one-sided test to the right and an α -level two-sided test, and the distribution of the test statistic is continuous, the critical value c^* of the one-sided test is defined by $\Pr_{H_0}[W(X) > c^*] = \alpha$, and the critical values c_l^{**} and c_u^{**} of the two-sided test are defined by $\Pr_{H_0}[W(X) < c_l^{**}] + \Pr_{H_0}[W(X) > c_u^{**}] = \alpha$. It is easy to see that in this case $c^* < c_l^{**}$ and values of $W(X)$ exist such that $c^* < W(X) < c_u^{**}$. When this happens, H_0 will be rejected with the one-sided test but will not be rejected with the two-sided test.

This point is further illustrated in Figure 1, where the top panel shows the significance level of a one-sided hypothesis test for the particular case of a normal distribution of the test statistic under H_0 , and the bottom panel shows a two-sided test with the same significance level and the same test statistic, where the significance level has been split symmetrically across both tails. As can be viewed in the figure, for all values of $W(X)$ between 1.64 and 1.96, the null hypothesis is rejected with a one-sided test but is *not* rejected with a two-sided test. The two-sided test requires a larger value of $W(X)$ to reject H_0 than the one-sided test shown in the figure, because the probability of Type I error on the upper tail is forced to be smaller in the two-sided

Figure 1 One-Sided Versus Two-Sided Hypothesis Test Under Normality

test ($\alpha/2$) than in the one-sided test (α). This illustrates how a two-sided test might require a more surprising value of $W(X)$ to reject the null hypothesis than a one-sided test, which makes the two-sided test more conservative.

A Numerical Example

Imagine a situation in which a researcher is interested in establishing whether two competing math text books have the effect of increasing the mathematical skills of elementary school students. In particular, the researcher is interested in whether assigning the practice exercises of the books as homework has an effect on math test scores. For this purpose, N students are randomly assigned to two different groups, which are referred to as Group A and Group B, of size N_A and N_B , respectively. Students in Group A are assigned the exercises in Book A as homework during the course of a month, and students in Group B are assigned the exercises in Book B as homework during the same period of time. Students solve the exercises individually and are not allowed to interact with one another. The researcher is interested in establishing whether children who are assigned the exercises in one book perform better in a math examination at the end of the experiment than children assigned the exercises in the other book, but based on the available information, the researcher has no prior belief as to which book is more effective than the other. In this case, a two-sided hypothesis test is appropriate, because the alternative hypothesis should be left unspecified.

Students are given a math examination at the beginning and at the end of the experiment, and the change in test scores is recorded for each student. Assuming that the difference in test scores is approximately normally distributed with means μ_A and μ_B in Groups A and B, respectively, and equal variance, the mean differential effect of the two types of exercises can be analyzed using a two-sided difference-in-means test to determine whether $\mu_A - \mu_B$ is different from zero. Formally, the null and alternative hypotheses are formulated as follows:

$$H_0 : \mu_A - \mu_B = 0,$$

$$H_1 : \mu_A - \mu_B \neq 0.$$

The researcher chooses to test H_0 using the test statistic

$$W = \frac{\bar{X}_A - \bar{X}_B}{\sqrt{s^2 \left(\frac{1}{N_A} + \frac{1}{N_B} \right)}},$$

where

$$s^2 = \left(\frac{1}{N_A + N_B - 2} \right) \left[\sum_{i=1}^{N_A} (X_{iA} - \bar{X}_A)^2 + \sum_{i=1}^{N_B} (X_{iB} - \bar{X}_B)^2 \right]$$

where $\bar{X}_A$ and $\bar{X}_B$ are the sample means of the change in test scores in Groups A and B, respectively, and X_{iA} and X_{iB} are the changes in test scores for student i in each group. W is the t statistic for the difference in means when variances are unknown but equal and has a t -distribution under H_0 with $N_A + N_B - 2$ degrees of freedom. However, because the number of degrees of freedom in this example is large ($N_A + N_B - 2 = 133$), the distribution of W can be approximated by a normal distribution.

Assuming there are 70 students in Group A and 65 students in Group B and that $\bar{X}_A = 0.1286$, $\bar{X}_B = 0.0461$,

$$\sum_{i=1}^{N_A} (X_{iA} - \bar{X}_A)^2 = 7.8429, \quad \sum_{i=1}^{N_B} (X_{iB} - \bar{X}_B)^2 = 2.8615,$$

the value of the test statistic is $W = 1.6866$. To decide whether to reject the null hypothesis that both types of exercises have the same effect at increasing the math skills of students as measured by the improvement in their test scores, the significance level of the test must be established. If the significance level is set at 5% and this mass is equally distributed on both tails, the rejection rule is

$$\text{Reject } H_0 \text{ if } |W(X)| > 1.96$$

$$\text{Do not reject } H_0 \text{ if } |W(X)| \leq 1.96$$

since 1.96 and -1.96 are, respectively, the 2.5% and 97.5% quantiles of the normal distribution. Given that $|W(X)| = 1.6866 < 1.96$, H_0 cannot be rejected and the researcher cannot reject the hypothesis that exercises in Book A are equally effective at improving math skills than exercises in Book B.

In this example, had the researcher performed a one-sided test with the alternative hypothesis that $\mu_A - \mu_B > 0$, the rejection rule would have been

$$\text{Reject } H_0 \text{ if } W(X) > 1.64,$$

$$\text{Do not reject } H_0 \text{ if } W(X) \leq 1.64,$$

and the null hypothesis would have been rejected in favor of the alternative hypothesis that the type of

exercises in Book A are more effective at increasing the mathematical skills of students than the type of exercises in Book B. Thus, using a two-sided test, the null hypothesis cannot be rejected, even when a one-sided test (to the right) would have rejected the null hypothesis.

TYPE I ERROR

Hypothesis testing is one of the most widely used procedures in statistical decision making. However, it can result in several errors. This entry focuses on the Type I error, which occurs when a true hypothesis is wrongly rejected.

Hypothesis Testing

Type I errors occur in statistics when hypothesis tests are used to make statistical decisions based on experimental data. In this decision process, a simple statement or null hypothesis is formulated on the true status of an unobserved phenomenon. At the same time, an alternative hypothesis is defined to reflect the opposite situation. For instance, a new drug is tested for its capacity to reduce high blood pressure. The null hypothesis states that the new drug does not change blood pressure. Any differences that are observed are explained by random variation in the measurement process. The alternative hypothesis can be formulated as “the drug reduces high blood pressure.”

Table I Schematic Representation of Possible Combinations between Hypothesis and Test Outcome

		Null hypothesis	
		True	False
Test outcome	Accepted	Correct	Type II error
	Rejected	Type I error	Correct

Once the appropriate hypotheses have been formulated, one would like to test whether the null can be rejected in favor of the alternative. At this point, an experiment can be designed, a relevant test statistic and its distribution under the null can be derived, and data can be collected. These elements are required in the process to arrive at one of the two following conclusions:

- The null hypothesis can be rejected in favor of the alternative because the observed pattern in the sample cannot be explained merely by random variation, or
- There is not enough evidence to reject the null in favor of the alternative because the observed pattern in the sample is most likely a result of chance.

When the statistical test favors a decision that is in agreement with reality, a correct decision has been made. However, this decision procedure can also result in several errors (see Table 1).

The null hypothesis can be wrongly rejected in favor of the alternative, even if the statement in the null is true. In this case, a Type I error has occurred. One can also fail to reject the null hypothesis when the alternative is true, which results in a Type II error. For instance, in the blood pressure example, a Type I error occurs if a statistically significant effect of the drug is found when in reality the drug does not influence blood pressure.

Why Type I Errors Occur

Hypothesis testing can be viewed as making an educated guess. Like with any other guess, it is possible to draw the wrong conclusion. The data that are used to validate the null hypothesis are drawn as a random sample from the study population. Just by chance, it is possible that this sample reflects a relationship that is not present in the population. Consider for instance four throws with a six-sided die. If the four throws result in four 1s, this could be interpreted as evidence that the die is loaded in favor of the outcome “1.” However, even with an honest die, a combination of

four 1s can occur once in every 1,296 (6^4) sequences of throws. If in this case the die would be marked as loaded, a Type I error has occurred. Unfortunately, one can never be certain whether a rejected hypothesis is a reflection of the true nature of the studied phenomenon or whether it is the result of an accidental relationship present in the sample.

Depending on the context, making a Type I error can have important consequences. In the early stage of the development of a new drug, a Type I error would imply that a significant effect is found when there is none. Although this error could be detected in a later stage when a more complicated trial has been implemented, this might come at a considerable economical expense for the company developing the drug. A Type I error is, therefore, often considered to be a serious error: If there is an effect detected, then one wants to be as sure as possible that the effect is not the result of random variation.

In practice, one will try to control for the proportion of errors that could be made. The hypothesis testing starts by specifying α , the probability of making a Type I error. This probability, which is also referred to as the significance level, is chosen as low as possible. Conventionally, a significance level of 5% or less is considered small enough to ensure that the result did not occur by chance. However, the user of this procedure should still be aware that a conclusion based on this significance level will still be wrong one in 20 times. Reducing the probability of observing a Type I error can easily be achieved by reducing the significance level of the test. If a significance level of 1% rather than 5% is selected, then the conclusion will be wrong only once in 100 times. If a significance level is set equal to 0, then the null hypothesis will never be wrongly rejected. In fact, in this case the null hypothesis will never be rejected at all. However, choosing a smaller significance level will also reduce the power of the test: Rejecting the null hypothesis will become more difficult, even when the alternative is true, unless you can also increase the sample size. As a result, the probability of observing a Type II error will be inflated. Because the probabilities of observing a Type I and a Type II error are inversely related, it might not always be easy to find a balance between the two.

What Is in a Null?

Observe that the classification of an error as a Type I or Type II depends on the definition of the null hypothesis. Consider, for instance, the blood pressure example, with reversed hypotheses: The null is formulated in terms of the experimental drug having an effect, and the alternative as the treatment not having an effect. In

this case a Type I error is made when treatment is found not to have an effect when in fact it does affect blood pressure. This error was previously labeled as Type II.

The choice of the hypotheses mainly depends on the interest of the study. Recall that hypothesis testing can result in one of two responses: Either the null hypothesis is rejected in favor of the alternative or it is not. Note that failing to reject the null is not the same as claiming that the null is true. One fails to reject the null when there is not enough evidence against it. Therefore, in conventional statistical practice, what one wants to prove is formulated as the alternative hypothesis. Technically, one is testing for “guilt” rather than “innocence.” Like in any judiciary system, a defendant (hypothesis) is considered innocent (true) until proven guilty (false) beyond a reasonable doubt.

Cumulative Type I Error Rates

A situation where Type I errors can become an important problem when not properly accounted for is when several hypotheses are tested simultaneously. Even though the probability of observing a Type I error within one test might be set at 5%, if several tests are performed simultaneously, then the probability of observing a Type I error in at least one of these tests will be higher than 5%. Indeed, the possibility of observing a Type I error occurs each time a statistical test is performed. The more tests are performed, the higher the probability that a false positive significant result is found in at least one of them, just by chance.

The impact of multiple testing on the overall Type I error rate can be determined as follows. Let α_i represent the Type I error rate of the individual test, and let k refer to the number of independent comparisons. Then, the overall Type I error rate can be approximated by the correction $1 - (1 - \alpha_i)^k$. For example, consider a hypothesis test with significance level set at 5%. When this test is performed 5 times simultaneously, the overall Type I error rate (i.e., the probability of observing a Type I error in at least one of the 5 tests) is inflated up to 22%. When this test is performed 10 times, the overall Type I error rate is inflated up to 40%; when this test is performed 20 times, the overall Type I error rate is inflated up to 64%, and so on. The more comparisons are performed, the higher the probability of observing a false positive result in at least one of them.

Still, it is possible to protect an analysis against an inflated Type I error rate resulting from multiple comparison testing. The approach is based on the idea that if the Type I error rate of each comparison is reduced sufficiently, then the overall Type I error rate will also

decrease. For instance, the Bonferroni procedure consists of resizing the α , for each individual comparison by dividing it by the number of comparisons. This strategy guarantees that the overall Type I error rate will not exceed the prespecified significance level. However, as mentioned before, reducing the probability of observing a Type I error for each individual test will make it more difficult to find significant results and will increase the probability of observing a Type II error. A bigger sample size might be required to increase the power of the test.

Yes or No

Type I errors occur in hypothesis testing as part of a testing procedure that results in a yes-or-no answer. One either rejects the null hypothesis or one concludes that there is not enough evidence against it. This conclusion is often based on the p value associated with the estimated test statistic. p values represent the probability of observing data at least as extreme as the data that were actually observed, given that the null hypothesis is true. Therefore, a p value can be interpreted as an indicator of the amount of evidence against the null: The smaller the p value, the stronger the evidence. In hypothesis testing, the p value is often compared with the prespecified significance level. This significance level is used as a cutoff point, where all p values below result in a rejection of the null, and all values above are interpreted as compatible with the null. The main disadvantage of this procedure can be illustrated as follows. If a p value of .06 is obtained from a test with a 5% significance level, then the null hypothesis will not be rejected, even though the evidence against it is strong. Clearly, reporting this p value rather than the rejection of the null on the 5% significance level would be much more informative.

Type I Errors in Real Life

Type I errors also frequently occur beyond the boundaries of statistical testing. Similar errors are observed in diagnostic tests. For instance, a pregnancy test could produce a positive result even in the absence of pregnancy. Note that with this type of diagnostic screening tests, Type II errors are often considered to be more serious than Type I errors. When tested positive, the test subject can be redirected to a more elaborate evaluation in which the initial positive result can be confirmed or not. In case a Type I error or a false positive result occurs at the time of screening, it can still be corrected at a later stage. However, in the opposite situation where the screening fails to detect the positive

result, the test subject might miss an important opportunity to receive appropriate care.

A false positive can also occur when a legitimate e-mail is mistakenly labeled as spam by a filter or when a smoke alarm goes off without a fire. An innocent person could be found guilty of a crime that he or she did not commit. In fact, in this case a Type I error would even be twice as bad. Not only does an innocent person have to go to jail, but the guilty party goes free as well.

TYPE II ERROR

Hypothesis testing is one of the most widely used quantitative methods in decision making. It answers a research question in terms of statistical (non-) significance of a null hypothesis. The procedure of hypothesis testing can result in several errors. This entry focuses on Type II errors, which occur when a false hypothesis is not rejected. A short introduction to hypothesis testing is provided, followed by an overview of factors influencing the occurrence of Type II errors and examples of Type II errors beyond the boundaries of statistics.

Hypothesis Testing

Developed by Jerzy Neyman and Egon S. Pearson, hypothesis testing has become one of the most widely used quantitative methodologies in almost all areas dealing with experiments and data. In this decision process, a simple statement or null hypothesis is formulated on the true status of an unobserved phenomenon. At the same time, an alternative hypothesis is defined to reflect the opposite situation. The outcome of the hypothesis testing can be one of the two following results:

- The null hypothesis can be rejected in favor of the alternative because the observed pattern in the sampled data cannot be explained merely by random variation.

- There is not enough evidence to reject the null in favor of the alternative because the observed pattern in the sampled data is most likely a result of chance.

Note that failing to reject the null is not the same as claiming that the null is true. In principle, one is testing for “guilt” rather than “innocence”: Like in any judicial system, a defendant (hypothesis) is considered innocent (true) until proven guilty (false) beyond any reasonable doubt. The alternative hypothesis will, therefore, always reflect the property that one would like to prove. Consider, for instance, a clinical trial comparing an experimental drug with a standard treatment. The purpose of the trial is to detect a difference in the effect of both drugs. The null hypothesis will state that the experimental drug is, on average, not better than the conventional drug. Any differences that are observed can be explained by random variation in the measurement process. The alternative hypothesis can be formulated in several ways. For instance, a two-sided alternative could state that the experimental drug has, on average, a different effect. If one expects to find an improvement, then a one-sided alternative like “the new drug is better, on average, than the conventional drug” can be considered.

Once the appropriate hypotheses have been formulated, one would like to test whether the null can be rejected in favor of the alternative. At this point, an experiment can be designed, a relevant test statistic and its distribution under the null can be derived, and data can be collected. When the test favors a decision that is in agreement with reality, a correct decision has been made. However, this decision process can also result in several errors (see Table 1).

On the one hand, a Type I error occurs when the null hypothesis is wrongly rejected in favor of the alternative. On the other hand, a Type II error is made when a false null hypothesis is not rejected. In the clinical trial example, a Type II error occurs if there is not enough evidence against the null, when in reality the drug has an effect different from that of the conventional treatment.

Table 1 Schematic Representation of Possible Combinations between Hypothesis and Test Outcome

		Null hypothesis	
		True	False
Test outcome	Accepted	Correct	Type II error
	Rejected	Type I error	Correct

Factors Influencing Occurrence

In practice, one tries to control for the proportion of errors that could occur. Controlling for the probability α of making a Type I error can be done relatively easily by specifying it at the start of the study. This probability, which is also referred to as the significance level, is chosen as low as possible. Controlling for the probability β of making a Type II error is less straightforward as β depends on the prespecified significance level, the sample size, and the effect size one wishes to detect.

In clinical trials, the probability of observing a Type I error is often prespecified at 5%. It was a convenient choice in times when researchers had to rely on Ronald A. Fisher's tables of critical values based on 5% and 1% significance levels. Through the years, statisticians have continued to use 5%, almost like a scientific dogma, even in the current age of computers and software that greatly facilitate statistical computing. This level is considered small enough to ensure that the result did not occur by chance. Still, one should be aware that a conclusion based on a 5% significance level will still be wrong 1 in 20 times. Reducing the probability of observing a Type I error can be achieved relatively easily. The investigator can choose to lessen the significance level associated with the test. If a significance level of 1% rather than 5% is selected, then the conclusion will be wrong only 1 in 100 times. Choosing a smaller significance level does, however, have the adverse effect of complicating the rejection of the null hypothesis, even when the alternative is true. As a result, reducing the Type I error rate will inflate the probability of observing a Type II error.

Still, for any specified level of significance, the probability of observing a Type II error can be reduced by increasing the sample size. Indeed, adding information to the test implies adding evidence to the decision process. This strategy will result in a more informed conclusion. Several reexaminations of “negative” (or nonsignificant) trials have shown that in many studies, Type II errors occurred because of undersampling. Too few subjects were included in the study to guarantee a sufficient power to detect a clinically relevant effect. Note that the power of a test corresponds to $1 - \beta$ (i.e., one minus the probability of observing a Type II error). When the power of the test is low, then a Type II error is more likely, and vice versa.

Nowadays, sample size calculations based on prespecified levels for the Type I and Type II errors have become common practice in clinical trials. Most investigators will accept a β level of around 0.2 or, equivalently, a power of 80%. That means that in 8 of 10 trials, a statistically significant effect will be observed if

the effect is in reality as large as the one that was pre-supposed. This also implies that in 2 of 10 trials, the null hypothesis will not be rejected in favor of the correct alternative, and it will therefore result in a Type II error. Selecting a Type II error rate equal to 0.1 or, equivalently, increasing the power of the test to 90% might require a substantial increase in the number of participants. This might not always be feasible from an economical point of view. Furthermore, if the phenomenon one wishes to study is infrequent, like a rare disease, it might not be practical either.

The probability of observing a Type II error also depends on the effect size that needs to be detected. Indeed, the smaller the effect, the lower the power of the test and, therefore, also the higher the probability of making a Type II error. As a result, a larger sample is required to detect a smaller effect.

Note that even if the null hypothesis is true, it will be unlikely that the observed effect size will be exactly zero. Random variation in the measurement process can cause some small deviations. If, in this case, the sample size of the study is chosen large enough, it will be possible to detect even this random variation. However, this statistically significant result would clearly not be scientifically relevant. Therefore, it should be decided at the start of a study what is the minimum effect size one wishes to detect. For instance, in the clinical trial example, detecting a 20% difference between the experimental drug and the conventional treatment might be more clinically relevant than detecting a difference of only 2%.

Furthermore, if the effect size is expected to be in a certain direction, then the alternative can also be defined as a one-sided statement. For instance, the new drug could be expected to perform at least as well as the standard treatment. Given that the power to detect a one-sided alternative is higher than that of detecting a two-sided alternative, choosing one over the other can also have a positive impact on the probability of observing a Type II error.

Once a meaningful difference is agreed on, together with an acceptable Type I and Type II error rate, an appropriate sample size can be calculated to perform a successful trial. The hypothesis testing then serves as a validation tool that the significant findings did not occur by chance.

The decision of whether a finding is statistically significant based on the relatively arbitrary 5% level has been the topic of many passionate discussions among statisticians since the 1900s. Type I and Type II errors occur only because of the way hypothesis testing was developed. Neyman and Pearson motivated their approach by stating that, without knowing which hypothesis is true, hypothesis testing provides a

rule to guide the decision process, hoping that in the long run, one will not be too often wrong. It does, however, not provide any information on whether the user will be wrong in one specific study. An alternative approach that does provide information on the current study is based on Fisher's p value. p values can be interpreted as the probability of observing data at least as extreme as the data that were actually observed, given that the null hypothesis is true. Therefore, a p value is an indicator of the amount of evidence against the null: The smaller the p value, the stronger the evidence. Neyman and Pearson actually used Fisher's idea in hypothesis testing, by comparing it with the Type I error rate: All p values below α result in the rejection of the null hypothesis. Incidentally, this can lead to situations in which one would ignore a potentially clinically relevant result because a p value of .06 was observed. If this p value were to be reported rather than a conclusion reflecting the result of the hypothesis testing, the reader could get a better impression of the amount of evidence against the null hypothesis. Given his knowledge about the field and previous studies, it could help him or her to make a more informed decision.

Beyond the Boundaries of Statistics

As the comparison of hypothesis testing with a judiciary system already illustrated, Type II errors are also frequently observed beyond the boundaries of statistics. A Type II error occurs when junk mail is not blocked by a spam filter or when a guilty person is not condemned by a lack of evidence. In some situations, Type II errors can even have serious consequences. For instance, a virus would not be detected by an antivirus system or a smoke alarm would not warn in case of fire. A pregnancy test can fail to detect pregnancy. With this type of diagnostic screening tests, Type II errors are often considered to be more serious than Type I errors. When testing positive for pregnancy or a disease like tuberculosis, Hepatitis A/B, or cancer to name but a few, the test subject will be referred to a more elaborate evaluation in which the initial positive result can be confirmed or denied. In case a Type I error or a false positive result occurs at the time of screening, it can still be corrected at a later stage. However, in the opposite situation in which the initial screening fails to detect the positive result, the test subject might miss an important opportunity to receive appropriate care.

TYPE III ERROR

Type III error has been defined in two primary ways. First, researchers have described a Type III error as occurring when a research study provides the right answer but for the wrong question or research hypothesis. For example, in public health research, when a research hypothesis predicts risk differences between groups or across time periods, the study design requires adequate characterization of all relevant groups and time periods. If discrepancies are found among the research hypothesis, time periods, and the methods used to test the hypothesis, these discrepancies can lead to what seems to be answers to a specific question, when in fact the results support a different question. Second, other researchers have stated that in statistical tests involving directional decisions, a Type III error can occur when one accepts a specific directional alternative when in fact another alternative is true. In this case, the Type III error has a conditional probability, γ , which is simply the probability of getting the direction of the effect wrong. The entry provides some examples of Type III errors and recommendations for avoiding Type III errors.

Examples

Stroke

As noted in the first definition, Type III errors can occur when one examines the causes of variation in risk for a disease between individuals, but it does not consider that the causes of interindividual risk might differ from the causes of disease rates over time, and from causes of rate differences between populations. For example, when determining the etiology of stroke, the sources of variation of risk might include differences between individuals in genetic vulnerability, current medical conditions, temporal changes in poverty, and access to health care, as well as population and societal differences in what type of health care system is available. Furthermore, each of these factors is distinct from

the proximal cause of stroke, namely the deprivation of oxygen to the brain. Certainly, each of the factors discussed previously contributes to the risk for stroke. A Type III error can occur when a study is designed to ascertain the inter-individual differences in risk for stroke within a given population, but it neglects to look for causes of stroke that are constant within the population being studied. A Type III error can also occur when neglecting risk factors for stroke related to variation between populations and across time. Furthermore, a Type III error might occur when one determines the risk for stroke in more than one population and finds interindividual differences in risk of stroke that produce variation of stroke outcomes within one population, but it fails to realize that the causes that produce interindividual differences in risk for stroke in one population might be different from the factors that produced differences in average risk for stroke between two or more populations.

Interactive Effects From Rehabilitation After Stroke

In a large, multisite, randomized controlled trial using leisure therapy and conventional occupational therapy administered to patients who have had a stroke, Chris Parker and colleagues failed to demonstrate a benefit for patients in terms of improved mood, leisure activity, or independence in activities of daily living measured at 6 and 12 months. Based on the second definition of Type III error, one possible explanation of the failure to demonstrate an effect in this study might be the failure to consider interactive effects of the interventions, which might have produced a Type III error in interpretation of the results.

Recommendations

To avoid a Type III error when interpreting the findings from adequately powered studies that use multiple interventions, one must be careful not to conclude that a negative finding indicates that all components of the intervention were ineffective. Also, one should reassess whether the study design adequately measures potential interactive effects that occur with the intervention. Furthermore, a negative finding should not cause one to overreact and ignore one's findings or to ignore plausible alternative hypotheses.

UMBRELLA TRIALS DESIGN

The umbrella trials design (UTD) is a type of clinical trial design aiming to test a medication(s) in human participants with the same type of disease but with different molecular biology. UTD is a research plan in which the impact of multiple novel therapies matched to different targets within one disease is investigated simultaneously in parallel substudies or cohorts in one large clinical trial. In contrast to traditional clinical trial designs, in which a single experimental therapy is evaluated in one clinical trial, umbrella trials consist of several arms or substudies testing different agents and allow adding new arms over time. UTD is the most common in clinical trials in oncology, but it can also be used in drug development for other diseases. This entry describes the general process for UTD, providing two examples of trials in oncology and presents major advantages and limitations of this design.

Examples of Trials With UTD

In general, the research process in cancer trials with UTD commences with tumor biopsy and subsequently screening the tumor sample for a specific set of mutations or biomarkers that can be matched to the drugs being studied in the trial. Then, if the target biomarkers are detected, patients are assigned to relevant substudies either randomly or according to a predefined algorithm that, among others, balances accrual among treatment groups in cases of patients positive for multiple makers. Usually, one of the substudies serves as the control with approved treatment considered as a standard of care (SOC); it is also possible to include a *nonmatch* or *default* substudy with patients negative on all eligible markers.

Two examples of clinical trials with UTD are (1) the Lung-MAP trial for patients with advanced squamous cell cancer of the lung and (2) the Biomarker-integrated Approaches of Targeted Therapy for Lung Cancer Elimination (BATTLE)-1 trial for patients with advanced nonsmall cell lung cancer. Both trials are multidrug, biomarker-driven master protocols with multiple substudies. However, they use different assignment methods for their substudies. In the original Lung-MAP study, patients were assigned to one of five substudies on the basis of genetic screening results: four studies with novel targeted therapies adjusted to specific biomarkers and one nonmatch study. They were randomized afterward within substudies to experimental therapy or SOC. In turn, in the BATTLE-1 trial, the initial cohort of eligible patients was randomly assigned to the four substudies irrespective of their marker, with some justifiable exceptions. This was followed by adaptive randomization based on the accumulating data from each ongoing substudy. In both master protocols, patients could enroll in other substudies after disease progression and receive different investigational drugs.

Advantages

Clinical trials with UTD enroll patients with one disease type, but they are further stratified to different molecular alterations. This approach provides more precise treatment adjusted to the disease of an individual participant. It aims to increase the likelihood that study participants will directly benefit from the trial by both tailoring the high-precision targeted therapy and allowing for patient transfer among substudies, thus offering alternative treatment options. In short, this methodology enhances the chances for patient benefit, serves as efficient resource management, and contributes to the advancement of personalized medicine.

Another advantage of UTD is the simultaneous evaluation of multiple treatment options, which enables efficient and accelerated drug development. A hierarchical and flexible structure allows for various modifications such as opening new substudies or closure of ineffective ones within one large trial infrastructure. Each of these substudies not only tests different therapies but can also constitute a clinical trial of each phase, follow distinct randomization schemes, measure various end points, or be conducted according to different timelines. Such flexibility and possibility for variability among substudies permit the entire master protocol to evolve with upcoming findings from interim analyses or new data in the state of the art.

Limitations

The UTD has some important limitations. First, it is usually considered a large-scale research endeavor with complex structure and conduct requiring multistakeholder collaboration.

Second, to enroll a sufficient number of patients with a specific type of disease divided into even rarer molecular subtypes into an umbrella clinical trial, numerous locations for trials may be necessary. Failure to recruit sufficient study participants may result in producing nonsignificant results. In addition, all patients in a substudy should harbor similar genetic changes within their disease. The case of one patient with one actionable tumor mutation and another patient with multiple targetable mutations within the same substudy may pose challenges to produce reliable research findings. Moreover, recruitment of patients with multiple mutations and repeated assignments of them to different arms of a trial may pose risk of receiving suboptimal treatment.

Third, adding new substudies prolongs the duration of the umbrella study and reduces the ability of blinding, as each investigational agent can have different modes of administration and frequency.

Fourth, due to unusual flexibility of trials with UTD allowing for changes in their methodology, the adding and dropping of treatment arms can influence research transparency and induce various types of bias.

UNBIASED ESTIMATOR

One of the important objectives of scientific studies is to estimate quantities of interest from a population of subjects. These quantities are called parameters, and the actual nature of the parameter varies from population to population and from study to study. For example, in a study designed to estimate the proportion of U.S. citizens who approve the president's economic stimulus plan, the parameter of interest is a proportion. In other cases, parameters may be the population mean, variance, median, and so on. In cases where the population values are represented by a parametric model, the parameters represent the whole population instead of a particular characteristic of it.

Parameters are estimated based on the sample values. Estimators are functions of sample observations used to estimate the parameter. It would be expected that a good estimator should result in an estimate that is close to the true value of the parameter. Because in practice the parameters are unknown, it is not possible to compare the estimate with the true value. Unbiasedness serves as a measure of closeness between an estimator and the parameter.

Suppose the population parameter θ is to be estimated based on the sample observations $X_1, X_2, \dots, X_n$. An estimator $\hat{\theta} = h(X_1, X_2, \dots, X_n)$ is an unbiased estimator of θ if the mean or expectation of $\hat{\theta}$ over all possible samples from the population results in θ . In statistical terms, $\hat{\theta} = h(X_1, X_2, \dots, X_n)$ is an unbiased estimator of θ if and only if

$$E(\hat{\theta}) = \theta$$

for all θ , where $E(\hat{\theta})$ represents the expected value of $\hat{\theta}$. That is, if in repeated sampling from the population, the average value of the estimates equals the true parameter value, then the estimator is unbiased.

As an example, suppose the population mean is to be estimated based on a random sample $X_1, X_2, \dots, X_n$

from the population, then the sample mean $\bar{X} = (X_1 + X_2 + \cdots + X_n)/n$ is an unbiased estimator of the population mean. Statistically,

$$\begin{aligned} E(\bar{X}) &= \frac{E(X_1 + X_2 + \cdots + X_n)}{n} \\ &= \frac{E(X_1) + E(X_2) + \cdots + E(X_n)}{n} \\ &= \frac{+ + \cdots +}{n} = \mu, \end{aligned}$$

for all μ . To see this, a pathological example will be used. Suppose the population consists of only five subjects and the measurements on these five subjects are listed as follows:

3, 5, 3, 2, and 2,

resulting in population mean

$$\mu = (3 + 5 + 3 + 2 + 2) / 5 = 3.$$

Now consider estimating based on without-replacement-samples, that is, samples containing distinct members of the population, of size 2 from this population. Table 1 shows possible samples and the corresponding sample means. Note that the average of the sample means is $(4.0 + 3.0 + 2.5 + 2.5 + 4.0 + 3.5 + 3.5 + 2.5 + 2.5 + 2.0) / 10 = 30 / 10 = 3 = \mu$.

Similarly, a sample proportion is an unbiased estimator of the population proportion. In general, the sample median is not an unbiased estimator of the

population median. Sample variance, defined by the formula

$$S^2 = \frac{\sum_{i=1}^n (X_i - \bar{X})^2}{n-1}$$

is an unbiased estimator of the population variance σ^2 .

When the population is infinite or large, it is not possible to investigate each and every member of the population to determine the population characteristics, referred to as parameters. An unbiased estimator of a population parameter closely approximates the parameter. Without evaluating the whole population, the population parameter can be computed with accuracy based on the unbiased estimator from a sample drawn from the population. This is because in repeated sampling, the unbiased estimator results in an average value that is equal to the parameter itself.

UNDERREPRESENTED GROUPS

A fundamental task of research involves determining what type of research design would fulfill the goals of research, which subsequently informs recruitment of participants or coresearchers. Failure to recruit a diverse sample or coresearchers may affect the size and demographic characteristics of the sample, which may limit the research project in numerous ways. Small samples and sample bias may reduce the statistical power of the study and diminish its applicability of findings and interventions. This entry outlines the relation of research design to participants and researchers, defines underrepresented groups, and outlines strategies to enhance the recruitment and retention of underrepresented research participants. All aspects of the research study (i.e., designing project, pre-fieldwork, protocol development, recruitment, pilot research, analysis, and dissemination) are assumed to be interlocking.

Determining Research Design and Role of Participants

Social science research has historically embraced a positivist philosophy that primarily has relied on large surveys using mostly quantitative measures. Because the process of “standardizing” measures has not reflected all people, individuals and groups with marginalized identities or experiences were often underrepresented in research or were justifiably mistrustful of the research enterprise. Alternatively, in participatory action research designs, participants are coresearchers and collaboratively determine the aims and methods of the project. Methodologically, diverse research approaches have been proliferating and include narrative, autoethnography, photovoice and photo-elicitation, and community-engaged scholarship. The research design and variations in the form and nature of participants have implications on the recruitment of participants and their motivation to support it through their involvement.

Defining an Underrepresented Group

Membership in an underrepresented group may vary depending on the nature of the discipline, the general phenomena being explored, and the particular research study. For example, a review of the psychology literature published by the main journals of the American Psychology Association (APA) found U.S. overrepresentation both in authorship and in the sample demographics, thus building an understanding of psychology based on only 5% of the world population and neglecting 95%. Individuals who are racially or ethnically minoritized are overrepresented among studies of the poor and underrepresented in studies of phenomenon prevalent in middle to upper socioeconomic class samples. Historically, studies of risk to the well-being of children and families have not focused on the affluent. Studies that focus on a particular racial or ethnic minority group may overly rely on a convenience sample, introducing sampling bias and threatening the validity of the findings as related to the target population. An underrepresented group in research, therefore, is defined by the previous lack of representation of the group in research generally or with respect to the particular outcomes and phenomena explored in a given study. Underrepresented groups may include the following: particular racial, ethnic, and socioeconomic groups that have been represented in the research literature, but perhaps with insufficient representation to reflect the full range of the population (e.g., cultural variation within ethnic groups, low-performing students of high socioeconomic status, or high-performing

students of low socioeconomic status); studies that sample exclusively from an underrepresented group (e.g., socioemotional adjustment of Native American youth with high academic achievement or of Asian-American youth with low achievement); or studies that sample protected or vulnerable populations such as youth, persons not familiar with English, or persons associated with a socially vulnerable identity (e.g., homeless, criminal record, HIV positive). Through a literature review and preliminary fieldwork, researchers should identify the range of the target sample population.

Strategies to Promote Retention and Engagement of Underrepresented Groups

Strategies to promote retention and engagement of underrepresented groups include the composition of a diverse research team, pre-fieldwork and entering into the community, development of measures and piloting the protocol, recruitment and sample maintenance, and steps taken subsequent to data collection. These strategies may be adapted to support various research designs (e.g., qualitative, quantitative, mixed methods), and for studies that target underrepresented groups exclusively or studies that aim to secure a relatively higher percentage or variation of underrepresented groups in a general research project.

Composition of Research Team

Assembling a diverse research team is important in order to reconcile the assets and liabilities associated with both in-group and out-group affiliations between the research team and the target population.

Having members of the research team who are themselves members of the underrepresented group may facilitate the recruitment of participants and provide other culturally valued consultations to the research design (e.g., development of instruments, interpretation of results). It is also important to note the limitations of in-group members in a research team. Like any research member, in-group members have researcher bias that contributes to biases in the study. For example, general concerns about socially desirable responses may be heightened when members of underrepresented groups are interviewed by a researcher from their group. Some respondents may feel more comfortable talking with an outsider because they believe that an outside researcher would be less likely to negatively judge behavior that an in-group researcher may consider as violating group norms. For these

reasons, issues of confidentiality of participants should be reviewed in detail during the informed consent and reiterated in the debriefing statement.

While in-group research members may share some key characteristic with members of the underrepresented group, the researcher may be perceived by prospective participants as being different in fundamental ways. For example, members of the underrepresented group may perceive the social class of the researcher as not reflecting their experiences. Like any other group, underrepresented groups are likely to contain significant variation within them, so a limited number of in-group researchers would not represent the full range of variations within the underrepresented population.

Strategies to Access an Underrepresented Community

Because participant recruitment typically defines the initial phase of engagement of a participant in a research study, the entry into a community requires culturally sensitive approaches that combine establishing both top-down and bottom-up credibility. Given that what is relevant to different underrepresented groups may vary both between and across groups, it is crucial for members of the research team to conduct pre-fieldwork to familiarize themselves with the range of values in the target population. Depending on the nature of the study and the desired sample, this pre-fieldwork may include exploring the extant data (e.g., demographic records maintained by government and other sources, news coverage), multimedia literature (e.g., books or films produced about and by the target population, social media), and guided and unguided tours. Familiarity with a target community will assist the research team in identifying its official and unofficial leaders.

The preferred approaches to access community leaders vary based on the nature of the research study, the target population and related institutions, and organizational affiliations of the research team. A research study that focuses exclusively on a particular cultural group in a defined geographic region may use approaches that are typical to ethnographic research, such as frequent attendance at community events and meeting with key officials either as individuals or as invited members of an advisory group. In such scenarios, approval by one community leader may help garner additional support for the study from other leaders and eventually from potential participants.

Research designs that seek to increase the participation rates of underrepresented groups in general studies need to establish such credibility with multiple groups, recognizing the complex social and political affinities

and conflicts between them. In addition, institutions (e.g., schools, community centers and neighborhood programs, laundry mats) that serve diverse youth and families may provide gateways for recruiting multiple underrepresented groups.

In order to forge formal relationships with a target research population, the research team must articulate a comprehensive overview of the research project in a concise and compelling manner. The research team should provide brief written materials about the research project to key decision makers or influencers, potential participants, and their caregivers. In addition to using culturally sensitive approaches that may include multiple formats and languages, the materials should clearly indicate the affiliations of the organizations sponsoring the research (e.g., university, government, service agency, nonprofit) and any funding sources. Certain affiliations may provide legitimacy in gaining official approval to enter a community or organization.

Alternately, certain research affiliations may represent threats to the target population because of suspicion about the motives of the research, particularly given the funding sources. Affiliations of the research project and their related outcomes (i.e., whether findings would be published that conflict with the mission of a collaborating organization or report illegal behavior) may further complicate the process of accessing an underrepresented or vulnerable group.

While seeking formal entry into a group, a research team may be working to identify informal entry points. Informal community leaders and informants (e.g., community elders, school secretaries, barbers, or beauticians) may provide instrumental advice regarding the development of measures related to the phenomena being studied as well as strategies to secure additional approval and participation in the study.

Development of Measures and the Protocol

Insights gathered through pre-fieldwork, consultation with formal and informal leaders, and pilot research in a community may substantively inform aspects of the research protocol including measures, methods, and incentives. Pre-fieldwork and communication with members of the target community may assist in developing a culturally sensitive protocol. For example, informal conversations may lead to changes in wording to make it better understood by the target population. Members of the target population may suggest questions or follow-up prompts to explore nuances that the research team may have been unaware of, but are salient to the target population. These suggestions enhance the study's ecological validity.

In addition, pilot research may suggest the need for significant changes to the delivery of the protocol. For example, a traditional paper/pencil questionnaire may be read to participants or administered via audio-enhanced technology. Decreasing the cognitive and literacy-based load for participants may increase the overall validity of participants' responses as well as facilitate completion rates by individuals who may not have otherwise participated given language processing level, reading ability, or age. Finally, adjusting the administration of the protocol may decrease the amount of time required to participate, thus promoting the involvement of more participants.

Incentives to participate may be intrinsic and extrinsic. Depending on the nature of the study (e.g., positive development, joy), members of underrepresented groups may feel motivated to contribute their underexplored perspectives to research and research-based applications and policies. The nature of the study and its research design (e.g., longitudinal, cross sectional) have implications on the frequency and amount of incentives. Informal community members may help identify what type of incentive would be desirable for participants and permissible within community and institutional review board guidelines. In addition to individual incentives, research leaders should consider providing institutions that facilitate the research study with organizational incentives. Even if the study is cross-sectional, it is important to maintain positive relations with the facilitating organizations as a type of institutional respect and so that they may assist future studies. For longitudinal studies where the success of the research is predicated on being able to maintain the same participants throughout the study, there may be incremental incentives in which the participants receive more of the incentive for each wave of data collection, perhaps with a "balloon payment" for the final data collection or entry into a raffle.

Recruitment and Sample Maintenance

When compared to less diverse samples, the time frame and budget allotted for a research project that seeks to increase intersectional participation of individuals from underrepresented groups may require more resources. Although investing in moving beyond convenience and snowball to purposeful sampling may not always yield a high number of participants, diverse sampling enriches the data. In order to address prospective participants' feelings of suspicion and doubt that may exist regarding research, the relationship building required to earn top-down and bottom-up credibility requires time. While some community-based institutions may be able to assist in recruiting

participants for a study with minimal researcher involvement, other institutions may be consumed with their own daily operations or otherwise not shift their priorities to match the researcher's agenda. Given this, research team members should plan on making numerous site visits first to negotiate institutional approval and then to secure consent and conduct the research. If minors are involved, this process may require additional negotiation and interfacing by phone or in person with caregivers.

The research team needs to convincingly communicate (1) why the research project is important generally, (2) why their participation in the project is valuable specifically, (3) what risks there are in participation, (4) the personal and collective benefits of participating for the individual and possibly the group or institution, and (5) the benefit of contributing to scientific knowledge, and the cost of not having their perspective represented, including evidence-based funding or policy decisions.

Steps Taken Subsequent to Data Collection

The parts of the research project are iterative, as should be the communication process with participants and the research and practice community. The role of the participants in the data analysis may depend on the nature of the research. In participatory and collaborative action research, participants reflect on the data and its interpretation, while participants may play no direct role in data analysis in other research designs. In all research, participants should be part of the dissemination loop; how this is determined may vary and include a research summary written in nontechnical language such as newsletters for participants, site reports, infographics, and other consultations that may be negotiated based on the nature of the project. For example, some organizations may be interested in including data collected by the research team in their own assessment of their program and services.

Final Thoughts

In order for research to make meaningful contributions to the field, research projects must be conceptualized and executed in a manner that involves an adequate sample to fulfill the goals of the research design. One major challenge to research has been the recruitment and retention of participants from underrepresented groups. Although minoritized groups are generally implied as constituting underrepresented groups in research, this entry assumes that underrepresented group status is defined as related to the topic being studied and how previous research may

have overrepresented or underrepresented a particular population.

The successful engagement of any participant, including those from underrepresented groups, requires that the prospective participant be persuaded that contributing to a research study may be relevant and worthwhile to the life and dignity of the participant, and perhaps more broadly as well. The particular strategies employed by a research team vary based on the individual or groups being targeted as well as the nature of the research design. Irrespective of the research design, the research team needs to develop a culturally sensitive approach to engage with the target population in a meaningful manner that promotes the insightful participation of all parties.

UNIT OF ANALYSIS

When engaging in research, it is essential to have a clear understanding from the outset what the study is trying to accomplish—that is, what the specific research question(s) is(are), and what data are necessary to

collect to answer the research question(s). Otherwise, confusion typically ensues. One of the most fundamental considerations in conducting research is to determine what the primary unit that will be the subject of statistical analysis is, or should be. This is called the unit of analysis. Often, it is dictated by the data that are collected, rather than by a sound theoretical justification. Therefore, it is necessary to be clear as to what the unit of analysis should be before data collection. For example, in educational research, the unit of analysis could be people or schools. The unit of analysis may be the same or different from the unit of generalization, the unit of sampling, or the unit of measurement.

To understand the unit of analysis, it is essential to understand these related terms. An example may help clarify the distinction between the terms. Consider the case where a researcher seeks to investigate the effect of a curriculum on student achievement. Data can be collected at a variety of levels: the student level, the classroom level, the school level, the district level, the state level, and so on. Here, the example is restricted to the first three levels: the student level, the classroom level, and the school level. Similarly, the researcher can sample schools, classrooms, or students to collect the data. The choice of which unit to choose for sampling and data collection depends, in part, on the unit of generalization. To understand the unit of generalization, it is useful to understand what it would mean to generalize at the three different levels. If the study seeks to generalize at the school level, that would mean that the researcher is interested in how implementing the new curriculum effects the achievement of students at the school level. The interest is not on individual achievement but on the average achievement for the school. Similarly, the researcher may wish to generalize to the classroom level, at which the results would be reported for each classroom. Last, the goal could be to determine the effect of the instruction at the individual level, and hence, the results of the individual would be paramount. Therefore, if the goal were to generalize at the school level, for instance, it would be wise to do the sampling at the school level, to be sure that there are enough schools on which valid inferences can be made, and that the sample of schools is representative. If the goal is at the individual student level, in contrast, then it may be possible to gather enough students on which to base valid inferences, and also that is representative, without having enough schools for a valid inference to be made. Therefore, prior to sampling and data collection, the unit of generalization should be determined.

It is typical that the unit of sampling and the unit of generalization are the same, but they may be different from the unit of measurement. Suppose in the example that the unit of generalization is to be schools.

Therefore, the results will be school-level achievement results, and the sampling will likely occur at the school level. However, the unit of measurement will likely take place at the student level. To determine the school-level achievement, it is necessary to collect data on student achievement and possibly then to aggregate that student-level data into school-level data, perhaps as the mean of the student-level results. It may be that other data are collected as well, not only achievement data on students, and as such data collection could take place at any and all of the three levels: at the student level, classroom level, and school level. At the student level, data may be collected on not only the achievement of the student but also on other variables such as the gender of the student, the ethnicity of the student, and so on. At the classroom level, data regarding the number of students in a classroom, the number of years of experience of the teacher, and the gender of the teacher may be collected. And at the school level, data regarding the total enrollment of the school, the demographic makeup of the school, the student-to-teacher ratio, and so on, can be collected. All these data can be used to assess the school-level performance. Therefore, although the unit of sampling was the school, the unit of measurement may be any one of the three levels, or some combination thereof. In this case, the unit of measurement is different from the unit of generalization and from the unit of sampling.

Typically, the unit of analysis is the same as the unit of generalization, although there are cases where this is not true. In the example, data are collected at the individual student level (and perhaps at the classroom level and the school level as well). These data are then aggregated to school-level data. In the simplest case, data could be collected on student achievement alone, and these results may be averaged for the school, resulting in a mean achievement for the school. This variable is a school-level variable and is what is used in the analysis for the study. It is worth noting that when the unit of analysis is the school, different data are required than would be necessary than if the unit of analysis were the student. In the most simplistic case, it is instructive to think about the mean of the achievement scores of the students. Because the mean is more stable than the individual score, valid inferences can result from analyzing a smaller number of means than would be advised when drawing inferences from individual observations or scores. So although it may be valid to draw inferences from 30 means, each based on 200 students, it would not usually be reasonable to use 30 individual observations to make valid inferences at the individual level.

When choosing the appropriate unit of analysis, the researcher should also be aware of the ecological

fallacy, which states that the conclusion(s) drawn at the group (in this case, school) level may not pertain to the individual (i.e., student), and conversely, that the conclusion(s) drawn based on the analysis of individual (i.e., student) level may not be accurate at the group (i.e., school) level. Therefore, when choosing the unit of analysis, it is essential to consider the unit of generalization, as the conclusions and inferences drawn as a result of the analysis may be accurate only at the level of the unit of analysis. Thus, if it is desired to draw conclusions about achievement at the school level, the unit of analysis, and generalization should be at the school level, not at the student level, regardless of the unit of measurement.

Thus far, the discussion of the unit of analysis has been relatively straightforward; basically, the unit of analysis is chosen as the unit of generalization, which is typically the unit of sampling as well. However, the unit of measurement may not be the same as the unit of sampling, generalization, and analysis. One important factor has been neglected in this discussion, namely that of the independence of observations. In many statistical analyses, an assumption of the independence of observations is made, and when data are nested, such as students within classrooms within schools, observations at one level may not be independent, whereas observations at another level may be. For instance, there may not be an independence of observations of students within the same classroom because the students share the common experience of that classroom. Conceptually, it can be made obvious by considering the results of students within a classroom relative to those in different classrooms. If students within a classroom perform more similarly to each other than they do to students in a different classroom, then there is a classroom-level effect in play and the independence of the observations at the classroom level is suspect. If, however, it can be assumed that the classrooms are independent, then classroom-level data should be used in the analysis. If being in the same school causes a dependence of measurement between classrooms, it would be necessary to aggregate classrooms into a school-level variable. This could continue until the observations for each unit are considered independent. Thus, when observations are independent at the school level, the unit of analysis should be the school level. Because of the ecological fallacy, the unit of generalization must also be at the school level. If it is desired to have the unit of analysis and generalization to be at the student level, then students who are from independent units can be sampled. That is, if there is dependency at the classroom level, but not at the school level, then students can be sampled from different schools for the analysis.

Methods that do not require the independence of units, such as hierarchical models, render the unit of analysis a nonissue. In this case, all units are used as units of analysis. In the preceding example, the unit of analysis at the first level is the student, at the second level it is the classroom, and at the third level it is the school. In this case, the dependence among the units is modeled (and estimated). Conclusions can then be drawn at any level using the appropriate results.

U-SHAPED CURVE

The U-shaped curve usually refers to the nonlinear relationship between two variables, in particular, a dependent and an independent variable. Because many analytic methods assume an underlying linear relationship, systematic deviation from linearity can lead to bias in estimation. Meaningful U-shaped relationships can be found in epidemiology (e.g., between risk factor and disease outcome or mortality), psychology (often age-related developments, such as delinquency or marital happiness), and economics (e.g., short-run cost curves between the variate cost and quantity).

In medicine, U-shaped risk curves have been found for risk factors such as cholesterol level, diastolic blood pressure, work stress, and alcohol use. Of these factors, the alleged U-shape relationship between alcohol use and disease risk has been the most controversial. By the 1920s, a U.S. study by Raymond Pearl already showed a depressed longevity for abstainers. At that time, with alcohol prohibition in effect, this was not a politically correct message. Many years later, better controlled cohort studies looking into what Alvan R. Feinstein in his *Science* article called the “menace of daily life” have also reported lowest risk estimates for light or moderate drinkers of alcoholic beverages. Heavier drinkers are at highest risk, as could be expected. However, abstainers or nondrinkers in general also are found to have a higher risk for several negative health outcomes.

This effect has been observed for overall mortality and specific categories such as cardiovascular diseases. For the latter, some studies report a J-shape rather than a U-shape, with little increased risk at higher consumption levels. Generally, the risk is estimated to be approximately 20% higher for abstainers, as shown in Figure 1 by Giovanni Corrao and colleagues.

During the last 20 years, as results from more and more cohort studies have been accumulating, the J-shaped risk curve has been considered to be the aggregate result of several biological processes underlying the most prevalent of pathologies in the Western world, coronary heart disease. For some diseases or bodily processes, any alcohol has an outright negative effect. Alcohol has been found to raise blood pressure even in small amounts, which in turn is a risk factor for cardiovascular disease. However, alcohol has a proven negative effect on the formation of thrombi or blood clots, which in itself is considered a risk factor for ischemic diseases (heart attack, brain infarctions). A major third process is the positive effect of alcohol use on the high-density cholesterol (HDL) level in the blood, which is considered to be a protective factor in the genesis of arterial plaques, eventually obstructing blood flow to vital tissues of heart or brain. Across the years, several other biological processes and genetic vulnerability factors have been suggested as potential candidates for the explanation of the lower risk for moderate drinkers of alcohol. The message of a potential beneficial health effect of alcohol use has caused considerable debate, as alcohol use at higher intake levels may be considered a serious health hazard. The detrimental effects of alcohol are less disputed, with monotonically increasing risk for outcomes such as injuries, liver functions, liver cirrhosis, and certain forms of cancer (e.g., breast cancer).

Next to the biological explanations of the J-shape, suggesting several direct (e.g., clotting) or indirect (high density cholesterol level) biological effects, some have provided alternative explanations, stemming from methodological flaws or specific design features. For example, with evidence from the British Regional Heart Study (BRHS), A. Gerald Shaper suggested that the lower effect could be the result of a mixture of nondrinkers with heterogeneous risk profiles. At the time, not all studies made a difference among lifetime abstainers, teetotalers, and ex-drinkers. From the BRHS cohort, it was obvious that the ex-drinkers were at the highest risk and that the risk of British teetotalers could not be distinguished from that of light drinkers. However, heterogeneity of risk in the nondrinker category cannot explain the U-shape at the lower end of the drinking scale.

Figure 1 Example of U- or J-Shaped Curve Between Alcohol Intake and Risk for Coronary Heart Disease

Source: Corrao, G., Rubbiati, L., Bagnardi, V., Zambon, A., & Poikolainen, K. (2000). Alcohol and coronary heart disease: A meta-analysis. *Addiction*, 95, 1505–1523. Copyright 2000 by Wiley-Blackwell, reprinted with permission.

Another explanation for the U- or J-shape at the lower end is the selection of high-risk individuals in the abstainer category, leading to what in epidemiology has been termed by Feinstein as *susceptibility bias*. Susceptibility bias would occur when persons more vulnerable to the disease would refrain from engaging in a drinking career. There is some evidence from a Dutch cross-sectional population study of a selection of young people with poorer health into the category of teetotalers, when health complaints among teetotalers increased with age as number of teetotalers in the population decreased with age. Solid empirical evidence for this phenomenon is difficult as it requires a follow-up of long duration of adolescent cohorts. In one such rare study of Bostonian teens, George Eman Vaillant indeed presented evidence for selection leading to an overrepresentation of people with a higher disease burden among abstainers. A variant of this is termed *protopathic bias*, when people with preexisting disease or with a high-risk profile are overrepresented among the nondrinkers. Empirical evidence for these phenomena remains inconclusive, however.

Three other design features have been brought forward as potentially creating a bias in estimates of risk at the lower end of the alcohol consumption curve. In all epidemiologic studies, alcohol use (risk factor) is measured close to the endpoint (disease outcome) in

cohorts that usually have passed middle age because incidence and mortality in younger age groups is quite low. Apart from a restricted time window of observation, this also means that risk assessments refer to recent alcohol intake at middle age, thereby disregarding the effects of drinking in the (average) first 20 to 30 years of life. Both aspects could produce a bias because changes in drinking status as a result of bad health would go unnoticed. Proof of such a bias was found in a New Zealand case-control study by Stijn Wouters and colleagues who found that cases were significantly more likely than controls to report recent abstinence from drinking because they felt unwell. The U- or J-shaped association between recent alcohol consumption and acute coronary heart disease seemed to be largely caused by the confounding effect of preclinical, usually not measured, symptoms on drinking. Third, it has been reported in recent reviews that the lower end of the J-shape becomes less pronounced as quality of the design increases.

Apart from the caveats in assessing and interpreting the J- or U-shaped curve, estimation of the exact shape of the curve might present problems. Els J. T. Goetghebeur and Stuart J. Pocock have warned against oversimplification with potential bias in estimating the nadir (lowest turning point) and upward slope on particularly the left side of a U-shape. The often sparse numbers of observations available make exact fitting difficult, and categorization leads to loss of information. Several approaches to (parametric) fitting are possible. The authors suggest sequential quadratic and linear tests for the downward trend from the left of the curve.

“VALIDITY”

Validity is defined by Samuel Messick as an integrated, evaluative judgment of the degree to which empirical evidence and theoretical rationales support the adequacy and appropriateness of inferences and actions based on test scores or other modes of assessment. This definition opens Messick’s chapter, “Validity,” in the third edition of *Educational Measurement*, which is a benchmark publication in the field. Although Messick’s conception of validity has generated some debate, this chapter has arguably provided the dominant scholarly representation of validity in educational measurement since its publication in 1989. Like the validity chapters in the preceding (1950, 1971) and subsequent (2006) editions of *Educational Measurement* (by Edward E. Cureton, Lee J. Cronbach, and Michael J. Kane, respectively), it is intended to provide guidance to those who develop and use tests or other assessments, as well as philosophical grounding for validity scholars. Key elements in Messick’s representation of validity, which are elaborated in the following discussion, include its tie to scientific hypothesis testing and theory building, the need to address two general threats to validity with two general types of evidence (convergent and discriminant), and the importance of attending to several aspects of validity that illuminate sets of issues and sources of evidence. Issues surrounding Messick’s conception of validity include his incorporation of consequences of testing as an aspect of validity and the extent to which his representation provides sufficient guidance for practitioners. This entry also discusses current issues regarding validity.

Definitions and Scope of Application

Validation entails ascertaining the degree to which multiple lines of evidence are consonant with the intended

inference (or “construct”), while establishing that alternative inferences are less well supported. This judgment takes into account the meaning of test scores as well as their relevance and utility for particular applied purposes, their value implications, and the social consequences of using them for applied decision making. Messick’s definition of validity signals that validity is a property of inferences based on test scores, not tests themselves; that it is a matter of degree, not all or none; and that it evolves as new evidence is brought to bear.

He uses the term *test* to refer not just to tests as typically conceived but to any means of observing or documenting consistent responses, behaviors, or attributes; *scores* subsume qualitative and quantitative summaries of these consistencies and can refer to groups, situations, or objects, as well as persons. The term *construct* refers not just to unobservable qualities assumed to account for performance on a test, as originally conceived, but to whatever concept(s) the test is designed to measure. Thus, *construct*, *score meaning*, and *intended inference* or *interpretation* can be used interchangeably, as can *construct validity* and *validity*. *Construct theory* encompasses (a) the definition of the construct (or “construct domain”) that specifies the boundaries and facets of the construct as well as (b) the expectations (hypotheses) about responses processes, consistencies in item responses, relationships among variables, and so on.

Key Elements in Messick’s Conception of Validity

The fit (or lack of fit) between the construct theory and the available evidence informs the overall judgment about the validity of the intended inference. Thus, validation incorporates all the experimental, statistical, and philosophical means by which hypotheses and scientific theories are evaluated. Messick also acknowledges the

need to balance the never-ending aspect of validation with the need to make the most responsible case to guide current use of the test.

Messick foregrounds two major threats to validity: *Construct underrepresentation* occurs when a test is too narrow in that it fails to capture important aspects of the construct; and *construct-irrelevant variance* occurs when a test is too broad in that it requires capabilities irrelevant or extraneous to the proposed construct. For instance, depending on the construct definition, a test of reading comprehension might be too narrow in that it focuses on short reading passages that are not typical of what students encounter in or out of school; or it might require irrelevant capabilities such as knowledge of specialized vocabulary. Such rival hypotheses to score meaning can be investigated by considering *convergent* and *discriminant* evidence. *Convergent* evidence indicates that test scores are related to other measures of the same construct and to other variables they should relate to as predicted by the construct theory; *discriminant* evidence indicates that test scores are not unduly related to measures of other constructs. For instance, scores on a multiple-choice test of reading comprehension might be expected to relate more closely (convergent evidence) to other measures of reading comprehension, perhaps using other texts or response formats. Conversely, test scores might be expected to relate less closely (discriminant evidence) to measures of the specific subject matter knowledge reflected in the reading passages on the test, indicating it is not primarily a measure of specialized knowledge.

Messick proposed six “aspects” or “components” of validity that cover a range of issues and sources of evidence to be considered in any test validation effort (foregrounded more distinctly in later publications). For each aspect, the goal is to ascertain the degree to which the evidence is consistent with the intended inference (anticipated by the construct theory) and less consistent with alternative inferences about score meaning. The *content* aspect considers the extent to which the content of the test is relevant to and representative of the construct definition. The *substantive* aspect considers the extent to which responses to the test are consistent with the construct definition; it includes evidence of the processes through which examinees respond to the test items and of consistencies among responses to different items. The *structural* aspect addresses the extent to which the scoring model is consistent with the construct theory; this includes attention to issues like how items are weighted or what dimensions are reflected in the scoring model. The *external* aspect addresses the extent to which the relationship between the test and other measures (of the

same and different constructs) are consistent (appropriately high, low, or interactive) with what the construct theory would predict. The *generalizability* aspect addresses the extent to which score meaning is consistent across relevant contexts, including population groups, settings, time periods, and task domains. Finally, the *consequential* aspect traces the social consequences of interpreting and using the test scores in particular ways, scrutinizing not only the intended outcomes but also unintended side effects, considering their fit with what the construct theory would predict and any threats to validity they illuminate.

Differing Conceptions of Validity

Messick’s representation of validity reflects an evolution in the concept to which he and other scholars have contributed, albeit not without some controversy and continuing debate. Features of this evolution now reflected in the widely endorsed *Standards for Educational and Psychological Testing* include (a) a move from different types of validity for different types of inferences (content, criterion, and construct validities) to a unitary concept of validity that combines multiples types of evidence into an overall judgment, (b) a more comprehensive set of aspects or categories of validity evidence (although Messick’s “aspects” do not fully overlap the sources of validity evidence in the *Standards*), and (c) attention to the consequences of testing as an aspect of validity (which is arguably the most controversial change). Other issues surrounding Messick’s work have included whether validity should refer to test-based *actions* as well as inferences, whether the meaning of scores can or should be evaluated separately from the uses to which they are put, and the extent to which his representation provides sufficient guidance for practitioners. These differing conceptions of validity and the issues that underlie them are addressed in the suggestions for further reading.

VALIDITY OF MEASUREMENT

Validity is an inferential process that, when applied to problems of measurement, includes questions internal to the entities being measured and external to those direct observations. As theoretical constructs are translated into variables, be they ideas, feelings, behaviors, or objects, their properties are appraised and interpreted. Conceptually speaking, measurement validity is the means by which investigators use such appraisals and interpretations to defend the existence of a construct. Procedures for establishing measurement validity differ according to disciplinary assumptions about the nature of science and what constitutes evidence. Thus, measurement validity involves a range of complex, multidimensional approaches to appraising and interpreting information that are governed by the characteristics of the variables being measured.

Because sound measurement involves a complete assessment of those properties that comprise a construct and only those properties, the validation process is governed by three kinds of questions. Investigators determine whether any scores used to represent a construct are truthful indicators of that construct (inferential validity), only the full range of possible indicators is sampled (external validity), and any indicators embedded in a measurement offer the necessary stability and accuracy needed to represent the construct (internal validity). Error is likely to be embedded in each of these levels of measurement. Anything falling outside these three parameters introduces another type of measurement error with exponential consequences dire enough to undermine even the most elegant research design.

These high standards have taught experienced researchers about the fallibility of all measurement efforts, fallibility that emanates from the struggle to define and defend what they hope to measure. Convincing validity arguments, in other words, distinguish

acceptable forms of error from damaging bias, offering advice on the scope, limitations, and potential uses of particular scores.

Conceptualizing Validity Arguments

A common misunderstanding of measurement validity emerges from the mistaken idea that a particular tool or instrument can be valid—the use of a tool with a particular population and/or for a specific purpose may be valid, but not the tool itself. The quest for truth and its varied definitions of tangible and intangible constructs places procedural constraints on validity arguments. Therefore, existing knowledge, such as how a measurement plan has worked in the past, is invariably compared with new, less well-understood possibilities in the validation process. As investigators design new research to improve the accuracy of truthful depictions of the world and the people in it, generative scholarship is grounded in the idea that measurement validity should gain strength across usage. Findings from initial samples ideally inform revisions or restrict applications of a specific tool in ways that offer progressively stronger representations of the truths that are to be conveyed. Measurement is the step in the research process in which investigators document how well or poorly they understand a truthful depiction of the construct under investigation.

Validity arguments differ in how much detail an investigator conveys using a measurement plan. Such arguments are strengthened by knowledge about the planned use of specific measurements in relation to the relative truth value of each measurement taken. For some purposes, it might be enough to determine whether something is present or absent, right or wrong. Yet, a single dichotomous depiction of a construct will not offer information on the underlying cause of the construct being measured, nor will it offer information on the qualities of the judgments made during the measurement activity. When such a measurement is taken once, there is little basis for interpreting the score; any information for validating the assessment must be extracted from outside the measurement situation, rendering any validity arguments weak. When dichotomous measurements are taken more than once, a validity argument can be strengthened by addressing at least some questions about the relative internal validity of the resulting scores if the two measurements are compared. Comparing internal and external measurement concerns yields more information than is possible when only external information is available. In addition, strong arguments extend external and internal evaluations to include inferential evaluations by considering relevant situational and theoretical claims

about the placement of specific measurements in relation to other known ideas.

However, most forms of measurement in a research plan are not grounded in simple dichotomous depictions of the construct to be measured. Complex constructs often include several matrices of decisions, including whether the scale being used is dichotomous or polytomous, whether a particular construct is unidimensional or multidimensional, and how many measurements must occur in a truthful depiction of the construct being measured. Questions related to a construct's magnitude, intensity, and duration may need to be answered before the truth value of a score can be validly interpreted, yet not all valid scores require information about each of these properties. Well-understood constructs are easier to measure because the designers of such tools can anticipate which aspects of the measurement process are central to any claim about the truth value of a score.

Disciplinary Differences

Scholars from more than one discipline have generated and combined three classes of measurement plans. An oversimplification of these approaches illustrates why measurement validity is central to the research enterprise.

Psychometric and Bayesian Approaches

Investigators who have relied heavily on psychometric and Bayesian approaches to measurement have done a thorough job of describing and defending a variety of measurement procedures and corresponding validation processes. Validity arguments constructed in this tradition rely on procedures that require iterative notions of progress and resistance to measuring ideas that are not thoroughly specified. Emphasizing stability as well as accuracy, this approach prioritizes replicability in how a tool functions across uses. Underspecified definitions of a construct are assumed to result in weak validity arguments, whereas highly nuanced definitions of a construct are assumed to result in strong validity arguments. New tools are commonly compared with existing measures in a way that places a stronger emphasis on internal and inferential validity than on external validity. For these reasons, this approach is the most resistant to change in the face of new theoretical claims.

To measure perspective-taking skills, for example, psychometric approaches would require the identification of those behaviors that constitute perspective-taking and which do not. A plan for the best way to identify, record, and evaluate each skill would include

procedures for interpreting each data point. Measurement validity would be explored at the construct, criterion, and content levels. Initial versions of a tool may include only some perspective-taking skills but would be expanded as new observations offer new knowledge about this complex construct.

Developmental Approaches

Investigators who study change sometimes question the idea that constructs will remain the same over time, across persons, and across situations by trying to measure what changes, when such change occurs, and how such change happens. Validity arguments built using this tradition focus on how to measure the structural features of a construct well enough to detect changes in those features without yielding a new construct. Most plans also include temporal changes in the presence or absence of any stable structures as well as individual and contextual differences in the expression of change. Like other plans, measurements of change are grounded in theoretical and empirical parsimony, yet track the magnitude, intensity, and duration of targeted constructs. Validity arguments focus on whether the construct to be measured becomes more complex and multidimensional, or simpler and unidimensional, over time. The qualities of the constructs themselves, in this approach, can become radically altered across different validity arguments, and truthful detection of that difference is defended when scores are interpreted.

Most efforts to measure change rely heavily on associations. To assess changes in children's conceptions of fairness in school, for example, measurements of how children define and use fairness would be taken by introducing them to targeted situations and systematically adding and removing alternative interpretations. Scores would be created by tracking the frequency of fairness accounts as well as the emotional valence associated with such judgments over time. Differences in how children define and use fairness when sharing their reasoning would offer information on possible structural and situational changes in their reasoning, but a complete plan would also require at least one temporal indicator.

Interpretive Approaches

A third group of investigators have questioned the very idea that constructs can be defined prior to the design of a measurement plan. Validity arguments aligned with this approach to systematic inquiry minimize the importance of replication and generalizability when identifying what to measure and how. These arguments should reveal the integrity of fleeting and

unpredictable measurement opportunities, documenting the procedures used to gather evidence without concern for finding the same result in another related measurement opportunity. Validity arguments still contain rule-governed logic but focus on philosophical interpretations of the information gathered as well as the dependable, credible ways in which it was gathered. A strong validity argument in this tradition establishes that other interpreters of targeted information come to the same conclusions generated by the initial interpreters.

Interpretive measurement plans are usually complex and involve comparisons across multiple data sources. A study of children's attachment networks, for example, might include photographs they take to depict their culture, eyewitness testimonies, visual and audio artifacts, written documents, and a series of conversations between agents involved in the measurement process. Measurement would involve the identification of key terms, semantic relationships, and behavioral depictions of social ties and interactional norms evident in each of these resources. Validity arguments would include critiques of the resulting thematic analysis from some or all of the people involved in the project.

Choosing an Approach

The procedures for establishing measurement validity across these three research approaches are likely to differ to a great extent, and programs of research may include some or all of these approaches. Psychometricians and others who focus heavily on replicability and generalizability in how a tool functions endeavor to accurately measure tangible, clearly defined constructs. Developmentalists who focus on change may value replicability and some form of generalizability but are as likely to study how constructs themselves change across persons, situations, and time. Interpretive scholars emphasize the association between existing data sources, specific philosophical and theoretical premises, and the processes of interpretation. Not surprisingly, validity arguments also differ in the extent to which they emphasize inferential, external, and internal validity, even though all three concerns are evident in strong arguments.

Building Validity Arguments

Consistent with these different research approaches, the procedural language used by investigators to capture their preferences varies widely across disciplines. Most arguments for measurement validity, however, include some claims about whether any scores used to represent a variable are truthful indicators of that variable, include only a full range of possible indicators,

and offer the necessary stability and accuracy required to represent the construct.

Psychometric Concerns

Capturing truthful measurements of a construct involves an additive process that incorporates all aspects of a measurement plan as well as details of the research design and context in which the research is conducted. For this reason, a strong validity argument involves the integration of inferential, external, and internal validity concerns. Investigators commonly build such arguments by comparing and contrasting the measurements taken using any new instrument with other, related tools.

Steps in this validation process have been given a variety of names but usually involve arguments about *construct-based validity* that includes the definitions of a construct as compared to other, related concepts. *Convergent validity* is evident when two related instruments truthfully depict the same construct, and *divergent validity* is evident when two related instruments correctly differ as expected on detectable dimensions. However, these inferential determinations are possible only when each tool meets a number of internal and external validity criteria.

Anticipating the generation of a construct validity argument, investigators identify the specific dimensions that must be sampled by a tool for that tool to truthfully measure the entire construct. The resulting *criterion validity* arguments outline how well those dimensions of a tool offer a complete and truthful depiction of the construct to be measured. In a unidimensional tool, there is no need to determine if the indicators of the construct differ across dimensions. Criterion validity is easily established when indicators of the construct show *concurrent validity* such that each indicator is highly associated with all other indicators of that construct.

Multidimensional tools require more work. Indicators of each dimension must be associated with one another but be different enough from alternative dimensions while ensuring that all dimensions are needed to truthfully represent the targeted construct. For multidimensional tools, evidence of concurrent validity is situated alongside evidence of *discriminant validity* to verify that the dimensions on a single tool are distinct, yet related to the construct under investigation.

In the past, psychometricians have built criterion validity arguments by focusing exclusively on unidimensional constructs and using existing tools to explore discriminant validity for new tools. Nevertheless, new technologies have made it relatively easy to explore criterion validity when constructs are multidimensional.

The most elementary aspect of building a strong validity argument involves establishing *content validity*. Such arguments include content analysis of the construct, the reliability with which the content can be detected and recorded, and the representativeness of each indicator in relation to the construct. In this as well as all the subsequent steps, probability theory serves as a guide for determining whether the tool as a whole adequately samples the construct to be measured, yet content knowledge is especially crucial for establishing content validity.

Developmental Concerns

Because developmental scientists focus on change, they have added new language for building validity arguments. The concept of generalizability holds a different meaning in this measurement approach, but standardization and calibration are specific cases of criterion and content validity, respectively.

Strong developmental arguments focus on the generalizability of any measurement procedures used to detect change because change is not tangible. Claims about development are evaluated in a generalizable manner when an assessment process is repeated accurately by results convey the intended transformations. In this way, validity arguments may focus on how well structural patterns emerge when the dimensions under investigation are tracked, the degree of synchrony in how change occurs, and/or the order in which events occur. Generalizability may also involve claims about how well measurements reflect contingent structures that are apparent only for some persons and settings, or normative structures that hold universal qualities.

For claims about generalizability to be credible, however, the degree and likelihood by which standardization is possible must be tracked across measurement events. Strong validity arguments illustrate which forms of standardization are trivial or otherwise undermine the truthful detection of change while building a case for essential components of the change process. Such arguments usually include information related to time, maturity, and the synchrony of various dimensions of change in a way that isolates the intended processes from other possible distractions.

Not surprisingly, then, measurement validity of this nature depends on whether the tools used to record change are properly calibrated. *Structural calibration* involves the detection of how well an instrument functions with and without externally imposed constraints. *Temporal calibration* involves adjustments related to the rate, magnitude, and/or duration of change. In each case, validity arguments also include information on the stability, order, and randomness that is expected and

distinguish these types of change from those associated with individual differences and diversity across persons.

Interpretive Concerns

Although the same basic three concerns can be detected in the validation of interpretive measurements, they take a radically different form. At the broadest level, interpretive measurement approaches do not start with a clearly defined construct. Instead, they focus most heavily on how evidence is gathered and interpreted. Criteria for descriptive validity, interpretive validity, generalizability, evaluative validity, and theoretical validity are continually being defined and refined as this iterative approach to research opens new avenues into discipline-driven scholarship. Variability in what is described, interpreted, evaluated, and generalized is constrained by how well or poorly the information being gathered aligns with the theories that are simultaneously evaluated in light of obtained evidence. Such confirmation involves a systematic labeling of the persuasiveness of evidence used to support any inferences being measured, the qualities of any interpersonal relationships involved in gathering such evidence, the performance of the researchers, and how the key ideas and descriptions evident in the data align with one another and with other indicators of actual events.

Criteria for building an interpretive validity argument are established by paying careful attention to the *dependability* and *credibility* of the evidence gathered. These steps involve thoughtful evaluations of the researchers and other informants, and the qualities of any artifacts gathered to support the inferences generated during data collection. Dependability typically focuses on stability, and credibility on accuracy.

At the most basic level, interpretive validity arguments involve efforts to minimize bias when determining the content of what to include and exclude from a measurement enterprise. Attempts to minimize bias include the accurate selection of information to include and exclude when making decisions about how to best represent the complete range of the relevant perspectives and contextual features. Rules governing various philosophical and theoretical traditions are used to constrain investigators' own biases, urging them to look beyond their own social position well enough to draw well-justified conclusions about the evidence under consideration.

Limiting Threats to Measurement Validity

Investigators establish measurement validity using formal logic. Just as tools are helpful for physical tasks, validity arguments offer guidance on how to resist the

human propensity to embrace logical fallacies. Three reminders can assist anyone seeking to establish measurement validity, regardless of their disciplinary stance.

Measure Everything With Precision

Any strong measurement plan is ideally grounded in precise measurements of every dimension. Measurement precision takes different forms depending on the measurement approaches embraced, and error in each step can introduce problematic consequences for later steps in the validation process. In some cases, a measurement plan can become overly rigid, while in others the plan can be problematically lax. Seemingly small measurement inaccuracies can sometimes foster monumental levels of bias. It is helpful, therefore, to learn from scholars who have put time and effort into understanding where and when to take liberties in gathering, recording, analyzing, and storing data.

Imagine Ideal Types of Evidence

Because different measurement approaches focus on different assumptions about an ideal, validity threats can be minimized by specifying what is to be assessed. For many types of research, for example, it is not possible to compare measured entities with the complete absence of such entities; there is no complete void or absolute 0 point in what is measured. Instead, most valid measurement plans include carefully crafted methods selected to offer a balanced representation of targeted variables, constructs, or concepts. Psychometric measurement is often conducted using theoretical blueprints that outline each dimension to be measured, how the dimensions are alike and how they differ before sampling indicators of each dimension. Developmental measurement is conducted by introducing and removing constraints in a manner that allows for the investigation of change. Interpretive measurement is conducted by comparing new measurements with the qualities of researchers and informants, tangible artifacts, and indicators of a variety of contextual features and, most importantly, the premises generated about the evidence. All approaches, in other words, actively uncover and challenge distortion.

Engage in Purposeful Measurement

Much harm has been done in the name of measurement, but careful planning can limit such potential. Validity is highly threatened when investigators have not clearly defined the limits and purposes of their research tools. Following those who name this concern *consequential validity*, a strong validity argument

should be grounded in a well-defined theoretical agenda that includes information on the level of generalizability the measurements truthfully represent. When a macro-level lens is used to generate conclusions about something that requires a microlevel assessment or vice versa, inferential error undermines the validity of any research design. When investigators specify their assumptions about whether their measurement agenda involves universal, normative, contingent, or situational factors, they build valid recommendations for sampling measurement opportunities, the characteristics of a strong sample, and possible uses for their measurement plan. Purposeful measurement involves truthful accounts of precise appraisals and interpretations.

VALIDITY OF RESEARCH CONCLUSIONS

Statistical conclusion validity refers to the degree to which the conclusions made about the null hypothesis are reasonable or correct. Because the null hypothesis typically states that a relationship between two

variables does not exist, the validity of a research conclusion also refers to whether a relationship exists between two variables. Although the validity of research conclusions is distinct from construct validity and external validity, it is important to distinguish conclusion validity clearly from internal validity. Internal validity involves whether a relationship between two variables is a plausibly causal one. The validity of a research conclusion is concerned only with the presence or absence of a relationship between two variables. Thus, conclusion validity answers the most basic of questions from a cumulative set of validity questions (followed by questions regarding internal validity, construct validity, and then external validity), as it requires only a decision regarding covariation (not causal aspects such as temporal precedence of the presumed cause occurring prior to the presumed effect and minimal alternative explanations).

The validity of research conclusions is often considered an issue of statistical inference. For instance, a researcher who conducts a study of the effect of a persuasion technique on attitudes about undocumented immigration will want to conclude whether a relationship exists between the presences or the absences of the persuasive technique and change (or lack thereof) in the attitudes. However, the validity of research conclusions is also relevant for qualitative or observational field research. For instance, a researcher who observes traffic patterns and acts of vehicular aggression might want to conclude whether a relationship exists between drivers who slow down to observe nearby accidents and the likelihood of additional auto accidents. Despite the fact that the conclusions of a qualitative study might be based on impressionistic data, the validity of the research conclusions might be assessed, that is, whether a reasonable conclusion has been made about the relationship between two variables.

Possible Conclusions and Possible Consequences

To understand fully how it is that research conclusions might be considered valid, one must first understand the basic logic of hypothesis testing. Essentially, there are only two possible conclusions to all research endeavors. The first possible conclusion is that the data provide a reasonably significant result (in quantitative research, such as correlational and experimental studies, this is referred to as a *statistically significant* result; the term *reasonably significant* is used here to encompass both quantitative and qualitative research). That is, the data are sufficiently discrepant from the relationship stated by the null hypothesis that the null hypothesis is rejected. Because the null hypothesis typically

asserts that a relationship between two variables does not exist, the significant result asserts that a relationship does exist.

The only other conclusion that might be made is that the data provide a nonsignificant result. That is, the data are not sufficiently discrepant from the relationship stated by the null hypothesis. Thus, the null hypothesis is retained. Note that the null hypothesis is not accepted. In other words, a nonsignificant result indicates uncertainty as to whether a relationship exists and does not necessarily indicate that no relationship exists.

There are only two possible consequences of the two possible conclusions, and each has two possible routes. First, the research conclusions might be correct. Retaining a null hypothesis that is *true* (i.e., one that cannot be rejected) or rejecting a null hypothesis that is false are two ways of reaching a correct research conclusion. Second, the research conclusions might be incorrect. The two ways of reaching incorrect research conclusions are to either reject a null hypothesis that is *true* (Type I error) or retain a null hypothesis that is false (Type II error).

All quantitative research conclusions are made with respect to a particular level of statistically based confidence. By convention, researchers use the .05 level of statistical significance as a criterion for valid research conclusions (assuming that the design, implementation, and analysis of the research are free from the threats to validity described in the following discussion). This means that the probability that the conclusion about a significant result is false (Type I error) is less than 5%. On average, the probability that the conclusion about a nonsignificant result is false (Type II error) is approximately 20%. The discrepancy in the probabilities of Type I and Type II errors reflects the fact that the significance criterion and power are positively related and that researchers are more concerned about making Type I errors than they are about making Type II errors.

Threats to the Validity of Research Conclusions

Several statistical factors and research design features can affect the validity of research conclusions. Simply put, any factor that increases the likelihood of making either a Type I error or a Type II error will reduce the validity of the research conclusions. Although the probability of a Type I error is ultimately held at the discretion of the researcher, conventional use dictates that this probability be held at the .05 level (or less) of statistical significance.

Factors that decrease statistical power increase the likelihood of making a Type II error. Thus, these same

factors can reduce the validity of research conclusions. These threats, which relate to power, include a small sample size, a more conservative criterion for determining statistical significance, large variance in the criterion variable (as a result of employing heterogeneous groups of subjects, failing to control for extraneous variables, or failing to employ reliable methods of manipulating and measuring variables), and employing the wrong statistical test (e.g., using a nondirectional test when a directional test is more appropriate).

Every statistical analysis depends on the nature of the variables manipulated and measured (e.g., categorical or continuous) and on several statistical assumptions. Thus, violation of the assumptions of a statistical test also serves as a threat to the validity of research conclusions. For instance, an independent *t*-test requires that the variances in the dependent variable, among the two groups being compared, be relatively equal (not statistically significantly different; homogeneity of variance). It is crucial that researchers take into consideration all of the assumptions inherent in the statistical tests that they employ. It is also important to recognize that increasing the number of statistical tests increases the probability of making a Type I error. The most valid research conclusions are likely to be made by researchers who keep an accurate account of the number of tests they conduct. One common practice is to adjust the significance criterion by dividing .05 by the number of tests conducted.

A practice known as *fishing* also can serve as a threat to the validity of research conclusions. A research study with valid conclusions is likely to have some theoretical basis that serves as a springboard for logical hypotheses to important questions. *Fishing expeditions*, in which lots of data are gathered and non-theory-guided statistical tests are employed, are typically easy to spot. They lack tests of logical hypotheses drawn from an existing theory or a theoretical perspective that emerges from previous findings.

Invalid research conclusions also might result from poor reliability of the measures employed, observations made, or treatments implemented. Treatments associated with an experimental condition, for instance, must be administered in a standard fashion. Valid research conclusions are most likely to emerge when each administration of the treatment is as similar to the other administrations as possible and random irrelevancies in the experimental setting are eliminated. Ultimately, reducing treatment administration variance (e.g., conducting each experimental session with the same instructions, the same experimenter, in the same room) will enhance the likelihood of obtaining a true difference between experimental conditions (if one truly exists).

Problems with random selection and random assignment always serve as potential threats to the validity of research conclusions. With the practical costs of highly valid research, random selection is a rare occurrence, contributing to a greater need for replication of research results. The use of within-subject designs can reduce the need for random assignment (because subjects in these designs serve as their own controls). Furthermore, the error variance that results from inadequate random assignment in other designs can be dealt with by controlling for relevant covariates in the statistical analysis.

Other Considerations in Dealing With the Threats to Conclusion Validity

Although statistical issues are highlighted here, researchers engaged in qualitative research are not immune to such issues. Such research might be more likely to violate the *Gricean* maxims of communication and conversation. For instance, it is well known that interview questions can shape a respondent's answers (a type of self-fulfilling prophecy). Subtle changes in the wording used in questions, and even the order of the questions, can have a significant impact on the validity and reliability of the data collected. It is also well known that people do not always behave the way they normally do when they are aware that others are observing them. Essentially, conclusions about significant relationships between variables might be made when in fact they do not exist (and vice versa). It is reasonable to expect that conclusion validity will improve with an awareness of how such confounds might emerge from such research.

It is reasonable to consider the possibility that failure to support a hypothesis, based on a reasonable theory or reliable experimental finding, is the result of invalid research conclusions even when the threat factors (described in the preceding section) are not of concern. Some relationships between variables might be very weak, or they might be very difficult to demonstrate through experimental methods. For instance, asymmetries in perceived similarity are known to exist (e.g., people judge the similarity of a zebra to a horse to be greater than the similarity of a horse to a zebra), but they can be very difficult to replicate in a single experiment. Simply recruiting larger and larger samples might not always result in greater power if the error in measurements also increases with additional subjects.

Besides successfully planning a reliable and high-powered research study, threats to conclusion validity might be addressed in one of three general ways. First, if the design and the nature of the data permit, issues of conclusion validity might be dealt with by arguments

that rule out the potential threats. For example, a researcher might rule out some extraneous variables if proper random assignment can be demonstrated. Manipulation checks are also quite useful in this regard. Second, replication, through altering the design of the research manipulations and observations, aids in verifying the conclusions. Observing the same result from a different *angle* can provide greater confidence that the relationship between the variables does or does not exist. Third, employing a different statistical analysis can increase power and thereby reduce the probability of a Type II error (e.g., analyzing data with regression procedures rather than analysis of variance tests).

VARIABILITY, MEASURE OF

Variability, meaning differences, is a critical construct in research and science. Objects and events that are constant do not require prediction or explanation. The advancement of science depends on the extent that the differences between objects and events are explainable

and predictable. The goal of the scientist and researcher is to create parsimonious scientific models that predict the variability between objects and events and to test those models against the real world. The ability of the scientist and researcher to measure variability allows the assessment of competing scientific models and theories about the world.

There is a confusing array of symbols in the statistical world, all measuring variability. When referring to a theoretical probability model, the variability is symbolized by $\text{VAR}(X)$ and might be described with Greek letters. With sample data, variability is measured conventionally using statistics such as the standard deviation, variance, and range. If the measure of variability is the standard deviation or variance, the variability is generally symbolized by the letter *s*. Measures of sample variance are used as estimates of model variability. Wide varieties of subscripts are used with both model and sample measures of variability to clarify the meaning of the measure. All measures share certain common elements and interpretations.

Theoretical probability models (probability distributions) are mathematical equations used to model distributions of real-world objects or events. In the case of theoretical probability models, variability has a precise definition. Because model parameters are most often symbolized by Greek letters and the variability of a theoretical probability model can often be expressed as functions of these parameters, theoretical model variability is often expressed as equations with Greek letters.

If a sample of tenured full professors was taken and each was asked about the number of hours per week they worked in their academic position, considerable variability would be found in the data. Some professors might work the absolute minimum required by their respective colleges and universities, whereas others might maintain long academic work weeks. The variability of the data could be measured either by using conventional statistics or, alternatively, by using the variance of the probability distribution created to model the data. If a normal distribution is used to model the data, then the conventional statistics and model values converge. If a normal curve model was found to be unacceptable because it is not possible to work negative hours in a week, then other measures of variability might be more appropriate.

The first step in the scientific method is to model the distribution and to quantify the amount of variability in the data. The second step is to create models to predict the data. In most cases, at least when the model works, the initial variability will be reduced. In the tenured professors example, the researcher might create a prediction model based on variables such as the

professor's department, age, years to retirement, health, and publication record. To the extent that the prediction model works, the differences (variability) between the predicted and the observed data will be small. Many statistical methods rely on a mathematical property of variability where variance measures can be broken down into component parts that are additive and might be summed to the whole. These methods work by "partitioning" the existing variability and then by interpreting each component. In the example, the total variability could be partitioned into that which could be predicted by the model and that which cannot.

Variability in Theoretical Probability Distributions

A theoretical probability distribution is a mathematical function of X that allows computation of probabilities for ranges or particular values, depending on whether X is continuous or discrete. For example, the normal distribution can be described by the following probability density function, where x is a random variable and μ and σ are parameters in the equation

$$f(x; \mu, \sigma) = \frac{1}{\sqrt{2\pi}\sigma} e^{-\frac{(x-\mu)^2}{2\sigma^2}}.$$

In a similar manner, the beta distribution can be described with the following probability density function, where x is a random variable and α and β are parameters in the equation:

$$f(x; \alpha, \beta) = \frac{\Gamma(\alpha + \beta)}{\Gamma(\alpha)\Gamma(\beta)} x^{\alpha-1} (1-x)^{\beta-1}.$$

The variance, $\text{VAR}(X)$, of a theoretical probability distribution is

$$\text{VAR}(X) = E(X - E(X))^2.$$

The expected value $E(X)$ can be thought of as a theoretical average. Thus, the $\text{VAR}(X)$ can be described in words as the theoretical average squared deviation of $X - E(X)$.

In the case of the normal distribution, it can be shown that the $\text{VAR}(X) = \sigma^2$, whereas the beta distribution has

$$\text{VAR}(X) = \frac{\alpha\beta}{(\alpha + \beta + 1)(\alpha + \beta)^2}.$$

The point of this illustration is not to confuse the reader with mathematical notation but to note that although the variance (σ^2) of the normal distribution is

perhaps best known and understood, variance is a characteristic of all theoretical distributions. Whenever the symbol σ or σ^2 is encountered in the theoretical foundation of a statistical model, an underlying distributional assumption of normality is likely.

Measuring Variability

The first step in measurement of variability is the measure of the objects or events themselves. The assumption is that the relative degree of differences between the objects or events is preserved in the numbers that are assigned to the objects or events. Thus, the starting point is a set of N numbers $\{X_1, X_2, \dots, X_N\}$ representing attributes of objects or events.

The second step involves checking for extreme scores, finding the largest and smallest scores in the set of numbers. A statistic called the range can be found by subtracting the smallest score from the largest, but it is generally not very useful as a measure of variability. Variations of the range, such as the scores on the boundaries of the middle 50% of the distribution, can be useful, especially in visualizations such as box-and-whiskers plots.

Because variability refers to differences, the fundamental mathematical operation used in measures of variability is subtraction. A little mathematical notation can make explanation much easier. Assume X_i is the actual measure of the attribute of the object or event and $\hat{X}_i$ is the prediction made by the scientific model for each measure. The squared differences between the observed measure of the object or event and the predicted measure are represented in Table 1 in the rightmost column where N is the number of objects or events in the set.

Squared differences are used instead of simple differences or absolute differences so that the differences will all be positive and additional useful mathematical properties will be present.

A high-quality measure of variability is a single number that possesses the necessary statistical properties to summarize adequately all the differences in the set. The variance (s^2) is preferred as a measure of

Table 1 Generalized Computation of Variability

i	X_i	$\hat{X}_i$	$X_i - \hat{X}_i$	$(X_i - \hat{X}_i)^2$
1	X_1	$\hat{X}_1$	$X_1 - \hat{X}_1$	$(X_1 - \hat{X}_1)^2$
2	X_2	$\hat{X}_2$	$X_2 - \hat{X}_2$	$(X_2 - \hat{X}_2)^2$
...	...	...	...	...
N	X_N	$\hat{X}_N$	$X_N - \hat{X}_N$	$(X_N - \hat{X}_N)^2$

variability, using all the scores in addition to having desired statistical properties, such as being unbiased, efficient, and sufficient. Because the units of measurement are squared as part of the computational formula for the variance, the variance will always be in units of measurement squared.

With minor differences, the variance is the average of the set of squared differences. The generalized formula for a variance estimate is

$$\text{Variance} = s^2 = \frac{(\text{sum of squares})}{(\text{degrees of freedom})} = \frac{SS}{df},$$

where the sum of squares (SS) is the sum of squared differences between the scores and the predicted values

$$\sum_{i=1}^N (X_i - \hat{X}_i)^2$$

and the degrees of freedom (df) are the number of scores minus the number of parameters (P) needed to estimate the predicted values ($N - P$).

Expressed mathematically, the formula for the variance is

$$s^2 = \frac{SS}{df} = \frac{\sum_{i=1}^N (X_i - \hat{X}_i)^2}{N - p},$$

where N is the number of scores, X_i is the set of scores, $\hat{X}_i$ is the predicted values, and P is the number of parameters used in estimating the predicted values.

Suppose, for example, the scores were {5, 6, 9, 14, and 21}, and the model predictions for the corresponding scores were {8, 7, 9, 12, and 19} with predictions based on two model parameters (see Table 2).

Table 2 Generalized Computation of Variability With Example Numbers

i	X_i	$\hat{X}_i$	$X_i - \hat{X}_i$	$(X_i - \hat{X}_i)^2$
1	5	8	$(5-8) = -3$	$-3^2 = 9$
2	6	7	$(6-7) = -1$	$-1^2 = 1$
3	9	9	$(9-9) = 0$	$0^2 = 0$
4	14	12	$(14-12) = 2$	$2^2 = 4$
5	21	19	$(21-19) = 2$	$2^2 = 4$
				$\sum_{i=1}^N (X_i - \hat{X}_i)^2 = 18$

The sum of squares would be

$$\sum_{i=1}^N (X_i - \hat{X}_i)^2 = 18.$$

The value of df would be $df = (N - P) = 5 - 2 = 3$, as there were five scores and the predictions were based on two parameters. In this case, the variance would be

$$\begin{aligned} s^2 &= \frac{SS}{df} = \frac{\sum_{i=1}^N (X_i - \hat{X}_i)^2}{N - P} \\ &= \frac{9+1+0+4+4}{5-2} = \frac{18}{3} = 6.0. \end{aligned}$$

Variance measures of this kind are often called *error variance* as they are measures of lack of fit of a model to a set of data.

Because the differences are squared, the variance measures the variability of the set of numbers in units of measurement squared. For example, if the unit of measurement was inches, variance would be measured in terms of inches squared. For that reason, the square root of the variance, called the standard deviation(s), is often used as a measure of variability as it converts the variability to the unit of measurement. The standard deviation is the square root of the variance:

$$s = \sqrt{s^2}.$$

Although the standard deviation measures variability in more easily interpretable units, the variance has several statistical properties that make it the preferred measure in many areas of research.

Special Cases: When the Model Is a Constant

In the special case when the predictions are all the same value, a constant ($\hat{X}_i = C$), the general formula can be simplified. Because the mean minimizes the SS and consequently the variance in this special case, it is almost always used as the constant ($\hat{X}_i = C = \bar{X}$). Thus, the formula for the variance becomes

$$s_{\text{total}}^2 = \frac{SS}{df} = \frac{\sum_{i=1}^N (X_i - \bar{X})^2}{N - 1},$$

where N is the number of scores, X_i is the set of scores, $\bar{X}$ is the mean, and the number of parameters needed to find the predicted value is 1.

In the case where $X = \{5, 6, 9, 14, \text{and } 21\}$, $\bar{X} = 11$, $N = 5$, and $P = 1$ (as shown in Table 3), substituting in the equation yields

Table 3 Example Computation of Sample Variance

i	X_i	$\hat{X}_i$	$X_i - \hat{X}_i$	$(X_i - \hat{X}_i)^2$
1	5	11	$(5-11) = -6$	$-6^2 = 36$
2	6	11	$(6-11) = -5$	$-5^2 = 25$
3	9	11	$(9-11) = -2$	$-2^2 = 4$
4	14	11	$(14-11) = 3$	$3^2 = 9$
5	21	11	$(21-11) = 10$	$10^2 = 100$
				$\sum_{i=1}^N (X_i - \hat{X}_i)^2 = 174$

$$s_{\text{total}}^2 = \frac{\sum_{i=1}^N (X_i - \bar{X})^2}{N - 1} = \frac{174}{4} = 42.5.$$

In this case, the standard deviation would be

$$s = \sqrt{s^2} = \sqrt{42.5} = 6.595.$$

The variance in this special case is called the *variance around the mean*, *total variance*, or *total variability*, although it is often referred to simply as the *variance*. When statistical techniques are employed that partition the variance into components, it would be preferable to use a more complete description.

Partitioning Variance

A very useful property of the variance, in both theory and practice, is that it might be partitioned into additive component parts. In general, the relationship can be expressed as

$$S^2 = s_1^2 + s_2^2.$$

In a simple case, for example, s^2 could be the total variability (s_{total}^2), s_1^2 could be the variability predicted by a simple regression model, and s_2^2 could be the error variability that the regression model could not predict:

$$s_{\text{total}}^2 = s_{\text{predicted}}^2 + s_{\text{error}}^2.$$

Although $s_{\text{predicted}}^2$ could be computed directly by comparing the model predictions with the constant model, it is most often computed by subtraction:

$$s_{\text{predicted}}^2 = s_{\text{total}}^2 - s_{\text{error}}^2.$$

In more complicated situations, the component variances can be partitioned further as

$$S^2 = s_1^2 + s_2^2 + s_3^2 + s_4^2 + \dots$$

In this example, S^2 could again be the total variability (s_{total}^2), s_1^2 could be the variability predicted by a simple model, s_2^2 could be the additional variability predicted by a more complete model, and s_3^2 could be the error variance that the more complete model could not predict.

Another example is where S^2 is the sum of the total variability of several measures (s_{total}^2), s_1^2 is the variability of the first principle component, s_2^2 the second, s_3^2 the third, and so forth.

Analysis of variance (ANOVA) is basically a procedure to partition the variance into components based on the experimental design and interpret the results based on the relative sizes of the various component parts.

In a theoretical analysis, classical test theory is based on a partitioning of total variance into *true* and *error* components. The theory develops ways of estimating the various component variances:

$$S_{\text{total}}^2 = S_{\text{true}}^2 + S_{\text{error}}^2.$$

Ratios of Variances

Often the main interest of the researcher is not on the absolute size of the variance and its component parts but on the relative size of the various components.

In a principal components analysis, for example, one computes the proportion of total variance that a given component can explain, $s_1^2 / s_{\text{total}}^2$.

In regression analysis, one statistic of major interest is R^2 , which is a ratio of predicted variability to total variability. Thus, R^2 can be interpreted as the proportion of total variance that can be explained by a given regression model:

$$R^2 = S_{\text{predicted}}^2 / S_{\text{total}}^2.$$

Another statistic, F , is basically the ratio of predicted variance to error variance

$$F = S_{\text{predicted}}^2 / S_{\text{error}}^2.$$

Uses of Variability

Measures of sample variability can be used as estimates of model parameters. If a researcher is willing to assume that the underlying distribution is a normal distribution, then the variance can be used as an estimate of the parameter σ^2 .

By partitioning variability and then computing ratios of the resulting components, many useful

statistical measures can be constructed. In addition, by linear transformations of variables, variance might be maximized or minimized such that new interpretations of the data are available. For example, this is the fundamental idea behind principal components analysis.

Conclusion

Anything that can be measured or computed, as long as all values are not identical, has variability. For example, computed statistics differ from sample to sample and have variability. The mean, for example, will differ from sample to sample and possess variability. This variability is called the standard error of the mean.

Variability and measures of variability are the building blocks for almost all types of statistical analysis. The goal of most research is to explain or predict the variability inherent in the world, and measures of variability are the key to that understanding. Partitioning the variance into components and then examining ratios of variances is a common thread that runs through many statistical procedures.

VARIABLE

Simply put, a variable is a measurement of something that holds at least two distinct values across participants within a study. In contrast, a constant holds the

same value across all study participants. Whereas constants such as the speed of light are frequently important for analyses in the natural sciences, the focus of social and behavioral sciences rarely concerns itself with constants. Thus, variables are the basic currency of behavioral research.

The Nature of Variables

Any discussion of variables necessarily must focus on two distinct aspects of these measures: (1) the attributes of variables and how they are measured and (2) the use of variables in scientific analyses. The former refers to the specifics of how the variation of a measure can be described and how variables differ based on their “level of measurement.” The latter refers to the utilization of variables in both research design and statistical analysis.

Variable Attributes

All variables must include at least two distinct values that differ across research subjects. These values, or categories, are the characteristics that describe the item of interest. For example, a fundamental component of the basic experimental design is the treatment variable. This measure consists of at least two possible categories: “treatment” and “no treatment” (or “control”). A more complex experimental design might also include a “placebo” group as a third value. Quite commonly, variables can include substantially larger numbers of values ranging from modestly more complex Likert scaling, which typically uses a five-category coding from “strongly disagree” to “strongly agree,” to extremely detailed measures such as IQ or income. These more detailed measures are frequently encountered when experimental design is not feasible and when researchers use some form of survey research.

Regardless of how detailed and complex the attributes of any variable becomes, all variables are subject to two requirements. First, the values for any variable must be mutually exclusive from one another. In other words, each subject can have only a single value on each variable in the study. For example, it would be inappropriate for the values of a variable to be male, female, and Latino because it is possible (and, in this case, quite likely) that many individuals might be both male *and* Latino or female *and* Latino. On the other hand, a variable that includes the more logical grouping of only male and female categories would satisfy the mutual exclusivity requirement because one cannot simultaneously be a male and a female.

Second, the attributes of any variable must be exhaustive. This requirement does not mean that every

possible value of a variable must be included in the measure. Rather, this requirement is satisfied if all research participants can be assigned, or self-selected, into a value provided. For example, a variable that measures a subject's race might include values such as "white," "black," "Asian," and "Native American/American Indian." The categories in this case would not be exhaustive because some individuals, such as a person of Australian Aboriginal descent or a multiracial person, would not fit into any single category. A simple fix in this particular case would be to add a "multiracial" category as well as an "other" category. The inclusion of residual categories like "other" in the preceding example is commonplace when such values represent extremely small portions of the population being studied or when the actual values of the residual groups are not directly relevant to the research question at hand.

Levels of Measurement

Although only the two requirements of variable attributes noted previously define what a variable must be, several other aspects of variable attributes serve to distinguish types of variables. These are usually referred to as the four levels of measurement of variables: nominal, ordinal, interval, and ratio.

A nominal variable, as the title suggests, is simply a naming variable. More specifically, a variable is said to be nominal if its categories are mutually exclusive and exhaustive. Thus, all variables are at least nominal in level. Common examples of nominal variables in social and behavioral sciences include gender, race, university class (i.e., freshman, sophomore, junior, and senior), and the like.

The next level, the ordinal variable, as the name suggests, adds the requirement of ordered attributes. In other words, a variable is considered ordinal if, in addition to the mutual exclusivity and exhaustive requirements, its attributes can be rank ordered. An important point to note is that the distance between ranked attributes of an ordinal variable can be quite disparate. For example, the commonly used ordinal measure of self-rated health, which typically includes the ordered attributes "poor," "fair," "good," "very good," and "excellent," consists of attributes that probably are spaced in unequal intervals (i.e., it is likely that the distance between the "excellent" and "very good" categories is quite different from that between "poor" and "fair" even though the differences in ranks are the same). Ordinal measures are frequently found in surveys where attitudes or behaviors are assessed using measures of levels of agreement (e.g., Likert scaling) or frequencies (e.g., categories ranging from "never" to "always").

The third level, the interval variable, has variable attributes that also can be ordered. However, unlike the ordinal measure, the spacing between attributes in an interval-level variable is equal. Thus, distances between variable attributes can be compared directly. For example, temperature in degrees Fahrenheit is a common textbook example of an interval-level variable. With this measure, one not only can indicate that 80 degrees is warmer than 40 degrees, but also it is valid to say that the distance from 40 to 60 degrees is the same as the distance from 60 to 80 degrees. However, because interval measures do not include a "true" zero point, one cannot make statements such as "80 degrees is twice as warm as 40 degrees." Interval-level measures are the least common of the four measurement levels found in the social and behavioral sciences and typically consist of created scales (e.g., IQ).

The final measurement level, the ratio level, differs from the interval level only in that variables in this level have a "true" zero point among their attributes. Thus, the attributes of such variables can be expressed as ratios. For example, income measured in U.S. dollars can be validly expressed in the form of a ratio. A subject with an annual income of \$40,000 can be said to have twice the annual income of another subject who reported only \$20,000. Ratio-level variables provide the most detailed information of any variable type allowing for the examination of the most complex research questions; however, obtaining this level of detailed measurement is often impractical because of difficulties in measuring social and behavioral phenomena at this level of precision as well as the expense of such detailed measurement.

Variables in Analyses

Although the attributes and measurement levels of variables describe the nature of such measures, variables are frequently referred to by terms related to their analytic use. These terms can be divided into two separate foci: (1) the conceptual use of variables in research design and theory testing and (2) the practical use of variables in statistical analyses.

Conceptual Use

In research design, it is necessary to translate theoretical assertions regarding "causes" and "effects" into hypotheses for scientific testing. In doing so, an additional vocabulary is used to describe variables in this conceptual logic. Depending on the particular research design, these terms differ subtly.

In a basic experimental design, the "cause" is usually termed the treatment variable and refers to the measure

that differs systematically across randomly assigned groups. The “effect” is translated into an outcome variable, which refers to the result of theoretical interest (e.g., in a clinical trial, the presence or absence of a medical condition). Additionally, a placebo variable, which measures the effect of the experiment itself on subjects, might be used as well as block variables that consider elements of the research design that cannot be randomized.

On the other hand, the language that is used to describe variables in survey research is somewhat different and reflects the analytic techniques typically used to analyze data from such research designs. In survey designs, the “cause” is usually called the independent variable, and almost always, there will be multiple independent variables in any set of analyses. The “effect” is usually termed the dependent variable, although it is sometimes referred to as the outcome variable just as in experimental research. Because survey designs rely on random sampling rather than on random subject assignment to the “treatment” or “control” categories of a treatment variable, another type of variable, the control variable, is usually incorporated into analyses. The use of control variables is an (imperfect) approximation of the control group assignment procedure where variables that are believed to affect the outcome of interest are included in statistical analyses to eliminate possible spurious variable associations. Typically, control variables in behavioral and social research consist of some combination of demographic measures (e.g., gender, race, age, etc.) and/or measures shown in previous research to affect the outcome under study.

Practical Use

Once theoretical concepts have been translated into observed measurements, analyses are completed to test theoretical assertions. In applying the appropriate analyses, variables are discussed with yet another set of terms.

For the purposes of statistical analysis, variables can be divided into two groupings: categorical variables and numerical variables. Categorical variables include any variables measured at either the nominal or the ordinal level. Numerical variables include any variables measured at the interval or ratio level. Analyses that use variables only at the nominal or ordinal levels of measurement are limited to simple descriptive statistics because of the nonnumeric nature of such measures, whereas the full set of arithmetic operations is possible with the variables measured at the interval or ratio levels. Frequently, however, analyses include both categorical and numerical variables, for example, by examining either categorical group differences across a numerical

variable (e.g., means testing) or through statistical modeling procedures. When statistical modeling is employed, a special type of categorical variable, the indicator variable (or “dummy” variable), is often used. Simply put, an indicator variable includes only two categories that indicate having or not having a particular value (e.g., being female or not female). Any categorical variable, regardless of the number of categories defined, can be decomposed into sets of indicator variables.

A final note of caution is warranted. It has become common practice to use the terms *discrete variable* and *continuous variable* synonymously with categorical and numerical variables, respectively. Technically, however, this is incorrect. Discrete variables are measures that can take on only a finite set of values, such as counts. Continuous variables, on the other hand, might consist of any value within a specified range. Thus, discrete and continuous variables are merely subtypes of the numerical variable. However, one can consider the indicator variable, although technically a categorical variable, also to be a discrete variable by noting that its two categories represent a finite set of numerical values (i.e., all or none). Indeed, it is this property of the indicator variable that allows for its use in statistical modeling.

VARIANCE

When describing a distribution of scores, one should use at least three indices: the shape of the distribution (e.g., unimodal, normal, and skewed), a measure of central tendency (e.g., mean and median), and a measure of the

spread of scores. The variance is an example of the latter measure. The importance of a measure for the spread of scores can be seen in the following example:

Distribution X: 93 95 97 99 100 101 103 105 107

Distribution Y: 75 80 90 95 100 105 110 120 125

Both distributions have the same mean ($\bar{X} = \bar{Y} = 100$), but the scores in distribution X cluster closer to the mean than those in distribution Y.

Several measures can be used to describe the spread of scores. The range (highest score minus the lowest score) is simple and easy to understand but takes into account only the two outermost scores. One aberrant score can greatly affect the value of the range and give a false impression of how scores actually cluster together. The semi-interquartile range gets around this problem by considering only the central 50% of scores but ignores half the scores and is not a useful measure in inferential statistics. The most commonly used measures of spread of scores are the variance and the standard deviation. The standard deviation is merely the square root of the variance, and thus, it is the variance that is the important indicator.

The variance is commonly referred to as the *average squared deviation from the mean*. Its formula (using notation for a sample of scores, X) is

$$S_x^2 = \frac{\sum(X - \bar{X})^2}{n} = \frac{SS_x}{n},$$

where

Capital S squared (S_x^2) is the symbol for the variance;

$\bar{X}$ ("X bar") is the mean of the scores;

$(X - \bar{X})$ indicates a deviation from the mean (how far away a score is from the mean);

The symbol Σ (capital Greek letter sigma) is a direction "to sum" or "add";

n is sample size; and

SS_x is the sum of the squared deviations from the mean (the numerator).

Notice several important aspects of the variance. The mean is the most commonly used measure of central tendency, and the variance is calculated by taking deviations from the mean. Thus, the variance shows how spread out scores are around the mean. Deviation scores are squared because the sum of the deviations from the mean, $\sum(X - \bar{X})$, always equals zero. An interesting feature of the variance is that the sum of the squared deviations from the mean, $\sum(X - \bar{X})^2$, is a

smaller value than the sum of the squared deviations taken from any other score.

Note also that because the sum of the squared deviations from the mean is divided by n , the variance itself is a type of mean: the mean of squared deviation scores. Finally, like the mean of the scores, the variance takes every score into account. This is generally considered a desirable quality, but in very skewed distributions or distributions with a few very aberrant scores, one might wish to use another measure.

As an example, here is the calculation of the variance for distribution X. The mean is

$$\bar{X} = \sum X / n = 900 / 9 = 100.$$

Next, take deviations from the mean, square them, and sum all of the squared deviations:

$$\begin{aligned}(93 - 100)^2 &= 49, \\ (95 - 100)^2 &= 25, \\ &\dots \\ (107 - 100)^2 &= 49, \\ SS_x &= \sum(X - \bar{X})^2 = 168.\end{aligned}$$

Then, divide by n to get the variance:

$$S_x^2 = SS_x / n = 168 / 9 = 18.67.$$

To return to original score units, calculate the standard deviation (S_x) by taking the square root of the variance:

$$S_x = \sqrt{18.67} = 4.32.$$

The variance also can be calculated by using raw scores:

$$S_x^2 = \frac{\sum X^2 - (\sum X)^2 / n}{n} = SS_x / n.$$

Notice that the numerator is just another formula for calculating the sum of the squared deviations from the mean. In this example, $\sum X = 900$ and $\sum X^2 = 90,168$. Calculation of S_x^2 proceeds as follows:

$$\begin{aligned}S_x^2 &= SS_x / n = \frac{90,168 - (900)^2 / 9}{9} \\ &= \frac{90,168 - 90,000}{9} \\ &= 168 / 9 = 18.67.\end{aligned}$$

Some textbooks calculate the variance by dividing SS_x by $n - 1$ rather than by n because dividing SS_x by $n - 1$ does not result in the variance for a given set of

scores (e.g., the sample of scores) but instead provides an unbiased estimate of the population variance. The sample variance (using n in the denominator) tends to be smaller than the population variance, but because interest usually is in the population parameter and not the sample statistic, many prefer to divide by $n - 1$. The formula for the unbiased estimate of the population variance is embedded in some of the most commonly used formulas in inferential statistics, such as t and F .

The mean as an index of central tendency is easy to understand, but it is not easy to understand the meaning of the variance. Here is a helpful guideline. If one converts the variance to the standard deviation, in normal (bell-shaped) distributions, 68.26% of the scores will be within 1 standard deviation of the mean, 95.44% will be within 2 standard deviations, and 99.74% will be within 3 standard deviations.

VISUAL ANALYSIS IN SINGLE-SUBJECT DESIGNS

Visual analysis of behavior data in single-subject research designs (also called *within-subject* or *single-case designs*) is used by researchers and clinicians to identify patterns of behavior and to determine the level of effect or control that environmental variables (i.e., interventions) have on specific behaviors. Single-subject researchers and clinicians use visual representations of behavior data (i.e., graphs) to assist in the clinical decision-making process to determine if particular interventions are effective and to inform potential changes to current interventions. The following

discussion of visual analysis provides a brief review of the visual presentation of behavior data and how graphically presented data are analyzed to determine the level of control established by a particular experimental investigation or clinical intervention.

Scientific Inquiry and Experimental Control

Scientific inquiry in the area of psychology or behavior analysis includes the systematic investigation of the effects of environmental (independent) variables on human behaviors (dependent variables). In order for single-subject researchers and clinicians to determine if interventions have a believable effect on behaviors of interest, they must establish that the interventions are controlling the behaviors and that other variables are not producing the intended behavior change. Absolute experimental control is not possible, particularly in applied settings; however, threats to the validity of the findings of a result can be mitigated, and visual analysis of data is critical to this process in single-subject research.

Generally, group research designs attempt to demonstrate experimental control by assigning research participants to two groups, a treatment group and a no-treatment control group. In contrast, single-subject research designs establish experimental control by comparing the past and present behavior patterns of an individual participant or client to determine if changes in the environment result in changes in behavior. Given the nature of single-subject research, visual analysis of repeated quantitative measures of the same behavior over time based on specific data collection and measurement systems allows researchers to better analyze these changes when compared to other analytic approaches.

Behavior Data Collection Measurement Systems

Quantitative behavioral data that are analyzed visually for both the purposes of research and clinical interventions can be collected via direct observation in a number of ways. The most common methods include counts of total occurrences, counts of occurrences per time, and percent occurrence given a number of possible opportunities to respond (e.g., a multiple-choice test). These data collection systems lend themselves well to visual presentation and analysis across periods of time or tests as well as in bar graphs and other summary presentations of data, both for analysis of experimental control and for clinical purposes in applied settings like schools and home therapy.

Visual Presentation of Data

Instead of data tables, statistical summaries, numerical formulas, lists of percentages, or other visual presentations of data (e.g., pie charts, Venn diagrams, histograms), single-subject researchers tend to use time-based graphs (i.e., Cartesian line graphs) to analyze changing behavior data across time across systematically presented conditions (Figure 1). The use of these types of presentations makes visual analysis easier than comparing numbers across textual tables of raw data.

The most common graphical presentations of data include line graphs, bar graphs, and scatterplot charts. In contrast to other presentations of data (e.g., statistical summaries, tables), line graphs and scatterplots allow for a fine-grained analysis of behavior change given environmental changes, while bar charts allow for a visual analysis of categories of behavioral responses.

Line Graphs

A line graph consists of a horizontal (x) axis with a temporal dimension, a vertical (y) axis that displays the quantitative value of the dependent variable or behavior of interest, and a data path with individual data points

at certain points in time. Line graphs are used to determine the extent of change of a behavior across time, observations, or clinical sessions. Line graphs often also include condition change lines to denote when substantial experimental or clinical changes are made and make experimental control easier to identify.

Bar Graphs

Bar graphs, or visual presentations of categories of behavior or responses, can be useful in particular situations. For example, when analyzing behavior across topics, or when presenting data on preferences or the results of a survey, bar charts can be used to better analyze sets of data. However, bar graphs do not allow an observer to easily make conclusions about experimental control or what might be influencing changes to recorded data.

Scatterplot Chart

A scatterplot chart allows a single-subject researcher or clinician to visualize behavior data relative to particular times of the day or days in a week. Raw data are summarized and presented given a discrete period of time, usually several weeks, and patterns across days

Figure 1 Example of a Single-Subject Research Design Line Graph

Note: This is an example of a simple single-subject research design line graph with baseline (i.e., no treatment) and intervention (i.e., treatment) experimental conditions representing the number of occurrences of a behavior per session.

and times are more easily identified. For example, a challenging behavior that generally occurs at higher rates on certain afternoons, or only on weekends, would be easy to visually identify with a scatterplot. However, similar to bar graphs, scatterplots do not immediately allow a researcher to determine the effects of an intervention.

Visual Analysis of Graphed Data

Visual analysis of data refers to reviewing graphical presentations of summarized raw behavior data to better understand the effects of environmental variables on the behavior or behaviors of interest in both research and clinical settings. Visual analysis also relies on repeated measurement of behavior across time generally plotted as horizontally successive data points connected with a line to form a data path. These data points and paths are analyzed according to their levels or quantitative value, trend, variability, and consistency across similar conditions.

Level

The level of data refers to the absolute value of the data given a particular period of time (e.g., hour, day, session) based on the chosen measurement system (e.g., count, rate, percentage). The level of the data is used to determine the response strength of a particular behavior, and this value can be compared to both past and future data points to determine if the strength, or probability of occurrence, of a behavior is changing over time. When analyzing whether an intervention has an effect on a particular behavior, one would compare baseline or no-intervention levels with levels observed during the intervention and then analyze how quickly the value changed. The stronger the intervention effect, the more quickly the value will change. In addition to a comparison of average levels across conditions, single-subject researchers often analyze individual data points to determine if there are any overlapping data points across different conditions. Data point overlaps suggest that the behavior is not well controlled by the experimental conditions as the behavior does not immediately change from one condition to the next.

Trend

The trend of a data path refers to the general trajectory of the path across time, sessions, or observations. The trend can be increasing, decreasing, or stable (no trend). The trend is used to determine whether quantitative values of behavior (e.g., rates, percent correct) change both within a condition (e.g., baseline/no intervention, intervention) and when comparing behavior from one condition to another. A trend is usually

considered to be established when three consecutive data points represent a similar trend (e.g., three consecutive increases, decreases, or no change).

Variability

The variability of a data path refers to the amount of change in the value of a behavior from one observation or session data point to the next. Data paths can have low or high variability; however, this analysis is somewhat subjective and depends on the behavior of interest and the scale of the vertical axis itself.

Consistency

It is also important to determine if behavior patterns are similar across the same conditions. The believability of experimental control in single-subject research designs is improved when the level, trend, and variability of data paths are relatively similar across subsequent no-intervention or intervention conditions as this demonstrates that the values of the behavior match each presented condition.

Baseline Logic

In single-subject research it is often said that the “subject acts as their own control” because unlike group comparison research, in single-subject research there is no control comparison group and experimental control is established by visually analyzing and comparing the values of an individual’s past behavior to their current behavior using a line graph. This type of visual analysis involves baseline logic, which includes comparing graphically presented patterns of past behavior to current behavior patterns as well as predicting future behavior and comparing those predictions to what actually occurs. Baseline logic consists of prediction, verification, and replication (Figure 2).

Prediction

Prediction is the behavior of a researcher that projects the data path of a behavior if no changes to the external environment were made. Essentially, if no changes are made, it is expected that the data path from a series of observations will continue with a similar level, trend, and variability until a change in the environment occurs that might affect the behavior of interest.

Verification

Verification occurs when a visual analysis of behavior data across conditions demonstrates that when the intervention is removed, the level, trend, and variability

Figure 2 An Example of Baseline Logic for Single-Subject Research Designs

Note: This is an example of how simple single-subject research design data are visually analyzed to determine if experimental control has been demonstrated within an experiment.

(a) Predicted data path from one condition to the next had no experimental change occurred.

(b) Demonstration of verification of original prediction.

(c) Demonstration of replication of previous change in behavior when intervention is introduced again.

return to similar patterns that were observed during the no-intervention condition. This suggests that the intervention might have had some effect on the behavior.

Replication

To provide further evidence that the independent variable is actually controlling the behavior of interest, within-subject replications are often conducted. The intervention is removed and then reapplied and the data paths are visually analyzed to determine if initial observations of control are observed multiple times with similar changes in data paths across subsequent sessions or across time.

Criticisms and Limitations of Single-Subject Research and Visual Analysis

While the believability of the control of environmental variables on target behaviors in single-subject research is very high given that most threats to experimental control are easy to mitigate with repeated observation and data collection across time, the external validity, or generalizability of the findings from single-subject research is inherently limited given that single-subject

research is conducted with one or only a couple participants per study. Single-subject research generalizability is established through systematic replications across dozens of single-subject studies. In contrast, with group comparison research, threats to the believability of a study's results are often difficult to mitigate; but given the large number of participants in studies and statistically significant results, the findings tend to be more widely applicable.

While visual analysis in single-subject research has been shown to be a very useful tool for determining whether interventions are believably controlling specific behaviors, some have criticized its overly simplistic approach and lack of incorporation of statistical analytic methods. In addition, while the visual analysis of line graphs appears to be a fairly straightforward exercise, lack of reliability across independent observers of the same graphed data paths is a common concern and single-subject researchers are actively engaged in improving these analytic skills among researchers and clinicians.

VISUAL DISPLAY OF QUANTITATIVE INFORMATION

Statistical graphics provide a way for researchers to present complex information from a data set that may not be easily conveyed by words alone. Edward Tufte, a statistician and artist, devoted his career to the field of statistical graphics. Originally trained as a political scientist at Yale University, Tufte eventually became a professor at his alma mater and taught courses on data analysis and graphics. In 1983, he published the influential book *The Visual Display of Quantitative Information*. This book focuses on principles to create elegant, informative graphics and also provides the reader with ample examples of both good graphics and

graphical elements to avoid. Tufte's book provides researchers with tools to display data and findings in a thoughtful and clear manner.

History and Graphical Deception

The Visual Display of Quantitative Information begins with a review of the history of graphics and credits the works of Johann Hinrich Lambert and William Playfair in the 1700s as ushering in the era of modern graphics. Tufte notes that the goal of early graphics was to communicate interpretations of a data set, but that around the 1900s the use of statistical graphics shifted toward focusing more on combatting deception than analyzing data. As an effect, graphics became simply a way to display what was obvious about the data—that is, until the introduction of John Tukey's graphics in the 1960s.

When creating a graphic, Tufte acknowledges the importance of a graphic's *lie factor*, which can be calculated in the following manner:

$$\text{Lie factor} = \frac{\text{Size of the effect shown in the graphic}}{\text{Size of the effect in the data itself}}$$

The lie factor should be around 1 to accurately convey the data to the reader (i.e., the graphic should mirror the size of the effect found in the data, not belittle or exaggerate it). Of note, overdecoration of a graphic, such as portraying bars in 3D when the data vary in two dimensions, should be avoided as it can create graphical deception. However, enough information should be provided to put the data in context and ensure nothing is missing.

The Importance of Ink in a Graphic

The remainder of the book focuses on principles and techniques to follow when creating good statistical graphics, the most important of which is, "Above all else, show the data." One way to ensure this principle is followed is by paying attention to the ink used in the creation of the graphic. Specifically, Tufte suggests aiming for a large *data-ink ratio*, which is calculated:

$$\text{(Data – ink) ratio} = \frac{\text{Data – ink}}{\text{Total ink used in the graphic}}$$

Paying attention to a graphic's data-ink (ink used to convey the data) ratio can help limit *non-data-ink* (ink used for purposes other than displaying data) and *redundant data-ink* (ink used to show the same information in multiple ways). Oftentimes, these types of ink can be erased without losing critical information.

For example, a bar chart that is both shaded and labeled has quite a bit of redundant data-ink which can be erased and still convey the data. Decorations are also considered non-data-ink or redundant data-ink and are called *chartjunk* by Tufte. Grids, coordinate lines, frames, and tick marks are common elements of chartjunk that can either be fully or partially removed without changing the graphic's interpretation. In fact, removing chartjunk can increase the ease of interpretation by limiting clutter that might obscure the data.

Another way to streamline a graphic's ink is to use ink to convey multiple details at once, which Tufte calls *multifunctioning graphical elements*. An example of a graphic that utilizes multifunctioning elements is the stem-and-leaf plot, which uses the same elements to display both the numbers that make up the data and its distribution. Lastly, when it comes to a graphic's ink, colored ink can often lead to a confusing graphic. Because the mind does not automatically assign order to specific colors, Tufte suggests using shades of gray to show order and/or density.

Data Density and Final Aesthetical Considerations

Another consideration when creating a graphic is maximizing the *data density*:

$$\text{Data density} = \frac{\text{Number of entries in the data matrix}}{\text{Area of graphic.}}$$

Tufte emphasizes that it is ideal for graphics to be created out of a large data matrix and therefore should

have a high data density. Data matrices that are smaller and less complex (e.g., 30 or fewer datapoints) should be saved instead for within the writing of the text or for a table. In addition, to increase the data density, the area of the graphic can be decreased. Oftentimes, the message of the graphic can still be conveyed even when shrunk down to a much smaller size, called the *shrink principle*. Such shrunk graphics can also be multiplied, showing differing variations of a variable in each graphic. These *small multiples* can easily show changes and differences across many groups. For instance, consider the small multiples example (Figure 1) displaying differences in anxiety ratings over time for participants starting an antianxiety medication (note the ease of comparison across participants).

The Visual Display of Quantitative Information ends by leaving the reader with a few final tips to follow when creating a graphic. First, line weights can convey different meanings and should be thin when possible so as to not distract the reader from the graphic's message. Simple in-text tables or elaborate out-of-text tables should be considered instead of a graphic if they better convey the data. Lastly, graphics in general should be more horizontal and less tall in their layout. Following the idea of the *Golden Rectangle* is a good rule of thumb when determining the area of a graphic: The graphic should be about 1 unit high and 1.618 units wide. A graphic around this size will be more pleasing to the eye and easier to read for the average user.

Informing others of a study's findings is a critical part of research. Oftentimes, words alone are not enough to describe a complex data set, and therefore graphics must be used. Tufte's book provides researchers with a

Figure 1 Changes in Anxiety Ratings Across Participants and Time

number of rules to create graphics that accurately and concisely convey the data's message.

VOLUNTEER BIAS

The term *volunteer bias* refers to a specific bias that can occur when the subjects who volunteer to participate in a research project are different in some ways from the general population. If this occurs, the researcher has sampled only a subset of the population, and consequently, the data gathered are not representative of all people, merely of those that choose to volunteer. Volunteer bias is a challenge to the external validity of any research project.

Differences Between Volunteers and Nonvolunteers

An underlying problem in volunteer bias is that volunteers and nonvolunteers are different in important ways. In an extensive review, Robert Rosenthal and Ralph Rosnow examined differences between volunteers and nonvolunteers. They reported that, in general, volunteers are more educated, come from a higher social class, are more intelligent, are more approval-motivated, and are more sociable. Volunteers are also more arousal-seeking, unconventional, nonauthoritarian, and nonconforming, and they have higher levels of empathy and lower levels of trait-anxiety. Females are more likely to volunteer than males, and Jewish people are more likely to volunteer than Protestants or Catholics. Medical research also has found that volunteers are generally healthier and are more likely to follow the treatment plan provided by their physician. Volunteers also have lower morbidity and mortality rates, are less likely to smoke, and are less likely to abuse alcohol.

Overcoming Volunteer Bias

Volunteer bias can emerge in any research study in which sampling is required. As the refusal rates to volunteer increase, the potential for volunteer bias is increased. A reduction of this bias can therefore be made by methods intended to increase rates of volunteering. For example, subjects are much more likely to volunteer for studies that they are interested in, and so researchers should ensure that the volunteer request captures the interest of the subject as much as possible. Also, subjects are less likely to volunteer if the topic is sensitive or threatening. Researchers can try to make the study as nonthreatening and comfortable as possible and ensure anonymity and confidentiality to the subject. In addition, subjects are more likely to volunteer if the study is perceived to be theoretically or practically important or if the recruitment is made by a person that the subjects are familiar with. Volunteer rates also increase with the perceived level of authority of the recruiter. Increasing the incentive to participate is also a good way to improve volunteer rates. Furthermore, researchers should be careful to make their studies as short and simple as possible; volunteering tends to decrease when the study requires a major commitment from subjects or if the study is not clear. The volunteer bias can be difficult to overcome, but researchers can reduce its likelihood with diligent planning and recruitment practices.

Example: Volunteer Bias in Sexuality Research

Although the volunteer bias can emerge in many research areas, it seems to be particularly problematic with topics that might be deemed sensitive by subjects. One such area is human sexuality research. To understand sexual behavior, researchers might want to sample a large group of subjects and ask them questions about their sex lives. Many potential subjects might be uncomfortable answering personal questions and will choose to not volunteer. Other subjects will have no reservations when talking about their sex lives. If the researcher gets data only from subjects that are more open about sex, the results might not represent the population as a whole. Research on the volunteer bias in sexuality research has confirmed several differences between volunteers and nonvolunteers. It has been reported that men are much more likely to volunteer for sex studies than women. In general, volunteers are more sexually experienced, less sexually inhibited, have less sexual guilt, and have more positive attitudes about their sexuality than nonvolunteers. Some studies have found that male volunteers are more likely to have

sexual dysfunctions than male nonvolunteers and that female volunteers are more likely to report history of sexual trauma than female nonvolunteers. Other studies find volunteers have more positive attitudes about erotica, masturbate more frequently, engage in more noncoital sexual experiences, have increased reports of homosexual behavior, and have more experience with less traditional sexual interactions.

The volunteer bias is likely to become more apparent as the intrusiveness of the measure increases. For example, many researchers are interested in studying factors that affect arousal levels in subjects. To do this, they might show them erotic pictures or movies and often measure arousal via devices like the vaginal photoplethysmograph. This device is inserted into the vagina and measures vasoengorgement and pooled blood changes. Although the research is certainly valid and needed, many subjects would stay away from such intrusiveness. The result is that the generalizability of

such research must be questioned. It is likely that arousal changes are different in these volunteer subjects than in the general population.

W

WAVE

Hearing the term *wave* might bring images of water moving toward shore. Waves in statistical analysis are similar to those of the ocean. Just like crests (highs) and troughs (lows) in examining patterns of moving water, waves are cycles of data analysis that extend in time for individuals (students) or groups of individuals (families or schools). A crest would represent when researchers are gathering data. A trough would represent a break in data collection. As such, waves are repeated measures of data collection. Statisticians collect data over multiple repeated measures in time because they are often interested in addressing research questions about human development or historical change. Sections that follow include examples of research studies where waves are used, important statistical considerations in the analysis of wave data, and historical trends in types of statistical techniques used to study wave data.

Two Examples of Wave Analysis

Wave analyses help researchers understand change and growth given a variety of variables of interest in the social sciences. Consider the investigator who would like to study whether motivation about learning remains stable, decreases, or increases in time as students move through the grade levels. Each grade level would represent a wave. The investigator might administer a motivation survey to students during every spring of each academic year starting with grade 3 and moving through high school. The goal would be to determine whether the average motivation scores stay the same or whether they change for the same group of students.

As another example, a researcher might want to study the recreational spending habits of families throughout the course of the year. Records of expenditure might be collected once every three months. The investigator might study how these expenses are correlated with those for essential needs (e.g., health or food). This example also involves waves of data collection like the motivation example. However, it is different in some ways. First, the units of analysis are not the same. Here, the investigator studied families, whereas in the motivation example, the study focused on students. Second, the frequency and duration of each wave are different. The motivation researcher studied change across years. By comparison, the family studies researcher was interested in fewer waves (four per year) and a shorter duration of time (every three months). Finally, there are more variables to analyze in the family spending study. Not only are there measures of time, but also the researcher examined two types of spending: essential needs and recreation. Differences in units of analysis, frequency and duration of time, and amount and type of variables studied lead to different statistical method considerations in the analysis of wave data.

Statistical Method Considerations

Statisticians have to think carefully about several data analysis considerations when conducting investigations that require waves: (1) the interval of the wave, (2) the frequency of waves, and (3) the amount and type of variables studied. Reviews of literature help investigators make decisions about all of these design elements. The interval of the wave is the length of each time period. In studies about learning, for example, report-card marking periods, semesters, or years make sense

as these are typical intervals of time that define the academic calendar.

The frequency of waves is also an important consideration. Not only does the frequency of waves relate to the kind of statistical analysis that can be selected to study change, but also various frequencies of data collection allow researchers to examine different shapes in trends. With few waves, researchers might only be able to detect linear changes. With more waves, researchers can compare linear (just increases *or* decreases) and nonlinear trends (increases *and* decreases over time).

Finally, waves can be used to study a few variables or many variables in time. Some of these variables can change by their scales of measurement. Motivation scores are often measured by administering surveys. Often, investigators will standardize these scores using *z* scores. Therefore, the survey scores represent an interval scale of measurement. By comparison, the amount of money spent would represent a ratio scale of measurement; however, the distribution of money spent at each wave might or might not be approximately normal. Characteristics about these variables lead to selections of different statistical procedures. Repeated measures analysis of variance (ANOVA) might be appropriate for the study of motivation. However, as a parametric test, it might not be the best choice for the study of spending habits. A nonparametric alternative should be selected.

History of Statistics Used in Wave Analysis

For many years, the statistical analyses employed to study wave data were those of the general linear model (GLM). These procedures included tools like the dependent *t* test (for two waves of data) and the repeated-measure ANOVA (for three or more waves of data). Harvey Keselman and colleagues have conducted many research investigations and have written reviews describing important considerations when conducting such analyses. In more recent times, advances in computer technology have permitted the analysis of very sophisticated statistical models. One type of analysis called growth-curve modeling allows for the inspection of wave data for nested or “multilevel” units of analysis where changes in time can be examined for students who are enrolled (or nested) in particular classrooms or schools. The motivation example described earlier, therefore, can be extended to see not only change for students but also whether their teachers influence change. Even more complex statistical models can be analyzed using software tools like *Mplus*. Here, the relationships among sets of variables collected at each wave can be analyzed to determine whether the

associations change. Finally, this analysis can also be multilevel (time within students and students within schools).

WEBER–FECHNER LAW

Several models have been proposed in the field of psychophysics to quantify relationships between any stimulus (e.g., touch, sound, light, and smell) and the perceived response by individuals. One such model is referred to as the Weber–Fechner Law. The Weber–Fechner Law, however, is not one law, but two separate laws: Weber’s Law and Fechner’s Law. Moreover, not all human senses respond to stimuli according to Fechner’s law (in fact many do not). Weber’s Law and special cases such as Fechner’s Law are each based on the “just noticeable difference threshold” concept.

The Difference Threshold or Just Noticeable Difference

When quantifying a difference threshold, the reason for doing so is to determine the minimum difference between two stimuli that can be detected. Researchers in the field of classical psychophysics pose the question this way: What is the just noticeable difference (JND) required to perceive that a comparison stimulus is different from a standard (or reference) stimulus?

Weber’s Law

Ernest Heinrich Weber was an early pioneer in the field of psychophysics, and it was Weber who developed the concept of the difference threshold or just noticeable difference. Weber published the results of experiments

in which he asked observers first to lift a standard weight and then a comparison weight and judge whether the comparison weight was greater than, equal to, or less than the standard weight. By having observers compare a large number of different standard and comparison weights, Weber was able to determine the smallest difference between two weights that could be detected reliably (i.e., the difference threshold). He found that the difference threshold or just noticeable difference was dependent on the weight of the standard (reference) stimulus. For example, if an observer can just notice the difference between a 100 g standard weight and a 103 g comparison weight, the JND in this example would be 3 g. Weber found, however, that if the weight of the standard was increased to 1,000 g, the JND was no longer 3 g but had increased to 30 g (i.e., the comparison weight must be heavier than 1,030 g to perceive a just noticeable difference). Weber investigated further and found that the size of the JND for most human senses (e.g., sight, sound, taste, and touch) is a constant fraction of the size of the standard stimulus. Expressed mathematically, this is known as Weber's Law:

$$\text{JND} = kS,$$

where k is a constant called the Weber fraction and S is the value of the standard stimulus. This equation is usually expressed in the form

$$k = \text{JND} / S.$$

Fechner's Law

Gustav Fechner derived a relationship between the intensity of a specific stimulus and the perceived (estimated) magnitude. To derive this relationship, Fechner made two important assumptions:

1. that the JND is a constant fraction of the stimulus (i.e., Weber's Law holds), and
2. that the JND is the basic unit of perceived magnitude, so that one JND is perceptually equal to another JND.

By accepting these assumptions, Fechner hypothesized that the magnitude of a stimulus can be determined by starting at the detection threshold (JND) and then adding JNDs. From this, Fechner derived the following mathematical relationship between perceived magnitude (P) and stimulus intensity (I):

$$P = k \log I,$$

where k is a constant fraction (Weber's Law). Using Fechner's Law, it can be determined whether doubling the intensity of a light makes it appear twice as bright. For example, a light that is 10 JND units above the detection threshold should be perceived as being twice as bright as a light with an intensity of 5 JND units above the detection threshold. If we set $k = 1$ and $I = 10$, then $P = 1.0$ because the log of 10 = 1.0. However, if the intensity of light is doubled to 20, then $P = 1.3$ (not 2.0). Thus, doubling the light's intensity does not double the perceived magnitude of brightness. The second assumption of the two made by Fechner has since been questioned by those working in the field of psychophysics, and Fechner's Law (a special case) has largely been replaced by Stevens's Power Law.

Stevens's Power Law

Stanley Smith Stevens proposed that the perceived magnitude of a stimulus (P) equals a constant (k) times the stimulus intensity (S), raised to a power (n). Stevens found that for all senses (in general), the relationship between any stimulus intensity (X) and estimated response magnitude (Y) is best described by a power law, and the exponent of the power law indicates whether a doubling of the stimulus results in a doubling in the perceived stimulus (i.e., linear) or whether a doubling of the stimulus causes *more or less* than a

Note: Curves showing the relationship between perceived magnitude (Y) and stimulus intensity (X) for curve A (brightness), curve B (electric shock), and curve C (line length), adapted from Goldstein (1989).

doubling of the perceived response. Stevens's Law was found to better quantify the stimulus-response curves for a number of sensory phenomena, such as loudness, brightness, smell, taste, vibration, line length, and electric shock. Stevens's Power Law can be demonstrated by plotting the logarithm of the intensity of the stimulus (X) versus the logarithm of the perceived (i.e., estimated) magnitude of the stimulus (Y).

Stevens described three types of stimulus-response curves (Figure 1). The first is called a response compression curve because the stimulus-response curve bends downward (curve A, Figure 1). For example, Stevens found that doubling light intensity (X) resulted in only a small change in perceived brightness (Y) because the exponent (n) was < 1.0 . Thus, as light intensity increases, the perceived response also increases but not as rapidly as the intensity.

A second type of stimulus-response curve includes those that bend upward, thereby exhibiting response expansion. For example, when electric shock is applied to the finger (curve B, Figure 1), the exponent (n) of this stimulus-response curve was 3.5 times higher (i.e., much higher than 1.0). This indicates that a doubling of the intensity of the shock would result in more than a doubling of the sensation of being shocked. In another example of response expansion, Stevens showed that sound 20 JND units above a threshold is perceived as being much more than twice as loud as sound that is 10 JND units above threshold.

The third type of stimulus-response curve is linear or approaches linearity (i.e., the power of the exponent, n , is 1.0 or close to 1.0). Observers who estimated the lengths of straight lines (Y) in response to being shown different line lengths (X) were found to produce linear stimulus-response curves (see curve C, Figure 1).

WEIBULL DISTRIBUTION

The Weibull distribution is named after the Swedish engineer Waloddi Weibull who used the distribution in a paper on the breaking strength of materials. As an example of Stigler's law of eponymy, Weibull was not the first to apply the distribution: Paul Rosen and Erich Rammner used it six years earlier to study the fineness of powdered coal. The distribution is used in areas as diverse as engineering (for reliability analysis), biostatistics (lifetime modeling and survival analysis), and psychology (for modeling response times).

The three-parameter Weibull cumulative distribution function (CDF) for a random variable T is defined as follows:

$$F(t) = \begin{cases} 0 & \text{for } t \leq \psi \\ 1 - \exp\left[-\left(\frac{t - \psi}{\theta}\right)^\beta\right] & \text{for } t > \psi, \end{cases} \quad (1)$$

with $\theta > 0$ and $\beta > 0$. The density function $f(t)$ equals

$$f(t) = \begin{cases} 0 & \text{for } t \leq \psi \\ \theta^{-\beta} \beta (t - \psi)^{\beta-1} \exp\left[-\left(\frac{t - \psi}{\theta}\right)^\beta\right] & \text{for } t > \psi. \end{cases} \quad (2)$$

In the remainder of this entry, it is assumed that the distribution or density function can only be nonzero for $t > \psi$, and this will not be written explicitly.

The three parameters ψ , θ , and β of the Weibull distribution are the location, scale, and shape parameter, respectively. Changing ψ results in a simple shift of the CDF and changing the scale parameter θ results in stretching or shrinking the CDF. The parameter β is a shape parameter because it affects the shape of the distribution (i.e., changing β affects more than just the location or the scale).

In Figure 1, the effects on the density function of changing each of these parameters in turn are shown. Parameter values are chosen in Figure 1 that result in densities that are realistic examples of common human response time densities. Weibull density functions are unimodal: For $\beta \leq 1$, the mode of the Weibull density functions is located at ψ but for $\beta > 1$, the single mode

is larger than ψ [and it is exactly at $t = \psi + \theta \left(\frac{\beta - 1}{\beta} \right)^{\frac{1}{\beta}}$].

Most typically, the Weibull density functions exhibit right skew, but with an increasing β , it becomes more symmetric. If β becomes larger than 3.602, the density becomes left-skewed.

Sometimes it is more convenient to use a rate parameterization instead of the scale parameterization as in Equations 1 and 2. Applied to the CDF then gives:

$$F(t) = 1 - \exp[-\lambda(t - \psi)^\beta] \quad (3)$$

with $\lambda = \theta^\beta$ (again, $\lambda > 0$). If the rate λ increases, the CDF becomes steeper and hence the density function will show less variability.

Properties

In this section, some properties of the Weibull distribution are investigated.

Mean, Variance, and Median

The mean of the Weibull distributed random variable T equals (using the location-scale parameterization):

$$E(T) = \psi + \theta \Gamma\left(1 + \frac{1}{\beta}\right),$$

where $\Gamma(x)$ is the gamma function. The variance of T is equal to $\text{Var}(T) = \theta^2 \left[\Gamma\left(1 + \frac{2}{\beta}\right) - \Gamma^2\left(1 + \frac{1}{\beta}\right) \right]$
 $= \theta^2 \Gamma\left(1 + \frac{2}{\beta}\right) - [E(T) - \psi]^2,$

from which it can be seen that for a fixed value of ψ , mean and variance are related. The median of the Weibull distribution is

$$\text{Median}(T) = \psi + \theta (\ln 2)^{\frac{1}{\beta}}. \quad (4)$$

All quantities can be expressed readily under the rate parameterization by replacing θ with $\lambda^{\frac{1}{\beta}}$.

Simulating Weibull Random Deviates

Simulating random draws from a Weibull distribution is easily done making use of the probability integral transform. In practice, one needs to draw a random number u , uniformly distributed between 0 and 1, and transform it as follows:

$$t = \psi + \theta [-\ln(u)]^{\frac{1}{\beta}} \quad (5)$$

and t is then a draw from a Weibull distribution.

Figure 1 Some Examples of the Weibull Density Functions with a Systematic Variation of the Parameters

Notes: In all panels, the density functions with the solid line have as parameter values: $\Psi = 0.3$, $\theta = 0.2$, and $\beta = 1.7$. The three density functions represented by the dashed line each differ in one of the parameters. In panel (a), the shift parameter Ψ is increased to 0.4 for the dashed line. In panel (b), the scale parameter θ equals 0.4 for the dashed line, and in panel (c), the shape parameter β is altered to 1.1.

Relation With Other Distributions and Stochastic Processes

If the shape parameter β equals 1, the three-parameter Weibull distribution simplifies to the two-parameter exponential distribution:

$$F(t) = 1 - \exp\left(-\frac{t - \psi}{\theta}\right).$$

It is known that when $\psi = 0$, the exponential distribution is the distribution of waiting times between subsequent events that are generated according to a homogeneous Poisson process $N(t)$ with rate $r = \frac{1}{\theta}$. If one assumes a nonhomogeneous Poisson process $N(t)$ with rate:

$$r(t) = \theta^{-\beta} \beta t^{\beta-1} \quad (6)$$

then the waiting time until the first event is Weibull distributed. Note that the rate in Equation 6 is also the hazard function of the Weibull distribution $[h(t) = \frac{f(t)}{1 - F(t)}]$, which is the instantaneous rate of failure at moment t , given that the failure did not yet happen until then. Depending on the value of β , the hazard rate is monotonically increasing (when $\beta > 1$), constant (when $\beta = 1$, which is the exponential case), or monotonically decreasing (when $\beta < 1$). Because of this type of hazard rate, the Weibull model is also called an accelerated failure time model.

Another interesting property of the Weibull distribution is the min-stable property. Assume a sample of n random variables $T_1, \dots, T_n$, independently drawn from the Weibull distribution with parameters Ψ , θ , and β . Let us denote the minimum of the sample of size n as $T_{1:n}$ (i.e., the smallest order statistic). Then the distribution function G of $T_{1:n}$ is equal to

$$G(t) = 1 - \Pr(T_1 > t, \dots, T_n > t) \\ = 1 - [1 - F(t)]^n \quad (7)$$

$$= 1 - \exp\left(-\left(\frac{t - \Psi}{n^{-1/\beta}\theta}\right)^\beta\right), \quad (8)$$

which is again a Weibull distribution with Ψ and β as location and shape parameters, respectively. The scale parameter has now become equal to $n^{-1/\beta}\theta$.

Limiting Distribution

The Weibull distribution also arises as an asymptotic distribution for the smallest order statistic of a sample of independently and identically distributed

random variables (if n grows to infinity), provided some regularity conditions hold (the distribution has a finite lower bound, and the left tail close to the lower bound behaves approximately as a power law). Of course, from Equation 7, it follows that if $n \rightarrow \infty$, the distribution becomes degenerate; hence, the theory of asymptotic distributions only holds after suitable normalization.

Weibull Regression Model

In many cases, there are measured predictors (collected in a vector x_i for unit i), and one assumes that, conditional on the predictor scores, the criterion variable T_i is Weibull distributed. Although all parameters might be linked to the predictors, the most common practice is to assume that the scale parameter θ or the rate parameter λ is a function of the predictors. Because scale and rate are restricted to be positive, usually a logarithmic transform is employed as follows:

$$\ln(\theta_i) = x_i' \beta.$$

In this case, the predictors have a multiplicative effect on the mean of the distribution.

Parameter Estimation

Many methods have been considered for estimating the Weibull parameters (e.g., method of moments or modified method of moments), but the most popular are maximum likelihood and Bayesian methods. Assuming Ψ is known, there are no problems with maximum likelihood estimation, although no closed-form solutions exist and the loglikelihood has to be maximized using numerical techniques. If Ψ is unknown and has to be estimated as well, problems might occur because the likelihood becomes infinite when $\hat{\Psi} = t_{1:n}$. This results in inconsistent estimates for the other parameters. As a solution, one might look for a local optimum of the likelihood, and then all asymptotic results for maximum likelihood hold given $\beta > 2$. However, the approach of local optima is not guaranteed to work universally either. As an alternative, one might consider a Bayesian estimation method. With the increasing availability of computing resources and the development of modern sampling techniques, Bayesian methods have become very popular. Of course, applying a Bayesian estimation method requires the specification of priors and no definitive guidelines exist regarding this issue.

WEIGHTS

Weights are numbers attached to observations in order to get unbiased and/or more efficient parameter estimates. These are used in stratified sampling, in regression when error variances are not homogeneous, in robust estimation when the sample contains heavier tails than that of the normal distribution or outliers, and in meta-analysis. When weights are updated iteratively, complicated maximum likelihood estimators (MLEs) can be obtained through simple formulas. Well-known examples in this direction are the generalized linear models and models based on t distributions.

Weights in Stratified Sampling

Stratified sampling is a method of sampling within subpopulations. Each subpopulation is called a stratum. When strata vary considerably in size or distribution, stratified sampling often improves the representativeness of the sample. By assigning a proper weight to each stratum, a more efficient estimator for the mean of the whole population will be obtained.

Suppose the entire population is divided into h strata. Let μ_j be the population mean for the j th stratum and p_j be the proportion of the j th stratum in the whole population, $j = 1, \dots, h$. Then the whole population mean is

$$\mu = \sum_{j=1}^h p_j \mu_j.$$

When a sample of size n is obtained, let n_j be the sample size of the j th stratum; then $n = n_1 + n_2 + \dots + n_h$. Let $\bar{y}_j$ and w_j be the sample mean and the attached weight of the j th stratum, respectively. Then the weighted sample mean $\bar{y}_w$ and its expected value $E(\bar{y}_w)$ are

$$\bar{y}_w = \sum_{j=1}^h w_j \bar{y}_j \quad (1)$$

and

$$E(\bar{y}_w) = \sum_{j=1}^h w_j \mu_j. \quad (2)$$

When all the p_j 's are known, the weights are often set to be $w_j = p_j$. Denote $\bar{y}_p$ as the weighted sample mean in Equation 1 with $w_j = p_j$, then it follows from Equation 2 that $\bar{y}_p$ is unbiased. Notice that the sampling proportion n_j/n does not necessarily equal the population proportion p_j in the above estimation. Stratified sampling allows a small stratum to have enough representation in the estimation.

In practice, either proportionate or disproportionate sampling is used to determine n_j . In proportionate sampling, n_j is set proportional to p_j . In disproportionate sampling, n_j is chosen to minimize the variance of $\bar{y}_p$. Notice that, unless all the μ_j 's are equal, proportionate sampling yields a $\bar{y}_p$ having a smaller variance than the arithmetic mean of the simple random sampling of size n . Disproportionate sampling almost always leads to a $\bar{y}_p$ that has a smaller variance than the one corresponding to proportionate sampling.

Weights in Weighted Least-Squares Regression

Let y_i be the response and $\mathbf{x}_i = (1, x_{i1}, \dots, x_{ip})$ be the set of predictors, $i = 1, 2, \dots, n$. The multiple regression model can be expressed as

$$y_i = \mathbf{x}_i \boldsymbol{\beta} + e_i = \beta_0 + x_{i1} \beta_1 + \dots + x_{ip} \beta_p + e_i, \quad (3)$$

where $\boldsymbol{\beta} = (\beta_0, \beta_1, \dots, \beta_p)'$ is the vector of regression coefficients, with $'$ being the notation for transpose, and e_i is the residual defined as the difference between the value of the dependent variable and the predicted value. Least squares (LS) that minimizes sum of squares of the residuals $\sum_{i=1}^n e_i^2$ is the most widely used method in estimating $\boldsymbol{\beta}$. Its justification needs three assumptions: All the e_i 's have expectations of zero, have a common variance σ^2 , and are uncorrelated. When all the three are met, the LS estimator

$$\hat{\boldsymbol{\beta}} = \left(\sum_{i=1}^n \mathbf{x}_i' \mathbf{x}_i \right)^{-1} \sum_{i=1}^n \mathbf{x}_i' y_i \quad (4)$$

is optimal among all estimators that are linear combinations of y_i 's in the sense of having a minimum variance. When any of the assumptions is violated, $\hat{\boldsymbol{\beta}}$ does not enjoy such an optimal property. With the intercept β_0 in Equation 3, $E(e_i) = 0$ is automatically satisfied.

When e_i 's are correlated or have heterogeneous variances, a better estimator than that in Equation 4 can be obtained by using proper weights. Consider the case when e_i 's are independent and $\sigma_i^2 = \text{Var}(e_i)$ are unequal but known. Then Equation 3 can be transformed into

$$y_i/\sigma_i = (x_i/\sigma_i)\beta + \varepsilon_i, \quad (5)$$

where $\varepsilon_i = e_i/\sigma_i$. Obviously, ε_i 's have equal variance of $\sigma^2 = 1$. Thus, the three assumptions are met for Equation 5. Letting $w_i = 1/\sigma_i^2$ and applying LS to Equation 5 yields the so-called weighted LS (WLS) estimator

$$\hat{\beta}_w = (\sum_{i=1}^n w_i x_i' x_i)^{-1} \sum_{i=1}^n w_i x_i' y_i. \quad (6)$$

When $w_i = 1$ in Equation 6, $\hat{\beta}_w$ becomes the $\hat{\beta}$ in Equation 4. When a certain e_i in Equation 3 has a huge variance σ_i^2 , the i th observation (x_i, y_i) will have a tiny weight $w_i = 1/\sigma_i^2$ in Equation 6, which explains why $\hat{\beta}_w$ enjoys the optimal property, whereas $\hat{\beta}$ does not.

When the e_i 's are correlated and normally distributed, the vector $(e_1, e_2, \dots, e_n)'$ can also be transformed into one whose elements are independent and identically distributed. LS applied to such a transformed regression equation is usually called the generalized least squares. Suppose the σ_i^2 's are unknown but can be estimated consistently by $\hat{\sigma}_i^2$'s. Then using $w_i = 1/\hat{\sigma}_i^2$ in Equation 6 also leads to an estimator that enjoys better properties than $\hat{\beta}$. When w_i is defined through a function that is proportional to

$$1/|\hat{e}_i| = 1/|y_i - x_i \hat{\beta}_w|,$$

iteratively updating Equation 6 leads to a robust estimator of β , which can be less biased and more efficient when outliers exist in the response variable in the sample. In particular, observations with huge errors have little effect on the robust estimator.

A special case of Equation 3 is when $p = 0$; then $\hat{\beta}_w$ reduces to the weighted mean

$$\hat{\mu} = \hat{\beta}_0 = \frac{\sum_{i=1}^n w_i y_i}{\sum_{i=1}^n w_i},$$

which is the commonly used formula for combining mean differences in meta analysis.

Weights in Robust M Estimators

The idea of robust estimation by iteratively reweighting observations has already been introduced. A wide class of robust estimators is called the M estimator, which is a generalization to maximum likelihood estimator. For

a p -variate sample $x_i, i = 1, 2, \dots, n$, from the normal distribution $N_p(\mu, \Sigma)$, the MLEs of the population mean vector μ and covariance matrix Σ are their sample counterparts

$$\bar{x} = \frac{1}{n} \sum_{i=1}^n x_i \text{ and } S = \frac{1}{n} \sum_{i=1}^n (x_i - \bar{x})(x_i - \bar{x})',$$

respectively. Most multivariate methods (e.g., principal components, factor analysis, and structural equation modeling) are based on analyzing S . When data are not normally distributed, S is not optimal. Actually, one outlier in the sample can make S meaningless. With data contamination, better estimators are obtained by

$$\begin{aligned} \hat{\mu}_w &= \frac{\sum_{i=1}^n w_{i1} x_i}{\sum_{i=1}^n w_{i1}} \text{ and} \\ \hat{\Sigma}_w &= \frac{1}{n} \sum_{i=1}^n w_{i2} (x_i - \hat{\mu})(x_i - \hat{\mu})', \end{aligned} \quad (7)$$

where w_{i1} and w_{i2} are weights defined through functions of the Mahalanobis distance

$$MD_i = [(x_i - \hat{\mu}_w)' \hat{\Sigma}_w^{-1} (x_i - \hat{\mu}_w)]^{1/2}.$$

With properly chosen functions $w_1(t)$ and $w_2(t)$, $w_{i1} = w_1(MD_i)$ and $w_{i2} = w_2(MD_i)$ are automatically determined at each given $(\hat{\mu}_w, \hat{\Sigma}_w)$. Robust M estimators $(\hat{\mu}_w, \hat{\Sigma}_w)$ will be obtained iteratively through Equation 7. Notice that x_i sitting further from $\hat{\mu}_w$ will have a greater MD_i . When $w_1(MD_i)$ and $w_2(MD_i)$ are monotonically decreasing functions of MD_i , observations sitting far from the center of the data cloud will have tiny w_{i1} and w_{i2} , which explains why $\hat{\mu}_w$ and $\hat{\Sigma}_w$ are robust or resistant to outliers/data contamination.

When the sample is from a distribution with heavier tails than that of the normal distribution, the estimators in Equation 7 are more efficient than $\bar{x}$ and S . When the population is truly normal, $\bar{x}$ and S are the best but are only slightly better than those in Equation 7. Thus, using the estimators in Equation 7 for data analysis generally leads to more reliable results than those based on analyzing $\bar{x}$ and S .

The median, α -trimmed mean, and winsorized mean are special cases of Equation 7. When $w_{i1} = w_{i2} = 1$, $\hat{\mu}_w$ becomes $\bar{x}$ and $\hat{\Sigma}_w$ becomes S . When the weights w_{i1} and w_{i2} are defined through the density of a multivariate t distribution, Equation 7 yields the MLEs of the mean vector and scatter matrix of the t distribution.

The w_{i1} and w_{i2} in Equation 7 can be defined using the residuals in a factor analysis model. Then solving an

equation parallel to Equation 7 leads to robust estimates of factor loadings, factor covariances, and error variances.

WELCH'S t TEST

Mean comparison is the central theme of many classical statistical procedures. The well-known independent-sample t test is often used to test the equality of two means from independent populations with equal variances, whereas Welch's t test is generally preferred when the variances are not equal.

Let $y_{11}, y_{21}, \dots, y_{n_1 1}$ and $y_{12}, y_{22}, \dots, y_{n_2 2}$ be two independent random samples from two populations with means (or expected values) $\mu_j = E(y_{ij})$ and variances $\sigma_j^2 = \text{Var}(y_{ij})$, $j = 1, 2$. The sample counterparts of μ_j and σ_j^2 are $\bar{y}_j = \frac{1}{n_j} \sum_{i=1}^{n_j} y_{ij}$, and $s_j^2 = \frac{1}{n_j - 1} \sum_{i=1}^{n_j} (y_{ij} - \bar{y}_j)^2$, respectively. Because $\bar{y}_j$ is an unbiased estimator of μ_j , any difference between μ_1 and μ_2 should be reflected by $\bar{y}_1 - \bar{y}_2$. Of course, even when the null hypothesis

$$H_0: \mu_1 = \mu_2 \quad (1)$$

holds, $\bar{y}_1 - \bar{y}_2$ does not hold in general because of the sampling error, which is characterized by the variance

$$v^2 = \text{Var}(\bar{y}_1 - \bar{y}_2) = \frac{\sigma_1^2}{n_1} + \frac{\sigma_2^2}{n_2}. \quad (2)$$

Notice that, when $\sigma_1^2 = \sigma_2^2 = \sigma^2$, v^2 will be simplified to $v_0^2 = \sigma^2(1/n_1 + 1/n_2)$, which is best estimated by

$$\hat{v}_0^2 = s_p^2(1/n_1 + 1/n_2), \quad (3)$$

where the pooled variance estimator s_p^2 is given by

$$s_p^2 = \frac{(n_1 - 1)s_1^2 + (n_2 - 1)s_2^2}{n_1 + n_2 - 2}.$$

The commonly used independent-sample t statistic,

$$t_s = \frac{\bar{y}_1 - \bar{y}_2}{s_p \sqrt{1/n_1 + 1/n_2}}, \quad (4)$$

is just the standardized mean difference using $\hat{v}_0$. As obtained by William S. Gosset in 1908, the t_s in Equation 4 follows $t(n_1 + n_2 - 2)$, the Student's t distribution with $n_1 + n_2 - 2$ degrees of freedom. It is commonly denoted by

$$t_s \sim t(n_1 + n_2 - 2), \quad (5)$$

Where “ $\sim$ ” stands for “following the distribution of.” When $\sigma_1^2 \neq \sigma_2^2$, $\hat{v}_0^2$ is no longer an unbiased estimator of v^2 , but $\hat{v}^2 = s_1^2/n_1 + s_2^2/n_2$ remains unbiased. A natural choice is to standardize $\bar{y}_1 - \bar{y}_2$ using $\hat{v}$, which leads to the so-called Welch's t statistic

$$t_w = \frac{\bar{y}_1 - \bar{y}_2}{\sqrt{s_1^2/n_1 + s_2^2/n_2}}. \quad (6)$$

The exact distribution of t_w can be characterized by a series or an integral, and it is far more complicated than Student's t distribution. Using complicated mathematics, Bernard L. Welch came up with

$$t_w \sim t(df_w), \quad (7)$$

where “ $\sim$ ” stands for “approximately following the distribution of” and df_w is the degrees of freedom given by

$$df_w = \frac{(s_1^2/n_1 + s_2^2/n_2)^2}{\frac{(s_1^2/n_1)^2}{n_1 - 1} + \frac{(s_2^2/n_2)^2}{n_2 - 1}}. \quad (8)$$

In other words, Example 7 means approximating the distribution of t_w by the t distribution with degrees of freedom df_w . The test that compares t_w against the distribution $t(df_w)$ for significance is called Welch's t test. Notice that the df_w in Equation 8 is not necessarily an integer.

It's worth mentioning that the approximation in Example 7 was also obtained by Franklin E. Satterthwaite in 1946 under a different context. Therefore, Example 7 is also called the Welch-Satterthwaite approximation.

Welch's t test is not only simple to use but also provides accurate control of the Type I error. Let α_w be the actual Type I error rates of Welch's t test. At nominal level $\alpha = .01, .05$, and $.1$, the maximum difference between α and α_w is approximately at .001 when both

n_1 and n_2 are greater than 5; and α_w will be closer to α as n_1 and n_2 increase.

Welch's t Test With Distribution Violations

Welch obtained the distribution $t(df_w)$ under the normality assumption. The approximation in Example 7 is affected by non-normal distributions, especially by the third central moments at smaller n_1 and n_2 .

The actual Type I error rate α_w depends on $E(t_w)$, the expected value of the t_w in Equation 6. When the two populations are normally distributed, $E(t_w) = 0$ under H_0 in Example 1. When the two populations are not normally distributed, under H_0 , $E(t_w)$ can be approximated by

$$\lambda_w = \frac{1}{2v^3} \left(\frac{\mu_{32}}{n_2^2} - \frac{\mu_{31}}{n_1^2} \right), \quad (9)$$

where v is given in Equation 2 and $\mu_{3j} = E[(Y_{ij} - \mu_j)^3]$ is the third central moment for the j th population, $j = 1, 2$. The fourth central moments have little effect on $E(t_w)$. The effect of $E(t_w)$ on the Type I error can be summarized as follows:

- When $\lambda_w = 0$, the expected value of t_w is closed to zero, and then α_w is very close to the nominal α . When two populations are normal, their third central moments are zero, and thus, $\lambda_w = 0$. Another case of $\lambda_w = 0$ is when two equal-sized samples are from distributions with the same third central moment.
- When $\lambda_w > 0$, Welch's t test tends to reject more on the right and less on the left. Because the over-rejection on the right is greater than the under-rejection on the left, the Type I error of the two-tailed Welch's t test α_w is typically greater than α .
- When $\lambda_w < 0$, the test tends to reject less on the right and more on the left, and $\alpha_w > \alpha$ for the two-tailed test.

Notice that the effect of non-normally distributed populations on α_w is most obvious when n_1 and n_2 are small, and it decreases as the two sample sizes increase. Actually, non-normal distributed populations only have a minimal effect on Welch's t test when both n_1 and n_2 are large, which can also be explained by Equation 9 being close to zero.

Welch's t Test Versus Student's t Test

Although it is unlikely for $\sigma_1^2 = \sigma_2^2$ with practical data, the Student's t test is still most widely used probably

because it has been taught in introductory textbooks. Under certain conditions, the Student's t test can perform well even when $\sigma_1^2 \neq \sigma_2^2$. The conditions are closely related to whether there exists a bias in the $\hat{v}_0^2$ of Equation 3. Notice that the true variance of $\bar{y}_1 - \bar{y}_2$ is given by the v^2 in Equation 2. The bias in the $\hat{v}_0^2$ is given by

$$b = E(\hat{v}_0^2) - v^2 = \frac{(n_1 + n_2 - 1)}{(n_1 + n_2 - 2)n_1n_2} (n_2 - n_1)(\sigma_2^2 - \sigma_1^2). \quad (10)$$

When $b > 0$, the expectation of $\hat{v}_0^2$ is larger than the true variance v^2 , so the statistic t_s in Equation 4 tends to be smaller than a statistic following the distribution of $t(n_1 + n_2 - 2)$; and it tends to be greater when $b < 0$. These will be reflected in the Type I error.

- When $n_1 = n_2 = n$, $b = 0$, and $\hat{v}_0^2 = \hat{v}^2 = (s_1^2 + s_2^2)/n$, and consequently, $t_s = t_w$. If $s_1^2 = s_2^2$ also holds, $df_s = df_w$ and the two tests lead to identical results. If $s_1^2 \neq s_2^2$ although the two tests are not identical, they still perform similarly and satisfactorily in practice because of $\hat{v}_0^2$ both and $\hat{v}^2$ being unbiased.
- When $n_1 \neq n_2$ while $\sigma_1^2 = \sigma_2^2$, $b = 0$, and both $\hat{v}_0^2$ and $\hat{v}^2$ are unbiased estimators of v^2 . But they are generally unequal because of the sampling error, and neither $t_s = t_w$ nor $df_s = df_w$ holds. However, the performances of both tests are still close to each other if s_1^2 and s_2^2 are not significantly different. When s_1^2 and s_2^2 are significantly different because of sampling errors, Welch's t test is preferred.
- When $n_1 \neq n_2$ and $\sigma_1^2 \neq \sigma_2^2$, $\hat{v}_0^2$ is biased for v^2 , as reflected by the b in Equation 10. The Student's t test cannot control the Type I error α properly even when both n_1 and n_2 are large. Let α_s be the actual type I error rate of the student's t test. when $b > 0$, α_s will be smaller than α because of a stochastically smaller t_s . When $b < 0$, α_s will be greater than α .

In conclusion, without knowing the value of σ_1^2 and σ_2^2 , Welch's t test performs satisfactorily in practice, with α_w being close to α . Actually, the degrees of freedom df_w in Equation 8 already takes $b \neq 0$ into consideration.

Other Related Tests for Mean Comparison

Other tests have been proposed for mean comparison with unequal variances. They tend to be more complicated than Welch's t test. Their gain in accuracy is often minimal because Welch's t test is already accurate enough. When $\sigma_1^2 \neq \sigma_2^2$ and n_1 and n_2 are not too small,

the bootstrap test based on the statistic t_w also performs very well in controlling the Type I error. But it needs much more computation.

The fact that Welch's t test is not sensitive to violation of the normality assumption when both sample sizes are very large does not mean that Welch's t test is robust to data contamination. When data are contaminated, the samples do not reflect the true characteristics of the populations. Then tests based on trimmed means, Winsorized means, or the robust M-estimators of μ_1 and μ_2 generally lead to a better control of the Type I error and to better evaluation of power. Because the exact distribution of a test statistic based on robust estimators is seldom known, it is usually approximated by the large sample statistical theory or bootstrap, thus also more complicated or more computational intensive.

Test for Equality of Variances

Because Student's t test is preferred to Welch's test under $\sigma_1^2 = \sigma_2^2$, a test on $\sigma_1^2 = \sigma_2^2$ is recommended before making the choice. Under the normality assumption, the best test for $\sigma_1^2 = \sigma_2^2$ is to compare the F statistic,

$$F = \frac{s_1^2}{s_2^2},$$

against the two tails of the F distribution with $n_1 - 1$ and $n_2 - 1$ degrees of freedom. However, this test is very sensitive to non-normality. With practical data, a more robust test is through the so-called Levene's statistic,

$$L = \frac{(n_1 + n_2 - 2)[n_1(\bar{z}_1 - \bar{z})^2 + n_2(\bar{z}_2 - \bar{z})^2]}{\sum_{i=1}^{n_1} (\bar{z}_{i1} - \bar{z}_1)^2 + \sum_{i=1}^{n_2} (\bar{z}_{i2} - \bar{z}_2)^2},$$

where $z_{ij} = |y_{ij} - \bar{y}_j|$, $\bar{y}_j$ is the mean of y_{ij} , $\bar{z}_j$ is the mean of z_{ij} , and $\bar{z}$ is the grand mean of z_{ij} , $j = 1, 2$. Levene's test is to compare L against the F distribution with degrees of freedom of 1 and $n_1 + n_2 - 2$.

Welch's t test should be used when the F or L statistic is significant, and Student's t test otherwise. Although failing to reject $\sigma_1^2 = \sigma_2^2$ does not imply that the two variances are equal, blindly using Student's t test without checking $\sigma_1^2 = \sigma_2^2$ can lead to meaningless Type I error or power.

Extension of Welch's t Test to Higher Dimensions

Mean comparison with unequal variances-covariances also poses a problem in higher dimensions, where exact inference is also hard to find.

Let $y_{11}, y_{21}, \dots, y_{n_1 1}$ and $y_{12}, y_{22}, \dots, y_{n_2 2}$ be two independent p -dimensional random samples from the normally distributed populations $N_p(\mu_1, \Sigma_1)$ and $N_p(\mu_2, \Sigma_2)$, respectively. The counterpart of Welch's t statistic is

$$T_w^2 = (\bar{y}_1 - \bar{y}_2)' \left(\frac{S_1}{n_1} + \frac{S_2}{n_2} \right)^{-1} (\bar{y}_1 - \bar{y}_2),$$

where $\bar{y}_j = \sum_{i=1}^{n_j} y_{ij} / n_j$ and

$S_j = \sum_{i=1}^{n_j} (y_{ij} - \bar{y}_j)(y_{ij} - \bar{y}_j)' / (n_j - 1)$, $j = 1, 2$. The counterpart of Student's t statistic is the well-known, two-sample Hotelling's statistic T_b^2 , typically introduced in textbooks of multivariate statistics. When $n_1 = n_2$, $T_w^2 = T_b^2$. Under $\Sigma_1 = \Sigma_2$, exact inference on $H_0: \mu_1 = \mu_2$ is obtained by using

$$\frac{(n_1 + n_2 - p - 1)}{p(n_1 + n_2 - 2)} T_b^2 \sim F_{p, (n_1 + n_2 - p - 1)},$$

where $F_{p, (n_1 + n_2 - p - 1)}$ is the F distribution with degrees of freedom p and $(n_1 + n_2 - p - 1)$. When $n_1 \neq n_2$ and $\Sigma_1 \neq \Sigma_2$, using Example 11 cannot control the Type I error. A better approach to control Type I error is to use the statistic T_w^2 whose distribution can be approximated by an F distribution with degrees of freedom being estimated from the data. The distribution of aT_w^2 can also be approximated by χ_b^2 , where both a and b need to be estimated from the data. Like Welch's t test in the unidimensional case, these approximations work very well when both n_1 and n_2 are not too small. But both approximations are affected by the third central moments when the populations are non-normally distributed and n_1 and n_2 are small. Similarly, T_w^2 is strongly affected by data contamination.

Comparing means with unequal variances-covariances is also called the Behrens-Fisher problem, which has been extensively studied in the statistics literature.

WENNBERG DESIGN

The Wennberg design is one of a number of variations of the randomized controlled trial (RCT), in which participants' preferences whether to receive the new treatment or the comparison treatment are taken into account. The primary purpose is to minimize refusals at the recruitment stage because of the reluctance of some participants to be randomized. It might also, however, increase compliance with the intervention and improve retention rates (reduce attrition) over time as patients are receiving their preferred treatment modality.

Rationale for the Design

Many procedures used in clinical research, such as random allocation, blinding of participants and raters, matching, stratification, and so forth, are done with one goal in mind—to reduce bias. In this context, bias means any systematic, nonrandom effect other than the intervention that can influence the results. The effect of the bias could be to weaken or distort the effect of the intervention or to spuriously overestimate its effect. However, one bias that cannot be dealt with using these techniques is the reluctance of some people to participate in a trial that simply randomizes them to the new treatment or the comparison condition, ignoring their preferences.

In some studies, as many as 80% of patients refuse to be randomized because they want either the new (and presumably better) treatment; do not want the

new treatment because it is unproven; or are concerned that they might be randomized to the comparison condition, which might in some cases be a placebo group. If these people were a random subset of the population of interest, then the effect would be “merely” a greater difficulty in achieving the desired sample size. However, studies done over the past 50 years have shown that those who agree to participate in a study differ systematically from those who refuse; among other things, there is a greater tendency for them to be married, employed in professional or skilled jobs, be from the upper half of the socioeconomic spectrum, be more concerned about their health, be less likely to smoke, to have children living at home, and be either Jewish or Protestant. Consequently, participants in a trial represent a biased subset of people, which jeopardizes the external validity of the study; that is, the ability to generalize the results to the population for whom the intervention is designed. Furthermore, study participants who did not receive their preferred intervention respond less favorably to the treatment to which they were allocated—an effect called *resentful demoralization*—which increases the likelihood that they will be nonadherent to the study protocol and to drop out before the study ends. This jeopardizes the internal validity of the trial (i.e., the freedom from alternative explanations of the obtained results).

Patient Preference Designs

There have been several attempts to deal with preference bias through modification of the classical RCT design in clinical research. At the core, the modifications are principally around allocation of subjects to either the treatment or control conditions. As expected, all of these designs offer some degree of decision authority to participants but at different stages of the consenting process. The Zelen randomization, for example, uses a post-randomization consent model—participants are randomized before consent is sought, and then only those in the group who will receive the experimental treatment are asked to consent. In the control arm, patients receive treatment as usual (TAU). Those selected to receive the experimental treatment can either refuse to participate, and therefore receive TAU, or agree and become part of the experimental group. The refusers are given the standard treatment but are analyzed as if they were in the treatment group. The main purpose of the design, therefore, is to reduce preference bias associated with being allocated to the control condition. However, this design is feasible only if the comparison group receives TAU (as opposed to, say, a placebo), and if consent is not required to gather any additional information from them. For these reasons, it has rarely been used.

A modification of this is the Zelen design with double randomization (also called the Brewin and Bradley Partially Randomized Preference Trial Design). It again begins with randomization before consent, but then patients in both groups are asked whether they agree to continue in the group to which they were assigned. If not, they are switched to the other group. This eliminates the problem of no consent being obtained from those in the control or TAU group, but it introduces a different problem, in that blinding the patients to group assignment is impossible. During the analysis phase, those assigned to the treatment and comparison groups through randomization, and those who switched into those groups, are analyzed separately to determine the degree to which patient preference might have affected the results.

As the title implies, the comprehensive cohort design combines a traditional RCT with a prospective cohort. As in a standard RCT design, participants are first asked whether they would like to participate, and whether they agree to be randomly assigned to either the treatment or the control (e.g., placebo or TAU) condition. However, in a standard RCT, if the participant refuses randomization, he or she is dropped from the study altogether. In the comprehensive cohort design, participants refusing randomization are asked whether they would prefer to be in either the treatment or the control arm of the study. The end result is four groups—treatment and control groups through randomization, and treatment and control groups through preference selection. Participants in the preference arms (those receiving experimental treatment and controls) are followed over time as in a prospective cohort design to assess outcomes. As with the Zelen double randomization design, the analysis allows one to see whether patient preference influences the outcome.

The essential feature of the Wennberg design, that which differentiates it from both the Zelen (without double randomization) and the comprehensive cohort designs, is that all participants are randomized to a either a “preference” group or an RCT group. At the point of entry into the study, participants who have consented to participate in the study are randomized to either the RCT arm or the preference arm of the design. Individuals in the preference arm are then allowed to choose whether they would want to have the experimental treatment or the comparator (which could be TAU or placebo). Participants in the RCT group are then randomized to either the treatment or comparison groups. The flow-through process is depicted in Figure 1. Similar to the comprehensive cohort design, the end result of randomization is the creation of four groups. Analysis across groups allows the researcher to estimate the influence of preferences on outcomes.

Figure 1 Flow of Participants in a Wennberg Design

Advantages and Limitations

The Wennberg design has some notable advantages over other designs that incorporate, or attempt to control for, participant preferences. First, randomization to the treatment and preference arms overcomes a significant limitation in the comprehensive cohort design: the bias resulting from refusing randomization in the first place. In the cohort design, preferences are not evenly distributed between groups within the preference arm because participants are free to choose which group they will join. Second, the Wennberg design overcomes a significant ethical problem created by Zelen’s design in that consent is achieved prior to randomization. Third, Zelen’s design requires the use of intention-to-treat analysis, which is not appropriate if the goal of the study is to determine the efficacy of the intervention (i.e., *can* the intervention work under ideal circumstances) as opposed to efficacy (i.e., *does* the intervention work in real life).

At the same time, the Wennberg design has its own limitations. Most notably, it is not at all clear the design actually overcomes preference bias. Respondents must still consent to be randomized, so those who prefer not to let chance determine allocation are likely to drop out of the study before randomization even occurs. Moreover, participants randomized to the RCT arm still have preferences, which can affect the outcomes across groups. There simply is no way of knowing the extent of this.

A second limitation is that the Wennberg design (along with the Brewin and Bradley and the comprehensive cohort design) states that the effect of

preference can be determined by comparing patients who choose a group against those who are randomized into it. However, there are concerns about comparing people in different groups because of the potential effects of unmeasured confounders; that is, other factors that are correlated with being in one group or the other, such as social class, education, and so forth. It is not guaranteed by any means that group differences solely result from the presence or absence of a preference.

Another concern relates to the conceptualization of “preferences” as a categorical rather than a dimensional construct. Some participants might have a strong preference toward a particular intervention, whereas others hold a more modest predilection, and yet others are altogether indifferent. In the Wennberg design, however, preference is treated in an essentially binary way—absent or present. No specific attempt is made to take level of preference into account during randomization. Closely related to this, participant preference is not known until after consent to randomization. Were such information available beforehand, it would be possible to randomize to control and intervention arms and then to group individuals within arms based on prior knowledge of preference. Such a design was described by David Torgerson and colleagues. By further taking into consideration level of preference, grouping could be made on the basis of relative preference or indifference to the intervention. So, for example, among those in the control arm, differentiation within this condition could be made based on whether the participant was indifferent to receiving treatment versus control, from those who preferred one option over the other.

Finally, a significant problem with all preference designs, and one to which the Wennberg is not immune, concerns the increased demand for sample size based on stratification by preference being incorporated into the design. In trials where the incident rate for a particular outcome (e.g., cardiac mortality after first infarct) is low, sample size requirements are already very large, just to follow two groups (experimental and control) over time. The stratification of treatment and control groups by preference (especially when moving beyond has or does not have a preference) into the design will further increase sample size, possibly to the point of rendering the trial infeasible in relation to both cost and time.

Current and Future Challenges

At the current time, patient-preference designs, in general, and the Wennberg design, in particular, are not used widely. A meta-analysis done in 2005 found only 27 trials that used a comprehensive cohort design and

5 that used a Wennberg design. However, given the increasing focus on patient-centered care and by taking patient preferences into account, it is likely that their use will increase in the future. At the same time, the complexity of incorporating preferences into the design in a meaningful way presents numerous challenges and a design that addresses all limitations has yet to be identified (and likely never will). The solution to the problem in the interim, however, is not to ignore preferences (assume they do not exist, do not influence results in a meaningful way, or are randomly distributed along with other subject characteristics as part of the RCT design). Rather, preferences can be ascertained (e.g., through survey or interview) and incorporated in statistical analysis of outcomes. In much the same way that demographic descriptions of treatment and control groups in RCTs have become perfunctory, the reporting of preference bias, and where appropriate, adjustment for preference in analysis of covariance, will at least allow readers to judge to what extent this bias might be operative. Indeed, this might be the only feasible option in some circumstances.

WHITE NOISE

The term *white noise* is most commonly used in the scientific literature to describe the properties of sound. The term is an analogy to color naming of frequencies in the visual light spectrum. Although white in the color spectrum is used to indicate the simultaneous presence of all visual frequencies of light, white noise refers to the

intensity of sound across a range of frequencies. However, there are important differences in applying this color naming strategy to sound. As anyone who has used a prism knows, each of the frequencies of light is simultaneously represented in white light, and through refraction, these different frequencies of light might be revealed as distinct colors. However, white noise means more than just the simultaneous presentation of all sound frequencies; it also means the presentation of equal intensity of sound across some specified range of sound frequencies (measured in hertz). To the human ear, white noise is generally described as sounding like a swooshing or hissing sound.

Scientific Application

White noise is one of the most common sound patterns referenced in scientific literature. However, white noise is not typically used as the primary stimulus; rather it is most frequently used as a control variable. White noise is used to control the auditory experience by masking extraneous noises and delivering a fairly equivalent intensity of sound stimulation across the frequency spectrum. It is usually impossible to control completely nuisance sounds generated from sources outside the laboratory as well as those sounds generated by the subject themselves. To overcome this problem, researchers have attempted to reduce sound contamination via various physical sound overliners. Once reduced to some manageable level, white noise is presented at intensity slightly higher than the unwanted sounds, preventing them from being perceived.

Although less common, white noise is sometimes used as a primary stimulus rather than just as a control variable for masking noise. For instance, white noise, when presented at low intensity, can facilitate habituation of tinnitus. When used as a primary stimulus in psychophysiological research, bursts of white noise have been shown to be more effective in eliciting a startle response than pure tones.

Confusion Over the Term *White Noise*

The term *white noise* is commonly used by the lay public as a very general term for any type of ambient background auditory stimulation. Many commercially available products are advertised as white noise generators that create sound like waterfalls, rain, and so on. This more broad use of the term creates some confusion when it makes its way into the scientific literature. In some areas of science, white noise is used to refer to general ambient background noise rather than more strictly referring to auditory stimulation at equal intensity across the frequency range.

In some scientific settings, the term *white noise* might be used to describe characteristics of sound other than just those of equal intensity. White noise has been used to refer to the *probability* that a frequency is presented across some range of time rather than the intensity of sound across some range of frequencies. Because this use of the term involves the probability of stimulus presentation, various distributions (e.g., Gaussian) might be used to define that probability.

Another source of confusion is that *white noise* is a term applied to scientific methodologies beyond just sound. In fact, white noise has been applied back to the study of the visual system from which the analogy was originally derived. In this way, white noise analysis is a method for studying any physiological system (auditory, visual, etc.) in which constant power density is the input to the system and the relationship to the output is tested.

Finally, white noise is really more of a theoretical construct rather than an actual sound characteristic. Several factors limit the actual realization of delivering true equal sound intensities across the frequency range, including the following: (a) the dynamic range of the instrument producing the sound that limits the frequencies generated; (b) the resonance of the ear canal might alter the frequency spectrum that makes it to the eardrum; and (c) the characteristics of the receiver will further limit this frequency spectrum. For instance, the human auditory system tends to perceive higher frequencies as more intense than lower frequencies (because of differences between place and rate coding of sound in the cochlea). Thus, although studies using white noise with humans involve delivery of sound at equal intensities across the frequency spectrum, they are not received at equal intensity.

White Is Not the Only Color of Noise

Other variations in characteristics of sound have been ascribed color names, beyond white noise. The most common variation is pink noise, in which the intensity of the sound is equal within each octave, but the intensity increases at a rate of 3 decibels per octave as frequency decreases. Pink noise can be used to overcome the bias of the auditory system for perceiving higher frequency sound by applying a spectral power density that might be received as more balanced across the frequency range. A more aggressive adjustment to the spectral power density is red noise, which involves increases of 6 decibels per octave with decreasing frequency.

WHOLE NETWORKS

Whole networks, also known as *sociocentric networks*, explore connections and relationships between actors within a defined collective or population. This may be an organization, a family, community, or a particular time-constrained activity (e.g., an innovation or diffusion of a new practice). The key difference between a whole network and an egocentric network is that whole networks facilitate exploration of direct and indirect connections across a broader frame of reference. As such, they can capture existing relationships, distant ties, and indirect connections, such as bridging ties and structural holes. Inherent to the study of whole networks is the design, structure, and parameters of the network. Within this entry, characteristic information on whole networks is provided, focusing on key learning points to support the functional and systematic research study related to whole networks.

Whole networks provide a structural design on which to explore the interdependence of relationships between individuals within an entire population. However, to fully identify, isolate, and interpret the connections within a whole network, network boundaries must be clearly articulated. The boundaries of the network effectively define the relationships under exploration and, therefore, are the fundamental determinants of the structure, participation, analysis, and outcome of a network study. If the network boundaries are too narrow or poorly defined, the capacity to explore these connections (ties) can be reduced.

Setting the boundary parameter thus allows for a more thorough exploration of the ties and relationships between (or absent) within a distinct group. Network boundaries are often determined based on attributes of the key individuals (actors), the nature of relationship (tie) between actors, or the participation and membership in specific activities or groups. Related to the boundary specification is sampling criteria, or inclusion

criteria, which identify members to a network. Inclusion and exclusion criteria must be driven by the nature of the network and substantially shape the parameters of the network. Depending on the research question, some examples on which to engage with potential network members are to categorize their demographic (e.g., job, financial status, age, group affiliation, education), geographic (e.g., address, proximity to focal location), or participatory (e.g., attendance at a particular event) information as a way to classify their inclusion in the network study. To ensure accuracy of data, particularly within a whole network, it is important to maintain a clear, theoretical, and empirical logic for the network boundary.

Data collection can be conducted through a number of different instruments including surveys and questionnaires, interviews, case studies, and archival information. While there are obvious benefits to using standardized techniques such as those listed, there are potential risks to the nature and quality of the data in terms of researcher subjectivity or incorrect population sampling. As such, it is necessary to incorporate measures of data triangulation and cross-validation into the research design prior to initiating the project. For example, multiple data points and measures can be integrated to allow for a more engaged data collection or reduced risk of researcher or data bias. This can also enhance the existing challenges of access, time, and resource commitments associated with whole network analysis.

If the network is clearly defined, bound, and sampled, analysis and interpretation of data become more straightforward. However, a fundamental principle of whole network analysis is the influence and role of the structure and environment in which a network is embedded. With whole networks, greater information on the associated context can be a fundamental aid in analysis and interpretation. Depending on the nature of the research question, this may include historical, political, social, temporal, geographic, or environmental contextual information. For respondents, it allows for greater understanding and rationale for their requested participation, and the contribution of the data can be greatly enhanced with information on the circumstances associated with the whole network.

A highly relevant aspect of network analysis, particularly when developing the research design, is the potential ethical and privacy issues of whole network membership. For example, anonymity may be compromised if respondents are asked to identify their connections, and sensitive information on group identity or strength of relationships may also lead to unintended consequences for participants. When designing the

research study, the ethical elements of network analysis should receive equal attention as technical issues.

Whole networks allow for a robust representation of the connections across and between individuals and also facilitates the exploration of indirect relationships, weak ties, boundary-spanning individuals, subgroups or cliques, or nonredundant ties. Inherent to this is the research design of the study, which can serve to support or limit the findings and connectivity of actors. Undertaking network analysis can be difficult and daunting in light of the amount of specialized, technical, and theoretical information available on networks. As discussed in this entry, determining the key research design elements prior to engaging with this in-depth material helps to facilitate an effective study.

WILCOXON RANK SUM TEST

The Wilcoxon rank sum test is a nonparametric test that may be used to assess whether the distributions of observations obtained between two separate groups on a dependent variable are systematically different from one another. Developed by Frank Wilcoxon in 1945, the test replaces the obtained values of a dependent variable with a rank score, and inferentially tests whether the sum of the ranks within each group is likely to be obtained by chance from the same population. As the test does not use group means and standard deviations as estimations of population

parameters, it is not beholden to the assumption of normality. It is therefore considered an excellent nonparametric alternative to the independent *t* test in cases where populations might not be normally distributed and the sample sizes of each group are small. Although the calculation of the Wilcoxon rank sum statistic is different from that employed by the Mann–Whitney *U* test, the two tests are fundamentally similar and linearly related, such that many texts refer to these rank-based statistics in unison as the Wilcoxon–Mann–Whitney (or Mann–Whitney–Wilcoxon) test for independent groups.

Rationale and Calculation

Much as in parametric testing, the Wilcoxon rank sum test makes its inferences by determining the probability that two independently obtained groups are sampled from the same population. If two groups are sampled from a population that does not vary across the levels of the independent variable, then there should be an equal probability that any score obtained on the dependent variable will fall into either experimental group. If group identity is conserved, and the obtained values are ranked in order from smallest to largest, each rank should have an equal likelihood of being in either of the experimental groups.

Take, for example, the distribution of a hypothetical data set of diastolic blood pressure measures from two groups of patients, one receiving a drug and another a placebo. If there were no effect of the drug treatment on blood pressure, the obtained measures might look as follows:

Blood pressure—drug (Group A): 70, 100, 78, 55, 67
 Blood pressure—placebo (Group B): 80, 60, 65, 90, 75

To rank these scores, all observations are placed in ascending order, and group identification is maintained, as shown in Table 1.

Descriptively, the values obtained from each group are randomly distributed among the ten ranks, providing little indication that the drug has an effect. If, on the other hand, the treatment had a favorable effect on blood pressure (causing it to be reduced in a group of hypertensive patients), the data might look like the following:

Blood pressure—drug (Group A): 55, 60, 65, 67, 75
 Blood pressure—placebo (Group B): 70, 78, 80, 90, 100

Again, the groups are combined and the data rank-ordered (see Table 2).

In this case, the distribution of scores from Group A (the drug treatment) appears shifted to the left of the

Table 1 Wilcoxon Rank Sum Test Example #1

Rank:	1	2	3	4	5	6	7	8	9	10
Score (BP):	55	60	65	67	70	75	78	80	90	100
Group:	A	B	B	A	A	B	A	B	B	A

Table 2 Wilcoxon Rank Sum Test Example #2

Rank:	1	2	3	4	5	6	7	8	9	10
Score (BP):	55	60	65	67	70	75	78	80	90	100
Group:	A	A	A	A	B	A	B	B	B	B

distribution of the scores from Group B (the placebo group). The Wilcoxon rank sum test determines the probability at which the assigned rankings for two groups would occur because of random sampling from the same population. It does this by summing all the rank scores in one (or both) experimental groups and by determining whether this sum of the ranks is likely to have been obtained from the same population by chance. As in parametric tests, if this probability is sufficiently low, then the null hypothesis is rejected.

The null hypothesis for the Wilcoxon rank sum test, therefore, is that the distribution of scores for Group A is the same as that of the independently sampled Group B. As with the independent t test, research hypotheses might be expressed as directional (i.e., that one group's scores should be lesser or greater than the other group's scores) or nondirectional (i.e., that the two groups' distributions are shifted with respect to each other), with the same advantage of increasing power for one-tailed hypothesis.

The calculation of the statistic itself is straightforward. The first step consists of ranking all the scores obtained from both groups, as shown above. Once this has been done, the ranks for each group are simply summed together. For example, for the data set in the first example in which the drug appears to *not* have had an effect on diastolic blood pressure (Table 1):

$$W_A = 1 + 4 + 5 + 7 + 10 = 27,$$

$$W_B = 2 + 3 + 6 + 8 + 9 = 28.$$

Note that the sums of the ranked scores for both groups are strikingly similar, suggesting that there is no difference in the distribution of the ranks between the two groups. In this case, the p value of the statistic is near .50, and the researcher may not reject the null hypothesis. For the hypothetical data set that *did* seem to show an effect of drug treatment in the second example (Table 2), the statistic is calculated as follows:

$$W_A = 1 + 2 + 3 + 4 + 6 = 16,$$

$$W_B = 5 + 7 + 8 + 9 + 10 = 39.$$

Note that the summed ranks of both groups are now quite different from one another, which is consistent with a possible shift in distribution of the original scores between the groups. The probability of obtaining each W might then be obtained via reference to tables, or it can be calculated with many statistical programs. The W need only be calculated for one group, as the two summed ranks (for Groups A and B) are directly proportional to one another, with $W_A = (\text{the sum of all ranks} - W_B)$. A description of the determination of p values for the Wilcoxon rank sum test follows in the next section. With regard to the drug-effective example, obtaining a rank sum of 16 or less for the drug group is likely to happen less than 2 percent of the time due to chance, leading to the rejection of the null hypothesis that the two groups were sampled from an identical distribution, and supporting a research hypothesis that the drug had a beneficial effect on blood pressure.

Determining the p Value of the W Statistic for Small Samples

Formally, determination of the p value of the Wilcoxon rank sum statistic involves calculating the probability of obtaining a given rank sum score by chance from the null population out of all possible combinations of summed rank scores that could be obtained from the two groups. As a means of example, the smallest two group sizes that could achieve a significant difference in a hypothesis test (assuming $\alpha = .05$, and even then only if the research hypothesis were one-tailed) is the case in which each group had three measures, and the resulting ranks were absolutely divided between the two experimental groups (see Table 3).

In this case, $W_A = 1 + 2 + 3 = 6$. Assuming that there are no differences between the groups (the null hypothesis), then if the ranks for Group A were determined at random by selecting 3 from 6 possible ranks, there are 20 different possible combinations of ranks that could be obtained. These sets and their summed rank values can be determined discretely, as shown in Table 4.

Thus, there is a probability of only .05 of obtaining a rank sum of 6, which can only be achieved with

Table 3 Wilcoxon Rank Sum Test Example #3

Rank:	1	2	3	4	5	6
Group:	A	A	A	B	B	B

rankings of {1, 2, 3} for Group A if both groups are sampled from the same population. With a typical α value of .05, that would lead to the rejection of the null hypothesis that the two groups were distributed equally, but only if the test were one-tailed in favor of Group A having the lower distribution. If the test were two tailed, the probability of Group A obtaining either the two extreme summed rank scores (6 or 15) is 2/20, or .10. Note that in this example, only the statistic for Group A has been evaluated. As noted, this is because W_A and W_B are directly dependent on each other. The probability of obtaining rank scores in Group B of {4, 5, 6} is equivalent to that of Group A obtaining {1, 2, 3} ($p = .05$). Either statistic (W_A or W_B) can be used to test the significance level between the two groups so long as directionality of the hypothesis (if any) is taken into account.

As the sizes of the groups increase, so does the number of possible combinations of rank scores that can be obtained. Assuming that there are no tied scores, expanding individual group sizes from 3 to 4 increases the possible combination of rank scores to 70 different sets (all possible nonrepeating combinations from 1, 2, 3, 4 to 5, 6, 7, 8). Figure 1 shows the frequency distribution of all possible summed ranks for four scores selected from eight possibilities.

Two things should be noticeable from this distribution. First, increasing the sizes of the groups broadens the range of summed ranks, with the tail regions of the distribution becoming defined more clearly. Significant scores of the statistic are determined by assessing the probability of obtaining a specific rank sum or lower (in the case of the left-hand tail) or higher (in the case of the right-hand tail), taking into account the directionality of the research hypothesis. As with other inferential tests, as groups get larger, the statistic becomes more powerful at discriminating real shifts between two distributions. Second, as group sizes increase (N_A and N_B), the possible rank scores become normally distributed around the mean of the probability distribution of possible summed ranks. As will be seen momentarily, this has implications for the computation of the statistic once both groups (A and B) have more than 10 observations.

Although cumbersome to develop, when N_A and N_B are less than 10 per group, these probability distributions should be used to determine whether an obtained W statistic is small (or large) enough to reject the null hypothesis. Fortunately, many computerized statistical packages readily can compute the Wilcoxon rank sum statistic and report the resulting p value. For those who wish to do the calculation of the statistic by hand, tables are available to determine significant W values at the lower tail and upper tail of the distributions

Table 4 Rank Sum Probability Distribution for Three of Six Ranked Scores

	<i>Sum</i>	<i>Proportion of Total</i>	<i>Cumulative Probability of Obtaining Rank</i>

2,5,6; 3,4,6	13	2/20	.90
3,5,6	14	1/20	.95
4,5,6	15	1/20	1.0

Figure 1 Frequency Distribution of All Possible Summed Rank Scores by Sampling Four Ranks from a Set of Eight

Note: This frequency distribution of the possible summed rank scores ($n = 4$ per group) shows a normal-like distribution with a mean rank score of 18.

for group sizes of 4 to 12, including those determined between uneven groups. Equal groups are not required in order to determine the needed probability distributions,

Table 5 Wilcoxon Rank Sum Test Cognitive Psychology Example

Rank:	1	2	3	4	5	6	7	8	9	10	11	12	13	14	15	16	17	18	19	20	21	22	23	24
Score:	5	6	6.5	7	7.3	7.5	8	8.5	9	9.5	9.7	10	10.2	11	11.5	12	12.2	12.6	13	14	14.5	16	16.3	20
Group:	A	A	A	A	A	A	A	A	A	B	B	A	B	B	B	A	B	B	B	B	B	A	B	B

and thus, the Wilcoxon rank sum test can be used on unequal group sizes.

Determining Significance for Larger Samples

When the group sizes of A and B are both above 10, the distribution of W_A might be approximated as a standard normal curve with the following parameters:

$$\mu_A = N(N_A + N_B + 1) / 2$$

and

$$\sigma_A = \sqrt{N_A N_B (N_A + N_B + 1) / 12},$$

where μ_A refers to the mean of the distribution of summed ranks W_A , σ_A refers to the standard deviation of the distribution of summed ranks W_A , and N_A and N_B refer to the number of observations within each group.

An obtained W_A might then be directly compared with the standard normal z distribution, as follows:

$$z = (W_A - \mu_A) / \sigma_A.$$

p values might then be obtained with reference to the standard normal curve.

Example

A psychologist is interested in determining the effect of practice on speed of completion of a complex cognitive task. Two groups of participants are obtained; the first group is given the opportunity to practice the cognitive task for half an hour (Group A), whereas the second group is given the opportunity to practice an unrelated motor task (Group B). Both groups are then tested on the cognitive task, and each participant's speed in completing the task is measured in seconds. After gathering the data, there is some concern that the distribution is skewed positively. Given the small size of each group, the experimenter decides to run a Wilcoxon rank sum test. The data obtained are the following:

Group A: 5, 6, 6.5, 7, 7.3, 7.5, 8, 8.5, 9, 10, 12, 16
 Group B: 9.5, 9.7, 10.2, 11, 11.5, 12.2, 12.6, 13, 14, 14.5, 16.3, 20

To calculate the Wilcoxon rank sum statistic:

Step 1: Rank the data from smallest to largest, independent of group (see Table 5).

Step 2: Compute the summed rank (W_A) for Group A:

$$W_A = 1 + 2 + 3 + 4 + 5 + 6 + 7 + 8 + 9 + 12 + 16 + 22,$$

$$W_A = 95.$$

Step 3: As the group sizes are greater than 10, the significance of W_A might be determined by using a normal approximation:

$$\mu_A = N_A (N_A + N_B + 1) / 2 = 12(12+12+1) / 2 = 150,$$

$$\sigma_A = \sqrt{N_A N_B (N_A + N_B + 1) / 12} = \sqrt{(12)(12)(12+12+1) / 12} = 17.3.$$

$$z = (W_A - \mu_A) / \sigma_A = (95 - 150) / 17.3 = -3.17$$

An obtained z score of -3.17 is well below the critical value of z for a two-tailed test (-1.96 , with an associated p value of less than .05 for a two-tailed test), leading the researcher to reject the null hypothesis that the data were equally distributed between groups. As might be expected, relevant practice led to faster performance during the cognitive task.

Ties

The Wilcoxon rank sum statistic assumes that all data can be ranked from smallest to largest, but in real experiments, it is often the case that two or more observations result in the same value on the dependent variable. When this happens, the common practice is to average the ranks across the two (or more) observations and assign the averaged rank to each observation (see Table 6).

In this case, the second and third ranked values are both assigned a rank of 2.5.

Table 6 Ranking Tied Scores

Rank:	1	2.5	2.5	4	5	6
Score:	10	12	12	15	19	30

Tied scores do impact the probability distributions used to determine p values for the statistic. In the case of larger group sizes, multiple ties alter the obtained σ_A , and the normal approximation shown above requires that σ_A be adjusted. Fortunately, this is done automatically by many statistical packages.

Strengths and Limitations

The primary strength of the Wilcoxon rank sum test, when compared with the parametric independent sample t test, is that it does not require that the collected observations be normally distributed for small sample sizes. Transformation of observations into rank scores attenuates the impact of outliers on the statistic, as is the case when parametric statistics are applied. In cases where the t test and the rank sum test have been compared on normally distributed data, the Wilcoxon statistic has been shown to have power that is nearly as great as the t test. However, although assumptions regarding normality might be waived during its use, the Wilcoxon test does assume that the shape or dispersion of the data is equivalent between groups. Recall that the test is predominantly designed to determine whether the distribution of the two groups is shifted significantly from one another, and the null hypothesis assumes that both groups are sampled from the same population. If the dispersion or shape of observed values from the dependent variable is different between the tested groups, then the validity of the resultant p values might be in question.

As with most statistical tests, the Wilcoxon rank sum test assumes that all observations are independent from one another, and that each observation is pulled from a continuous population. The latter assumption makes the Wilcoxon test most appropriate for use on interval and ratio data, although some have argued its applicability to ordinal data as well. The fundamental logic of the test has been applied to different experimental designs, including that of hypothesis testing with paired observations (the Wilcoxon signed rank test), multiple-group testing (the Kruskal–Wallace test), and clustered data.

WINPEPI

WINPEPI is a suite of freeware programs for personal computers (PCs) that is designed to meet a range of statistical requirements for epidemiologists and biomedical researchers. This entry describes the features, uses, advantages, and disadvantages of WINPEPI.

Background

WINPEPI is an acronym for programs for epidemiologists. An original DOS-based version was adapted for use with Microsoft Windows in the early 2000s (WINPEPI or Pepi-for-Windows). The latest update (version 11.65) was released in 2016. The main author of WINPEPI, Joe Abramson, died in 2017, and there have been no subsequent updates since his death. Nevertheless, the programs remain compatible with Windows 10 and is available from the following website: <http://www.brixtonhealth.com/pepi4windows.html>. Manuals for each of the individual programs can also be downloaded from the same source. There are also two YouTube videos although both are in Portuguese. They do, however, illustrate how to navigate the programs.

Available Programs

There are seven programs:

- DESCRIBE.EXE calculates descriptive statistics for all forms of data (dichotomous, nominal, ordinal, or continuous) including survival. In addition to rates and proportions, it can perform direct and indirect standardization with the availability of world, European, and African standard populations for use in age standardization. It can also appraise screening or diagnostic tests, alongside the necessary power calculations. In addition, it can perform the meta-analyses of results of screening tests from multiple studies.

- PAIRSetc.EXE can analyze observations from cohort and case-control studies with matched controls as well as before-after studies. As in the other modules, it accepts dichotomous, nominal, ordinal, or continuous variables including stratified data. It can also measure the agreement between observations including the weighted kappa for multiple ratings, inter- and intra-rater reliability, and intraclass correlation coefficients.
- COMPARE2.EXE is for comparisons of two independent groups for categorical (dichotomous, nominal, or ordinal) or numerical data (including survival times). Its primary use is in the analyses and meta-analyses of cross-sectional, cohort, and case-control studies and trials. Data can be stratified allowing adjustment for confounding as well as the meta-analysis of results from multiple studies using fixed-effect and random-effects models. In the case of the latter, WINPEPI can handle computed effect sizes or p values as well as raw dichotomous and continuous data. This allows for the input of adjusted data and so permits greater flexibility than alternative freeware. There is the option of a forest plot, although this does not generate a high-quality graphic. WINPEPI also gives estimates of the possible effect of publication bias including the Fail-Safe N , regression asymmetry test, and Kendall's tau. In addition, the program can perform sensitivity analyses of the effect excluding each study in turn to detect studies that may have an undue influence on the findings. Lastly, this module can also calculate power and sample size and take into account the effect of clustering through the use of intraclass correlation, the value of which must be derived from other studies.
- LOGISTIC.EXE performs multiple logistic regression including propensity score analysis. Unlike most of the other programs, it can upload data files that have been copied into the WINPEPI folder.
- POISSON.EXE performs multiple Poisson regression including a graphic display of the relationship between standardized residuals and their expected normal scores. Other than the logistic program, this is the only program that allows the upload of data files.
- WHATIS.EXE is a calculator that can store constants, interim results, and formulae. It can also compute confidence intervals and p values for a range of statistics as well as time lapses between two dates.
- ETCETERA.EXE has miscellaneous functions including randomization and random sampling (simple, stratified, or balanced) and adjustment of p values derived from multiple tests. It can assess the internal consistency and discriminatory power of a scale through the computation of Cronbach's alpha

and other coefficients, and indices of conformity with a Guttman scale. Both simple and multiple linear regression are available. The program can also use Bayesian methods to assess credibility for a reported association rather than sole reliance on statistical tests of significance. Lastly, it can derive p values from confidence intervals for the absolute or relative difference between two values as well as compare numerical data from three or more samples.

Use

WINPEPI can be downloaded as an executable file (WinPepiSetup.exe) or as a ZIP archive from which to access the installation program. A further option is to download an alternative WinPepiFiles.zip version, which contains all the components of WINPEPI, but no installation program. This is particularly useful if the researcher does not have the necessary administrative rights to use an installation program. The small file size (12.2 mb) means it can also be stored and installed on a USB stick or external drive.

WINPEPI has a traditional graphical user interface. The opening menu provides access to all the programs and their manuals, and to a "Finder." This is an alphabetical index of over 700 entries, including statistical procedures, measures, and study types, that point the user to the appropriate programs and modules. By default, all results (except graphs) are automatically saved in a single file (pepi.txt) in the WINPEPI folder, which can be accessed via the opening menu. In practice, it is often better to copy and paste these into a word processor file. This is because moving away from the displayed output means that it is lost and it can only be found by exiting that particular module, opening the pepi.txt file and scrolling through it to find the relevant results. WINPEPI draws time-series and box-and-whisker diagrams, epidemic or receiver operating characteristic curves, forest plots, and other diagrams. Graphs can be saved as BMP files but no other type of image file.

Advantages

As evident from the discussion thus far, the program is versatile with a wide range of both commonly used procedures and those that are not easy to find elsewhere. Indeed, it has been described as a "Swiss army knife" for epidemiologists and biomedical researchers. The small file size means it can be downloaded onto a USB stick or movable drive, allowing use on a number of different machines without downloading the program onto each. In addition, installation on a PC does not require administrator rights, given it can be

downloaded as either an executable file or zip folder. It is reasonably intuitive and supported by extensive and detailed manuals, so no training is required.

Disadvantages

The program is only available in Windows and, because the developer has died, updates are unlikely. The source code is written in Delphi 5 and it is unclear if the key functions could be refactored into another statistical package such as R while retaining the original program's simplicity of use. Linked to this is the possibility that it may not work with future versions of Windows. This results in a rather basic user interface. Data have to be entered manually without the ability to import data files from other programs. It is possible to cut and paste entries but they must be in plain text. The only exceptions are in the case of the LOGISTIC and POISSON modules and, even then, the file has to meet very particular specifications. Similarly, the output cannot be easily exported and the program does not generate tables that can be readily incorporated into manuscripts. Similarly, graphics such as forest plots often require manual editing and may not be of sufficient quality to include in submissions. Some commonly used procedures in epidemiology such as Cox regression are not available. Lastly, using WINPEPI requires some epidemiological knowledge to take full advantage of the wide range of functions, as currently there is no available support aside from the two YouTube videos in Portuguese. These are restricted to discussion of *t*-tests and the chi-square test.

Although WINPEPI is highly versatile freeware that is a useful compliment to other programs, it is unlikely to meet all the needs of a researcher.

WINSORIZE

Winsorization is one method of handling outliers in a distribution of data and giving the distribution more desirable statistical properties. To Winsorize, one converts the values of data points that are outlyingly high to the value of the highest data point not considered to be an outlier. For example, if a survey item on respondents' number of past-year sexual partners yielded substantial frequencies of answers of 0, 1, 2, 3, 5, 7, and 10 and one answer of 100, then Winsorization would convert the 100 to 10. The outlyingly high values are reduced in magnitude (or *reined in*) to a value that is still large but not as extreme. An analogous procedure can also handle outliers at the low end of the distribution; these values would be increased to the lowest value not considered an outlier. Winsorizing thus preserves information that a case had among the highest (or lowest) values in a distribution but protects against some of the harmful effects of outliers. An alternative to Winsorizing is trimming, in which outliers are removed instead of converted to other values. Winsorizing and trimming are both known as *robust statistics*.

There are at least two reasons for Winsorizing (or trimming): to avoid an outlier's potentially disproportionate influence on statistical analyses (e.g., Pearson correlation) and to try to ensure that estimates of a population parameter (e.g., the mean) from repeated samplings tend to take on similar values (statistical efficiency). Before Winsorizing or trimming, one should conduct the usual diagnostics on apparent outliers to determine whether they stem from faulty data recording or are legitimate values from a phenomenon that can generate extreme values.

Winsorizing has typically been used in univariate contexts (i.e., detecting and processing outliers for one variable at a time). For univariate statistics such as a variable's mean, Winsorizing may be helpful. However, the absence of univariate outliers in either of two

variables does not preclude multivariate outliers (i.e., a case's combination of values on two or more variables appearing aberrant). Recent research emphasizes the need for detection of multivariate outliers via Mahalanobis distances and related metrics. Univariate Winsorizing of each variable in a model is not necessarily effective in combating multivariate outliers, whereas research on *multivariate Winsorizing* appears rare and complex, as exemplified by Pringle, Allen, Payne, Dalal, and Marchant's (2012) attempt to "ensure that spatial outliers did not overly influence the fit of a statistical model" (p. 62).

Researchers face several decisions regarding outliers and their treatment: Are outliers present at sufficient magnitude to warrant modifying the data? If so, which technique should be used? What number or proportion of scores should be Winsorized (or trimmed)? Does it appear that one or both sides of a distribution warrant modification? Some authors have offered suggestions (see Further Readings). The statistical software packages STATA, SAS, and R have commands or macros for Winsorizing; in other programs, one can save an existing variable under a new name (to preserve the original) and then manually Winsorize the new variable.

Debate over Winsorization has become polarized in recent years. Some statisticians vehemently discourage its use due to potential loss of fidelity to the underlying process that generated the data and distortion of parameter estimates. Others just as fervently defend its use, as a safeguard against missing findings that would be obscured by outliers and for its ability to enhance statistical power in some circumstances. Still others advocate Winsorizing only in limited conditions (e.g., to preserve power). For multiple-regression studies, some authors urge alternative techniques to Winsorizing variables. One is quantile regression, which predicts medians or other percentiles (which are not sensitive to outliers) on the dependent variable as a function of independent variables. Another is maximum likelihood estimation with heavy-tailed distributions (e.g., Cauchy distribution), in which extreme values are more common. One of the newest lines of Winsorization research, tailored to more descriptive goals, involves creating composites of multiple indicator variables, some of which contain outlier values.

Regardless of how one specifically handles outliers, the literature contains two broader recommendations for promoting effective communication. First, researchers should conduct sensitivity analyses, reporting findings both with the original outlier-containing data left alone and also implementing the data-modification approach (e.g., Winsorizing, trimming). Second, researchers should transparently convey any data modifications implemented, including number and

percentage of cases Winsorized or trimmed, at what ends of the distribution, and what the outlying values were. Ideally, one would preregister one's study at an online repository such as the Open Science Framework or AsPredicted, including the *a priori* policies one would follow to handle outliers.

WITHIN-SUBJECTS DESIGN

A *within-subjects design* refers to a study design where two or more measures are obtained from a sample of subjects. This type of design is also referred to as a *repeated measures design*. Three common circumstances lead to within-subjects designs. First, each subject is observed repeatedly in different conditions and the same measure is used as the outcome variable across the conditions. A main goal is to compare mean differences of the outcome variable across the conditions. Second, several related outcomes are measured collectively from each subject, such as an instrument with subscales, or related behavioral measures. Profile analysis is often conducted to evaluate the mean profile

of subjects' scores across measures. Third, subjects' behaviors are measured at multiple occasions over time to study phenomena related to learning or developmental processes. Trend analysis is often used to examine linear, quadratic, and other forms of change in such studies. Sometimes the term *repeated measures design* is used for referring specifically to this latter application. More generally, within-subjects designs and repeated measures designs are used interchangeably, and these designs include but are not limited to longitudinal studies.

In contrast to within-subjects designs, when only one measure is obtained for each subject or unit, but the subjects are distinguished by some factors, the design is referred to as a *between-subjects design*. In examining the effects of a studied factor, a between-subjects factor compares different groups of subjects (e.g., treatment vs. comparison groups), whereas a within-subject factor compares different measurements within the same group of subjects (e.g., pretreatment vs. posttreatment measures). When a design consists of both between-subjects and within-subjects factors, the design is referred to as a *mixed design* or *split-plot design*. A split-plot design can encompass the advantages of both between-subjects and within-subjects factors and thus is commonly used in the social and behavioral sciences.

Advantages and Disadvantages

In experimental settings, subjects often differ substantially from one another for reasons unrelated to the studied factor(s). In between-subjects designs, differences among subjects are uncontrolled and are treated as random error. By contrast, in within-subjects designs, individual differences can be separated from the error term, as the same subjects are observed under multiple conditions, and thus, each subject can serve as his or her own control. Consequently, a major advantage of within-subjects designs is their ability to control for individual differences or heterogeneity among subjects. Moreover, one can obtain substantially greater information by collecting multiple scores from each subject. A practical implication of both the removal of individual differences from the error term and the collection of a larger number of observations from the same subjects is that statistical power can be increased to detect treatment effects in within-subjects designs.

Along with these important advantages, within-subjects designs also bring complexities and challenges to data analysis. In some experiments, treatment conditions are administered simultaneously in such a way that their order is not relevant. More commonly, however, treatments are administered one after the other

and thus the order of treatments is a matter for concern because subjects might systematically change depending on the order. *Order effects* or *practice effects* exist if treatments administered earlier to a subject continue to have an effect that carries over to influence the subject's behavior during subsequent treatment conditions. For example, there might exist a general improvement on related tests (e.g., learning effect) or a decrease in performance (e.g., fatigue effect). A strategy commonly implemented to prevent order effects from contaminating the treatment effects is *counterbalancing*, which is a technique of ordering sequences of conditions so that each treatment is administered first, second, third, and so on, an equal number of times across subjects. This type of design is known as a *crossover* or *counterbalanced* design. The logic behind the crossover design is that any main effect of order will be controlled for and, as a result, the crossover within-subjects design possesses stronger internal validity than a design without counterbalancing.

A more serious problem occurs when carryover effects from one condition to another are not the same across treatment conditions. This phenomenon is referred to as a *differential carryover effect*. For example, if a strategy training or a psychotherapy intervention administered in an earlier condition is truly effective, this treatment will impact subjects' outcomes in subsequent control or comparison conditions and the carryover effect in this direction will be greater than in the opposite direction. One possibility to dilute differential carryover effects is to allow a long "wash-out" period, but it can be difficult to determine how long a period is sufficient, and some carryover effects might not wash out for a long time. When differential carryover effects are anticipated, it would be more appropriate to examine the treatment effects as a between-subjects factor.

Within-Subjects Designs With Two Levels

In the simplest within-subjects design, a within-subjects factor has two levels. A common example is an experiment measuring pretreatment and posttreatment scores from each subject. Other examples include studies observing two responses from each subject such as mathematics and reading scores or morning and evening reports, as well as designs where a pair of subjects are considered as the unit of the analysis such as twin, parent-offspring dyad, and other matched-pair designs.

A statistical model for a one-way analysis of variance (ANOVA) can be represented as follows:

$$Y_{ij} = \mu + \alpha_j + \epsilon_{ij},$$

$$i = 1, \dots, n, \quad j = 1, \dots, a, \quad (1)$$

where Y_{ij} is the outcome variable for subject i in condition j , μ is the population grand mean, $\alpha_j = \mu_j - \mu$ is the effect associated with condition j , defined as the deviation of the population group mean μ_j from the population grand mean, and ϵ_{ij} is the error term for subject i in condition j . There are n subjects and the number of conditions is two ($a = 2$), and thus, the total number of observations is $n \times 2$.

Although ϵ_{ij} is generally assumed to be independent in between-subjects designs (exceptions include hierarchical and clustered designs), error terms from the same subjects, ϵ_{i1} and ϵ_{i2} , are likely to be correlated in within-subjects designs. Therefore, ANOVA as applied to between-subjects designs that assume independent errors would not be valid for the analysis of within-subjects designs.

Alternatively, by defining a variable $D_i = Y_{i2} - Y_{i1}$, a new model can be defined as

$$D_i = \mu_d + \epsilon_i, i = 1, \dots, n \quad (2)$$

where $\mu_d = \alpha_2 - \alpha_1$. Then, the null hypothesis can be specified as

$$H_0 : \mu_d = 0 \quad (3)$$

and a test statistic can be defined as

$$t = \frac{\bar{D}}{s_d / \sqrt{n}} \quad (4)$$

where $\bar{D} = \sum_i^n D_i / n$ and $s_d = \sqrt{\frac{\sum_i^n (D_i - \bar{D})^2}{n - 1}}$. This test statistic follows a t distribution with $n - 1$ degrees of freedom. The t test for a two-level within-subjects factor is referred to as the *paired* or *dependent sample t test*.

Table 1 presents hypothetical data, modified from an experimental textbook written by Scott Maxwell and Harold Delaney. Suppose that a perceptual psychologist studying the human visual system is interested in determining the extent to which interfering visual stimuli slow the ability to recognize letters. In a laboratory, subjects were told that they would see either the letter T or I displayed on the screen of a tachistoscope. The target letter was shown at three different conditions—0° off-center, 4° off-center, and 8° off-center—to examine the effect of angle. The outcome measure was reaction time required by a subject to identify the correct target letter, measured in milliseconds. Only the first two conditions, 0° and 4° angles, were used for the paired t test in this section. All three conditions are analyzed in the next section. For the paired t test, a

difference score for each subject is calculated and then averaged across the subjects. The test statistic is defined as the average difference score divided by its standard error:

$$t = \frac{10.750}{3.895} = 2.760.$$

With 19 degrees of freedom and a p value of .012, one would conclude that angle significantly delayed the reaction time at $\alpha = .05$.

Table 1 Hypothetical Reaction-Time Data

Subject	0° angle	4° angle	8° angle
1	645	650	670
2	655	680	700
3	535	540	550
4	735	740	760
5	655	680	700

Within-Subjects Designs With Three or More Levels

The analysis of within-subjects designs becomes considerably more complicated when the number of levels is greater than or equal to three ($a \geq 3$). For example, if there is a follow-up in addition to pretreatment and posttreatment measurements, the paired t test is no longer applicable to examine the three conditions simultaneously. Two distinctive methods are available for the analysis of within-subjects factors with three or more levels—a univariate mixed-model approach and a multivariate approach. The univariate approach has been used traditionally, but there is an increasing interest in the multivariate approach. Both approaches are explained in the following section and then compared.

Univariate Mixed-Model Approach

As its name indicates, the univariate mixed-model approach implements the ANOVA for mixed-effects designs with both fixed and random factors. Specifically, in addition to a fixed factor A , subjects are treated as a random factor so that subject variability can be separated from the error term. Extending the one-factor model in Equation 1, the mixed-model can be represented as follows:

$$Y_{ij} = \mu + \alpha_j + \pi_i + (\alpha\pi)_{ij} + \varepsilon_{ij}, \quad (5)$$

$$i = 1, \dots, n, \quad j = 1, \dots, a,$$

where π_i is the effect associated with subject i and $(\alpha\pi)_{ij}$ is the effect of the interaction of subject i and condition j of the within-subjects factor, in addition to the other terms defined earlier. For testing the effect of the within-subject factor A , the hypothesis can be defined as

$$H_0 : \alpha_1 = \alpha_2 = \dots = \alpha_a = 0 \quad (6)$$

implying no differences on the outcome measures across the different conditions. The test statistic for the hypothesis in Equation 6 is defined as

$$F = \frac{MS_A}{MS_{A \times S}} \quad (7)$$

which follows an F distribution with numerator and denominator degrees of freedom of $(a - 1)$ and $(a - 1) \times (n - 1)$, respectively.

In addition to the usual assumptions of ANOVA for between-subjects designs, within-subjects designs require homogeneity of the treatment-difference variances. Consider a new set of variables $D_{ijk} = Y_{ij} - Y_{ik}$, $i = 1, \dots, n$, $j = 1, \dots, a$, $k = 1, \dots, a$, $j \neq k$ defined by all possible pairwise differences of the original variables. The additional assumption implies that

the variances of these treatment difference variables must all be equal in the population. Huynh and Feldt and Rouanet and Lépine showed independently that the homogeneity of treatment-difference variances assumption is equivalent to assuming that the population covariance matrix has a certain form, namely *sphericity* or *circularity*. However, sphericity and circularity can only be defined using matrix algebra. Therefore, a special case of sphericity, *compound symmetry*, is often considered instead.

Compound symmetry requires that all the variances of outcome variables be equal and all the covariances be equal in the population. Thus, the variance-covariance matrix of $a = 4$ outcome variables has the following form:

$$\sigma^2 \begin{bmatrix} 1 & \rho & \rho & \rho \\ \rho & 1 & \rho & \rho \\ \rho & \rho & 1 & \rho \\ \rho & \rho & \rho & 1 \end{bmatrix}.$$

This restricted condition is unlikely to hold in longitudinal designs, as adjacent scores are likely to be more highly correlated than scores observed at times spaced farther apart. Although it is often confused with sphericity and is misunderstood as an assumption of within-subjects designs, compound symmetry is a sufficient but not necessary condition for sphericity such that if compound symmetry is satisfied, then sphericity is satisfied. The reverse is not always true.

When sphericity is not satisfied, one can make adjustments to the F test using the Box, Huynh-Feldt, or lower bound corrections by reducing the degrees of freedom of the F distribution, thereby increasing the critical value of the F statistics. Specifically, the F statistic in Equation 7 approximately follows an F distribution with numerator degrees of freedom equal to $\varepsilon(a - 1)$ and denominator degrees of freedom equal to $\varepsilon(a - 1)(n - 1)$. The parameter ε reflects the severity of the violation. It has a value of one under sphericity and is no smaller than $1/(a - 1)$. The more severe the violation, the smaller ε and, thus, the smaller adjusted degrees of freedom. Statistical packages usually provide four different test results based on the three corrections along with the unadjusted test:

1. Geisser–Greenhouse's lower bound $\varepsilon = \frac{1}{a - 1}$: Too stringent most of the time.
2. Box's correction using $\hat{\varepsilon}$ (also known as Greenhouse–Geisser's correction).
3. Huynh–Feldt's correction using $\tilde{\varepsilon}$.
4. Sphericity assumed (unadjusted) $\varepsilon = 1$: Too lenient when the assumption is violated.

The four adjustments are ordered from most stringent to lenient ($\frac{1}{a-1} \leq \hat{\epsilon} \leq \tilde{\epsilon} \leq 1$). If the null hypothesis can be rejected by the most conservative criterion (1) or cannot be rejected by the unadjusted (4), the decision is clear. If Equations 1–3 or Equations 2–4 provide consistent conclusions, one might follow their direction and disregard the inconsistency resulting from Equations 4 or 1, respectively, as these two extremes provide only the boundaries for a given a and n and do not reflect the degree of violation in a particular data set. On the other hand, $\hat{\epsilon}$ and $\tilde{\epsilon}$ are functions of the sample covariance matrix and often provide similar values for a given data set. Although it is rarely observed in practice, Equations 2 and 3 can provide conflicting results, and if so, the univariate mixed-model approach does not provide a univocal conclusion. In such a situation, one might focus on tests of contrasts (single degree of freedom hypothesis testing) or use multivariate tests.

Multivariate Approach

An alternative approach to the univariate mixed-model approach is multivariate analysis of variance (MANOVA) in which the repeated measures of each subject are treated as values on different correlated variables. Whereas the mixed-model approach assumes univariate normality, the multivariate approach assumes multivariate normality. Instead of sums of squares in the univariate analysis of variance, MANOVA uses positive-definite matrices to decompose the different sources of variation, namely the hypothesis variance-covariance matrix $\mathbf{H}$ and the error variance-covariance matrix $\mathbf{E}$. The diagonal entries of these matrices are the same kinds of sums of squares that appear in univariate ANOVA. The off-diagonal entries are cross products of corresponding variables.

The multivariate approach is built in to many computer programs for statistical analysis, which provide several multivariate tests for the hypothesis identical to the univariate approach in Equation 6. The four most common MANOVA tests are Wilks's lambda, Pillai's trace, Hotelling's trace, and Roy's largest root. The first three can be viewed as compound or omnibus tests, whereas Roy's largest root is determined by the contrast that shows the largest effects.

MANOVA is based on $\mathbf{HE}^{-1}$, the product of the hypothesis sum of squares and cross-product (SSCP) matrix and the inverse of the error SSCP matrix. Let λ_j be the j th eigenvalue of $\mathbf{HE}^{-1}$, $j = 1, \dots, a$, where a is the number of outcome variables. The four test statistics are defined as follows:

$$\text{Wilks's lambda} = \frac{|\mathbf{E}|}{|\mathbf{H} + \mathbf{E}|} = \prod_{j=1}^a \frac{1}{1 + \lambda_j},$$

$$\text{Pillai's trace} = \text{trace}[\mathbf{H}(\mathbf{H} + \mathbf{E})^{-1}] = \sum_{j=1}^a \frac{\lambda_j}{1 + \lambda_j},$$

$$\text{Hotelling's trace} = \text{trace}(\mathbf{HE}^{-1}) = \sum_{j=1}^a \lambda_j,$$

$$\text{Roy's largest root} = \max(\lambda_j).$$

In Wilks's lambda, $|\cdot|$ denotes the determinant of a square matrix and $\prod$ denotes the product of a series. Note that all four test statistics are functions of the eigenvalues of $\mathbf{HE}^{-1}$. Some computer programs print out eigenvalues and eigenvectors along with the test statistics. Computer programs also convert the values of these tests to F statistics so that the well-known F distribution can be used for examining the null hypothesis. In some cases, this conversion is exact; in others, it is approximate. Although the converted F values are often equal or similar across different multivariate tests, it is also possible that the F values for the four tests and corresponding p values are different. With multiple factors, it is also possible that the four tests provide the same F value for main effects but not for interaction effects, as the tests vary in the emphasis they place on different aspects of the group difference.

The power of these tests depends on many factors, and none of them outperforms the others under all circumstances. Wilks's lambda is the most commonly reported and was found to perform similarly to Hotelling's trace under most conditions. Although (1- Λ) is often interpreted as the proportion of variance accounted for by the model effect, it should be noted that this quantity can be misleading especially with small sample sizes. Pillai's trace has been shown to be the most robust to violations of model assumptions and therefore might be more appropriate than others for small data and/or unequal sample sizes across conditions. When there is a main contrast that interprets the differences among the treatments, Roy's largest root might be appropriate.

Unlike the univariate mixed-model approach, the multivariate approach does not require the sphericity assumption. Instead, it allows any pattern of variances and correlations among the outcome variables. This flexibility of variance structure is a strength of the multivariate approach when the assumptions of the univariate approach are not met. However, the increased robustness has a cost when sphericity holds, and F statistics for the multivariate tests are generally smaller than their univariate counterpart and have fewer degrees of freedom. Recall that the numerator and

denominator degrees of freedom of the F distribution for the univariate test was $(a-1)$ and $(a-1) \times (n-1)$, respectively. The corresponding degrees of freedom for the multivariate tests are $(a-1)$ and $(n-a + 1)$. This is because the multivariate approach estimates all variances and correlations and, thus, requires more parameters to be estimated than the univariate approach.

Univariate Approach Versus Multivariate Approach

A researcher should choose one of the two approaches, rather than switch between them on an ad hoc basis, even though statistical packages often

provide the results of univariate and multivariate analysis side by side. Power considerations do not uniformly favor either approach. They have some shared and unique assumptions. Important differences with respect to assumptions are that the univariate approach requires sphericity and that the multivariate approach assumes multivariate normality. When one of them is questionable, a method that does not require the particular assumption might be preferred.

Considering the increase in the number of parameters, the multivariate approach might not be effective when sample sizes are small, especially if the number of repeated measures is large. When repeated measures consist of several different variables, the univariate

88 Angle – 48 angle		6.75	4.535	1.489	19	0.153

approach should not be used, whereas the multivariate tests are still applicable. When all within-subjects factors have two levels, the two approaches are equivalent and both univariate and multivariate analysis provide the same conclusion. Also, the univariate and multivariate approaches are identical in testing single degree-of-freedom hypotheses based on contrasts among the treatment means.

The example in Table 1 is now revisited, and this time all three conditions are analyzed simultaneously. The results of the univariate mixed-effects model analysis and the multivariate tests are summarized in Table 2. The F statistic for the univariate test was 6.264. If sphericity were satisfied for the data, the hypothesis df and error df would have been 2 and 38, respectively. However, the estimated ϵ was considerably smaller than one, and thus, an adjustment should be made in evaluating the significance of the F value. Box's and Huynh-Feldt's corrections indicated that the hypothesis df and error df should be reduced to 75% and 80%, respectively. It was found that the p values for the univariate approach were .010 based on Box's adjustment and .008 based on Huynh-Feldt's adjustment. The univariate analysis also includes results from the unadjusted test and the low-bound adjustment. In this example, p values based on the four univariate tests range from .004 to .022. Thus, based on the univariate approach, one would conclude that the distraction (angle) significantly delays reaction time at $\alpha = .05$.

The four multivariate test statistics—Wilks's lambda, Pillai's trace, Hotelling's trace, and Roy's largest root—were converted to F statistics, and they provided the same F value of 4.346. With the hypothesis df of 2 and error df of 18, the corresponding p value is .029. Therefore, based on the multivariate approach, one would also conclude that interfering visual stimuli in this experiment significantly delayed the reaction time at $\alpha = .05$.

In addition, three tests of contrasts were conducted for all pairs of conditions. The results are summarized at the bottom of Table 2. It was found that latency was significant for both the 4° and 8° angles compared to the 0° angle condition, but the difference between the 4° and 8° angles was not significant.

Further Topics

When a design consists of a between-subjects factor A and a within-subjects factor B , the design can be denoted as $A \times (B \times S)$. Computer programs often provide separate ANOVA tables for between-subjects effects and within-subjects effects. If the estimated ϵ is

smaller than one, univariate F tests should be adjusted for B and $A \times B$ but not for the effects of between-subjects factor A .

In a design with multiple within-subjects factors, different error terms are used for different within-subjects effects. Consider a factorial design with two within-subjects factors A and B . The main effects of A are tested against $A \times S$ (i.e., $F = \frac{MS_A}{MS_{A \times S}}$), the main

effects of B are tested against $B \times S$, and the interaction effects of $A \times B$ are tested against $A \times B \times S$. All three effects are subject to adjustment if sphericity is violated. Three different ϵ values are estimated for the three effects, and thus, adjustments in the degrees of freedom would be different for the main and interaction effects.

There are many important issues one should consider when designing and analyzing within-subjects designs, including power and effect size, missing data, and quasi- F statistics. Although most of these are relevant to designs of experiments in general rather than specific to within-subjects designs, dependency among repeated measures adds complexity to these issues. For example, in addition to means and variances, correlations also should be considered in estimating effect sizes and calculating sample sizes. Missingness occurs often not randomly but systematically in longitudinal studies and, thus, not only attrition itself but also the pattern of attrition can be an issue in repeated measures over time. As the number of between-subjects and within-subjects factors increases, the design becomes complicated and there is sometimes no exact error term for the effect of interest and the researcher needs to construct quasi- F statistics.

YATES'S CORRECTION

Frank Yates's correction is an adjustment that might be applied to a chi-square analysis when evaluating the association between two dichotomous variables. Such data are often presented in the form of frequencies in a 2×2 contingency table. In this context, chi-square is a test of independence, as it is intended to evaluate whether the two variables are associated (vs. independent) in the population from which the sample of participants was drawn. However, the traditional Pearson's chi-square statistic might not be applicable to all cases of 2×2 contingency tables. Yates's correction was designed to adjust the Pearson chi-square test of independence to make it applicable to 2×2 contingency tables with very small expected frequencies; however, its applicability has been hotly debated.

2×2 Contingency Tables, Expected Frequencies, and Chi-Square

Yates's correction is applicable to 2×2 contingency tables, which reflect the association between two dichotomous variables. Common in many areas of research, a dichotomous variable has only two possible values—for example, the variable “biological sex” is generally treated as having only two values (i.e., male vs. female), and a particular study might treat “personality pathology status” as having only two values (i.e., pathology present vs. pathology absent). Yates's correction can be used to evaluate, for example, the degree to which the presence or absence of personality pathology is contingent on one's biological sex.

Table 1 presents the frequencies of co-occurrences between values of two dichotomous variables—biological sex and personality pathology status. For example,

Table 1 Frequencies of Co-Occurrences Between Values of Two Dichotomous Variables

<i>Biological Sex</i>	<i>Personality Pathology Status</i>		<i>Total</i>
	<i>Pathology Absent</i>	<i>Pathology Present</i>	
Female	15	1	16
Male	16	8	24
Total	31	9	40

this table shows that, from a total of 40 hypothetical participants, 15 are females without personality pathology and 1 is a female with personality pathology.

The frequencies in this contingency table indicate some degree of association between biological sex and personality pathology. Specifically, personality pathology is present in fully 33% of the males in the sample ($8/24 = .333$ false) but in only 6% of the females ($1/16 = .063$ false). These results suggest that personality pathology is contingent, to some degree, on biological sex in this sample—pathology is more likely to be observed in a male in the sample than in a female. Although these data provide clear information about the sample of participants being studied, they provide less direct information about a broader population.

To address the link between the sample's data and the broader population, a Pearson chi-square value is often used to evaluate the statistical significance of the association expressed in a contingency table. That is, the Pearson chi-square is an inferential statistic used to gauge whether the two variables are associated with each other in the population from which the sample was randomly drawn. A chi-square value is calculated from the deviations between (a) the frequencies actually observed in the sample and (b) a set of frequencies

expected under the null hypothesis that the two variables are not associated with each other in the population (i.e., that the variables are independent). An *expected frequency* is determined for each cell in a contingency table, computed as

$$E = \frac{(\text{Row Total})(\text{Column Total})}{(\text{Total Sample Size})}.$$

For example, the cell representing the number of females without personality pathology has an expected frequency of $E = (16)(31)/(40) = 12.4$, and the cell representing the number of females with personality pathology has an expected frequency of $E = (16)(9)/(40) = 3.6$. These values indicate that, based on (a) the knowledge that there are 16 females in the sample of 40 participants, (b) the knowledge that 31 of the participants do not have personality pathology and 9 do, and (c) the null hypothesis that biological sex and personality pathology are not associated with each other, one would expect to find approximately 12 females without personality pathology and 4 females with pathology. These expected frequencies deviate from the frequencies actually observed in the sample (i.e., there were actually 15 females without personality pathology and only 1 female with pathology), which begins to indicate that the null hypothesis is incorrect. That is, to the degree that the cells' expected frequencies (which, recall, are based on the null hypothesis that the two variables *are not* associated with each other) deviate from the observed frequencies, researchers gain confidence that the null hypothesis is wrong and that the variables actually *are* associated with each other in the population from which the sample was drawn. Chi-square is calculated from these deviations and summed across all cells in the contingency table. A relatively large chi-square value reflects relatively strong confidence that the two variables are in fact associated with each other in the population.

For the example data, the chi-square value is $\chi^2 = 4.038$ (with 1 degree of freedom), which is significant at $p = .044$. Based on these results, researchers might infer that biological sex and personality pathology are associated with each other (i.e., one variable is at least partially contingent on the other) in the population from which the 40 participants were sampled.

Purpose of Yates's Correction

Yates's correction is intended to adjust chi-square when evaluating the statistical significance of a 2×2 contingency table. In 1934, Yates developed the correction for contingency tables having one or more expected frequencies that are very small. In such cases, certain distributional properties of the Pearson chi-square might not be validly applied, and Yates's correction is intended to account for this problem.

The potential need for Yates's correction emerges from a technical issue concerning the distributions underlying inferences based on the chi-square statistic. The chi-square distribution is continuous, but when applied to contingency tables, it is used to approximate a noncontinuous (i.e., discrete) distribution. This problem is particularly pronounced for contingency tables with small expected frequencies. The effect of this problem is that the traditional calculation of chi-square might produce values that are too large and probabilities that are too small, leading researchers to reject null hypotheses incorrectly. For example, the chi-square presented earlier ($\chi^2 = 4.038$) was judged to be statistically significant, implying that the null hypothesis (i.e., that the two variables are independent) is incorrect. However, because of the small expected frequency of the number of females with personality pathology, this judgment might be incorrect. That is, biological sex might actually not be associated with personality pathology in the population from which the sample was drawn.

To account for these problems, Yates developed the *correction for continuity*. This correction is intended to adjust the traditional chi-square value by decreasing its magnitude, thereby increasing the resulting probability value and avoiding incorrect rejections of the null hypothesis.

Calculating Yates's Correction

Yates's correction is calculated easily from the values in a 2×2 contingency table. As an adjustment to the Pearson chi-square, it emerges from deviations between cells' observed frequencies and their expected frequencies. Specifically, it is calculated as

$$\chi_{\text{Yates}}^2 = \sum \frac{(|O - E| - .5)^2}{E},$$

where O is the observed frequency of a given cell and E is the expected frequency of that cell. Applied to the example data, Yates's corrected chi-square is

$$\begin{aligned} \chi_{\text{Yates}}^2 &= \frac{(|15 - 12.4| - .5)^2}{12.4} \\ &+ \frac{(|1 - 3.6| - .5)^2}{3.6} \\ &+ \frac{(|16 - 18.6| - .5)^2}{18.6} \\ &+ \frac{(|8 - 5.4| - .5)^2}{5.4}, \\ \chi_{\text{Yates}}^2 &= 2.634. \end{aligned}$$

Table 2 Cell Labels Used for Alternative Computation of Yates's Corrected Chi-Square Value

Variable 1	Variable 2	
	Level 1	Level 2
Level 1	a	b
Level 2	c	d

Examining the distribution of chi-square values with 1 degree of freedom, it can be found that this value is associated with a probability of $p = .105$. In contrast to the original Pearson chi-square value, the nonsignificant result of Yates's correction leads to the conclusion that biological sex might very well *not* be associated with personality pathology in the population from which the sample was drawn.

Readers might encounter an alternative method of calculating Yates's correction. This method emerges directly from the observed frequencies in the contingency table, with the cells identified as shown in Table 2.

Using these labels (and with N indicating the total number of observations in the table, $N = a + b + c + d$ false), Yates's corrected chi-square can be computed as

$$\chi^2_{\text{Yates}} = \frac{N(|ad - bc| - N/2)^2}{(a+b)(c+d)(a+c)(b+d)}.$$

Again, as applied to the example data, corrected chi square is

$$\chi^2_{\text{Yates}} = \frac{40(|15 \times 8 - 1 \times 16| - 40/2)^2}{(15+1)(16+8)(15+16)(1+8)},$$

$$\chi^2_{\text{Yates}} = 2.634.$$

Although it is calculated easily from the values in a contingency table, Yates's corrected chi-square is also provided by several common statistical software packages. For example, SPSS (IBM® SPSS® 18.0, formerly called PASW® Statistics) presents it as the "Continuity Correction" value from the Crosstabs procedure, and SAS (SAS Institute, Cary, NC) presents it as the "Continuity Adj. Chi-Square" from the Frequency procedure.

Controversy Regarding the Use of Yates's Correction

Since its development in 1934, Yates's correction has generated considerable debate. Some researchers and

statisticians argue that it can be appropriate and useful, whereas others argue otherwise.

Those who argue for its use cite Yates's original suggestion that the correction decreases the chance of making Type I errors (i.e., incorrectly rejecting the null hypothesis) when examining contingency tables with small expected values. However, even among those who support the use of Yates's correction, there is disagreement about the situations in which the correction should be used. Although some statisticians call for its use when one or more expected values is 5 or less, others call for its use when expected frequencies are 10 or less, and still others call for its use at all times, noting that it is highly similar to the uncorrected Pearson chi-square when expected frequencies are large.

Those who argue against Yates's correction cite evidence that the correction is too conservative, potentially inappropriate for many actual research situations, and ultimately not necessary. Some evidence indicates that Yates's correction produces p values that are too large, leading researchers to commit too many Type II errors (i.e., incorrectly failing to reject the null hypothesis). That is, Yates's correction might lead researchers to conclude mistakenly that there is no association between two variables, when in fact the two variables are associated with each other in the population from which participants were drawn. Others argue against the widespread use of Yates's correction by suggesting that it is appropriate only when the marginals (i.e., the total frequencies in the rows and columns) are fixed, which, they argue, is rare in most research situations. Finally, there is evidence that, despite Yates's original concerns about the applicability of the Pearson chi-square in cases where expected frequencies are small, the Pearson chi-square is robust in such cases. Thus, this evidence suggests that there might be no need for Yates's correction at all.

In sum, there are mixed recommendations regarding the use of Yates's correction. Some argue that it should be used for 2×2 contingency tables with small expected values, others suggest that it should be used in all cases, others suggest that it should be used in no cases (preferring to use the simple Pearson chi-square or Fisher's exact test), and still others suggest that it could be presented along with other statistics such as the Pearson chi-square value or Fisher's exact test.

YATES'S NOTATION

Yates's notation, named for Frank Yates, is, like the ruler, so useful and so seemingly natural that it is difficult to imagine what researchers did before its invention. Yates's notation indicates the factor levels of treatments in two-level experiments, predominantly but not exclusively, factorial and fractional factorial experiments.

Let each factor in a two-level experiment be denoted by a capital letter. The levels of each factor might be thought of as high and low. For a specific treatment in the experiment, in Yates's notation, one writes the lowercase letter of each factor that is set at the high level and no letter for each factor set at the low level. The treatment with all factors at their low levels is denoted by (1). See Table 1 for an example of where the low levels are denoted by “–” and the high levels by “+.” Contrasts for main effects are easily determined, up to a multiplicative constant, simply by summing the mean of all treatments with a given letter present and by subtracting the sum of the means of all treatments with the given letter absent. In the example, the main effect for Factor A is one half the sum of the ac and ab treatment means minus the sum of the (1) and bc treatment means.

Table 1 Yates's Notation for a Fractional Factorial Design

Yates Notation for Treatment	Factor A	Factor B	Factor C
(1)	–	–	–
ac	+	–	+
bc	–	+	+
ab	+	+	–

If one thinks of the low levels of each factor as having value 0 and the high levels as having value 1, then the Yates's notation for a particular treatment is simply the product of the factors (written in lowercase) raised to the power corresponding to the low or high level. Thus, a treatment with Factor A at the low level but Factors B and C at the high level is written as $a^0b^1c^1 = bc$. This multiplicative representation is the reason that the treatment with all factors at the low level is written as (1) instead of 0.

Yates's notation leads to Yates's standard ordering. For a factorial design, treatments are ordered so that the leftmost letter cycles most rapidly and the rightmost letter cycles most slowly. Equivalently, the treatments are ordered first by the level of the rightmost factor, then the level of the second rightmost factor, and so on. For fractional factorial experiments, only enough factors are used in the ordering to generate a complete factorial (Factors A and B in the example). Although the actual treatment order would be randomized, Yates's ordering gives a convenient layout for a summary table and allows for a quick visual check of the proper factor combinations.

The earliest use of Yates's notation seems to be in Yates's 1935 article.

YOKED CONTROL PROCEDURE

The yoked control procedure is a research design used in operant conditioning experiments in which matched research subjects are yoked (joined together) by receiving the same reinforcement but with different

contingencies. Operant conditioning is said to have occurred when the frequency of a class of behavior is changed by its consequences. Reinforcement occurs when the rate of the behavior increases; punishment occurs when the rate of the behavior decreases. These behavioral changes represent the operation of the law of effect, first formulated by Edward L. Thorndike.

Consider the most celebrated case of operant conditioning. Burrhus F. Skinner placed a hungry rat into a small box containing a lever and a food cup. During Phase 1, the rat's rate of lever pressing was quite low; this unconditioned rate of responding is called the "operant level." During Phase 2, Skinner arranged a contingency in which each lever press delivered a small pellet of food into the cup; now, the rat's rate of lever pressing regularly rose—so-called acquisition via reinforcement. During Phase 3, Skinner removed that contingency by discontinuing feedings after presses; now, the rat's rate of lever pressing progressively fell toward operant level—so-called extinction via nonreinforcement.

The lever press–food contingency might or might not be responsible for the increase in responding in Phase 2. Another plausible possibility lurks. Perhaps intermittent feeding made the hungry rat more active; this upsurge in activity might have increased the rat's lever pressing and many other behaviors that Skinner did not choose to measure.

One way to disentangle this interpretive confounding is to deploy the *yoked control procedure*. Imagine two conditioning boxes instead of only one, with a different rat in each. The research project would unfold for the experimental rat just as described. But, the yoked control rat would be treated differently in Phase 2; there, the yoked control rat would experience the same number and temporal pattern of feedings as the experimental rat, but there would be no contingency between its lever presses and pellet deliveries. Only the experimental rat could produce food by lever pressing in Phase 2; the yoked control rat could not. Hence, it would be expected that the experimental animal would respond more than the yoked control animal in Phase 2 if the lever press–food contingency were contributing to the experimental animal's observed rate of responding.

Pay special attention to the possibility that—even though there is no programmed contingency between lever pressing and food delivery in Phase 2—the yoked control rat might sometimes experience a *chance* conjunction between pressing the lever and food presentation. Such chance conjunctions might be sufficient to increase the incidence of lever pressing, what Skinner termed "superstitious" conditioning. Such superstitious conditioning would tend to minimize the disparity between the behavior of the experimental rat and the yoked control rat.

Also pay attention to the possibility that individual animals might differ in their reactivity to the presentation of food—whether delivered contingently or non-contingently upon behavior. Such possible disparities have been thought by some theorists to compromise the utility of the yoked control procedure. Although there are reasons for concern, the expected effects of such disparities might be small compared with the many merits of the procedure. Furthermore, yoking need not only be accomplished *between* subjects; yoking can also be accomplished *within* subjects.

For instance, imagine one additional phase of training for the experimental rat discussed above. During Phase 4, a computer would play back the same number and temporal pattern of feedings as the experimental rat had received in Phase 2. If heightened activity alone were engendered by these feedings, then the rat's lever pressing in Phase 4 should be the same as it was in Phase 2; however, if the lever press–food contingency were vital to performance, then the rat's responding in Phase 4 should be much lower than it had been in Phase 2. In either case, the critical comparisons would be made for the same animal; individual differences in reactivity to food would not be expected to affect the obtained results.

Now, consider what has proven to be the most salient use of the yoked control procedure beyond assessing the role of response–reinforcer contingency in operant conditioning. Here, researchers seek to isolate the involvement of response–reinforcer contingency in a possible laboratory model of clinical depression—*learned helplessness*. Such studies deploy the so-called *triadic design* entailing three animals: (1) an animal that can terminate electric shock by means of a response like lever pressing (the escapable-shock subject), (2) an animal that cannot terminate the shock (the yoked-inescapable-shock subject), and (3) an animal that receives no shock whatsoever (the no-shock subject), which is either placed into the experimental apparatus or is allowed to remain in its home cage. Following these three treatments, all rats are taught a different shock-escape response like rotating a small wheel.

The learning of wheel rotation is often fast and similar for the escapable-shock rats and for the no-shock rats, but learning is often dramatically slower for the yoked-inescapable-shock rats. It is believed that the yoked-inescapable-shock animals exhibit learned helplessness, presumably because, in initial training, they learn that nothing they do matters; they receive the full duration of electric shocks despite all of their best efforts to terminate them. Studies employing the triadic design further suggest that the behavioral deficits after inescapable shock exposure are not caused by shock-induced stress; rather, the uncontrollability of the shock seems to be the critical factor.

Thus, the yoked control procedure is a powerful means of assessing both the direct and the indirect effects of response–reinforcer contingency on operant behavior. The yoked control procedure is also very widely used. A cursory search yielded the following list of organisms that have been studied using the yoked control procedure: college students, human infants, monkeys, dogs, rabbits, rats, mice, guinea pigs, pigeons, fish, snails, sea hares, and cockroaches. That long list will surely grow; it stands as striking testimony to the value of this important experimental design.

Z

Z DISTRIBUTION

The z distribution is rigorously called the *standard normal distribution* in probability and statistics textbooks and in the literature. A random variable with a standard normal distribution is called a *standard normal random variable*. Because Z is usually used to represent a standard normal random variable, the standard normal distribution is sometimes called the z distribution for convenience by practitioners. In the following, the convention of representing a random variable with a capital letter and a specific value of the random variable with the corresponding lowercase letter is used.

The standard normal distribution is one of the most important probability distributions in probability theory and statistics. Many random phenomena follow a normal distribution or approximately a normal distribution and can be represented by a normal random variable. A normal random variable can be transformed into a standard normal random variable through standardization. Many other random variables, such as the χ^2 random variables, the t random variables, and the F random variables, can be written as functions of the standard normal random variable.

Notation

The standard normal distribution is a special case of the normal distribution family. A general normal random variable, denoted by X , with mean or expected value μ_X and variance σ_X^2 is denoted by $X \sim N(\mu_X, \sigma_X^2)$. The mean μ_X and the variance σ_X^2 are the parameters of the normal distribution. The positive square root σ_X of the variance σ_X^2 is the standard deviation of the random variable (i.e., $\sigma_X = \sqrt{\sigma_X^2}$). The mean is a

measure of location or measure of central tendency of the random variable (i.e., where the values of the random variable are concentrated), and the variance is a measure of variation of the random variable (i.e., how spread the values of the random variable are). Each pair of the parameters μ_X and σ_X^2 determines a specific member of the normal distribution family. The mean of a general normal random variable μ_X might be any real number but that of the standard normal random variable, denoted by μ_Z , is 0 (i.e., $\mu_Z = 0$). The variance of a general normal random variable σ_X^2 might be any finite positive number but that of the standard normal random variable, denoted by σ_Z^2 , is 1 (i.e., $\sigma_Z^2 = 1$). Hence, the random variable Z with a standard normal distribution is usually denoted by $Z \sim N(0,1)$.

Density Function and the Standard Normal Curve

The density function of a general normal distribution or of a general normal random variable X with mean μ_X and variance σ_X^2 is given by

$$f(x) = \frac{1}{\sqrt{2\pi\sigma_X^2}} e^{-\frac{(x-\mu_X)^2}{2\sigma_X^2}}, \text{ for } -\infty < x < \infty,$$

where $\pi = 3.1415926535\dots$

and $e = 2.7182818284\dots$

With $\mu_Z = 0$ and $\sigma_Z^2 = 1$, the standard normal distribution or a standard normal random variable Z has a density function

$$f(z) = \frac{1}{\sqrt{2\pi}} e^{-\frac{z^2}{2}}, \text{ for } -\infty < z < \infty.$$

A plot of the standard normal density function with the horizontal axis representing the values of z and the vertical axis representing the values of $f(z)$ is usually called the *standard normal curve*. Such a plot is shown in Figure 1. The standard normal curve has its peak at $z = \mu_z = 0$. Although z might take on any real value, the standard normal curve asymptotically touches the horizontal axis at -3 and $+3$. Due to its appearance, the normal curve is also usually called the *bell curve* or the *bell-shaped curve*.

Probability

The probability that Z is in an interval between z_1 and z_2 with $z_1 \leq z_2$, denoted by $P(z_1 < Z \leq z_2)$, is given by

$$P(z_1 < Z \leq z_2) = \int_{z_1}^{z_2} f(z) dz = \int_{z_1}^{z_2} \frac{1}{\sqrt{2\pi}} e^{-\frac{z^2}{2}} dz.$$

Graphically, this probability is represented by the area between z_1 and z_2 under the standard normal curve, as shown in Figure 2. Because the area under the curve represents probability, the total area under the curve is 1 [i.e., $P(-\infty < Z < \infty) = 1$]. The probability for Z to be from $-\infty$ to any value z [i.e., $P(-\infty < Z \leq z) = P(Z \leq z)$] is called the cumulative probability of Z . Because $f(z)$ is not algebraically integrable, any area under the standard normal curve can be obtained numerically. For the convenience of the users,

Figure 1 The Standard Normal Curve

Figure 2 Probability Represented by the Area Under the Standard Normal Curve

the area under the standard normal curve is widely tabulated, is built into functions in spreadsheet software, and is built into functions of statistics software.

The Standard Normal Probability Table

The table showing the probabilities of the standard normal random Z in different intervals (i.e., the values of the areas under the standard normal curve) is usually called the *standard normal distribution table* or the *standard normal probability table*. Standard normal probability tables can be found in any textbooks in any disciplines wherever probability is used or is covered as a topic. Different books might present the probabilities in different ways. Some of them give probabilities for Z to be in the interval between 0 and any positive value z , some others give the cumulative probabilities for Z to be from $-\infty$ to a certain positive value z , whereas still others give probabilities for Z to be in the tail area on the right from a certain positive value z to $+\infty$. All these tables are equivalent regardless of which area under the standard normal curve is given. A standard normal probability table is given in Table 1 showing the area under the standard normal curve from 0 to a positive value z (see Figure 3).

Usually the probabilities are shown for values of Z between 0 and 3 in an increment of 0.01. The value of z is divided into two parts. The first part, including the whole number digit and the first decimal digit, is shown on the left margin. The second part, including the second decimal digit, is shown on the top margin. To find the probability for Z to be in the interval between 0 and a given positive value z [i.e., $P(0 < Z \leq z)$], using Table 1, look up the whole digit and the first decimal digit of z in the left margin to determine the row and look up the second decimal digit on the top margin to determine the column. The probability is then found at the intersection of the row and column. To find $P(0 < Z \leq 0.85)$, for example, look for 0.8 in the left margin and 0.05 in the top margin. Across from

0.8 and down from 0.05, 0.30234 is found [i.e., $P(0 < Z \leq 0.85) = 0.30234$]. Because the standard normal distribution is symmetric, $P(-z_2 < Z \leq -z_1) = P(z_1 < Z \leq z_2)$ holds for $z_1 \leq z_2$. Hence, $P(-0.85 < Z \leq 0) = P(0 < Z \leq 0.85) = 0.30234$ for the above example.

With this relationship and using additions and subtractions, you can find the probability for Z to be in any interval. For example, to find $P(-z_2 \leq Z - z_1)$ with $z_2 > z_1 > 0$, you can look up $P(0 < Z \leq z_2)$ and $P(0 < Z \leq z_1)$ and then find $P(-z_2 < Z \leq -z_1) = P(z_1 < Z \leq z_2) = P(0 < Z \leq z_2) - P(0 < Z \leq z_1)$. To find $(-1.52 \leq Z \leq -0.35)$ using Table 1, for example, look for $P(0 < Z \leq 1.52) = 0.43574$ and $P(0 < Z \leq 0.35) = 0.13683$ and then find $(-1.52 < Z \leq -0.35) = P(0.35 < Z \leq 1.52) = P(0 < Z \leq 1.52) - P(0 < Z \leq 0.35) = 0.43574 - 0.13683 = 0.29891$. To find $P(Z \leq -0.55)$, as another example, look for $P(0 < Z \leq 0.55) = 0.20885$ and then find $P(Z \leq -0.55) = P(Z \geq 0.55) = 0.5 - P(0 < Z \leq 0.55) = 0.5 - 0.20885 = 0.29115$.

The standard normal probability table also can be used inversely to find the values of Z if you know the probability that Z is in a certain but unknown interval. Given a certain probability for Z to be between 0 and z with z unknown, you can then look up a number in the body of the table that is equal to or is closest to this probability, find the whole digit and the first decimal digit of z in the left margin in the row, and find the second decimal digit of z in the top margin. To find z given $P(0 < Z \leq z) = 0.32$ using Table 1, for example, look up 0.32121 that is closest to 0.32 and then find 0.9 in the left margin and 0.02 on the top margin (i.e., $z \approx 0.92$).

Standardization

For a random variable X with mean μ_X and variance σ_X^2 , the transformation

$$Z = \frac{X - \mu_X}{\sigma_X}$$

is called *standardization* and Z is called the *standardized random variable*. The standardized random variable has a mean $\mu_Z = 0$ and a variance $\sigma_Z^2 = 1$. If X is normally distributed, then Z is a standard normal random variable. Any normal random variable in the normal distribution family can be transformed into the standard normal random variable through standardization. To find the probability that a general normal random variable X , with mean μ_X and variance σ_X^2 , is between any two values x_1 and x_2 , the following transformation is used:

$$\begin{aligned} P(x_1 < X \leq x_2) \\ &= P\left(\frac{x_1 - \mu_X}{\sigma_X} < \frac{X - \mu_X}{\sigma_X} \leq \frac{x_2 - \mu_X}{\sigma_X}\right) \\ &= P(z_1 < Z \leq z_2). \end{aligned}$$

As an example, suppose X is a normal random variable with $\mu_X = 100$ and $\sigma_X^2 = 625$ and one wants to find $P(42 < X \leq 121)$. Using the transformation above, one finds

$$\begin{aligned} P(42 < X \leq 121) \\ &= P\left(\frac{42 - 100}{25} < \frac{X - \mu_X}{\sigma_X} \leq \frac{121 - 100}{25}\right) \\ &= P(-1.68 < Z \leq 0.84) = 0.45352 + 0.29955 \\ &= 0.75307. \end{aligned}$$

Because any normal random variable can be transformed into the standard normal random variable, the standard normal probability table is the only table needed for the entire normal distribution family.

Spreadsheet Functions

Two functions are available in Microsoft Excel (Microsoft Corporation, Redmond, WA) for the standard normal distribution. The function to find the probability of the standard normal distribution is `NORMSDIST(z)`. This function takes one argument “ z ” that is the value z of the standard random variable Z and returns the cumulative probability that Z is less than or equal to z [i.e., $P(Z \leq z)$]. For example, the entry `=NORMSDIST(1.645)` in any cell of a Microsoft Excel spreadsheet returns the values 0.950015 [i.e., $P(Z \leq 1.645) = 0.950015$]. The function to find the value of z given the cumulative probability that Z is less than or equal to z is `NORMSINV(probability)`. This function takes one argument “probability” that is the cumulative probability that Z is less than or equal to z and returns the value of z . For example, the entry `=NORMSINV(0.950015)` in any cell of a Microsoft Excel spreadsheet returns the value 1.645.

Furthermore, there are built-in functions in commonly used spreadsheet software and statistical software packages to find probabilities and percentiles of the general normal distribution. Two functions are available in Microsoft Excel.

The `NORMDIST(x, mean, standard_dev, cumulative)` function takes four arguments. The first argument “ x ” is a specific value x of the normal random variable X . The second argument “mean” is the mean μ_X of the normal random variable X . The third argument “standard_dev” is the standard deviation σ_X of the normal

random variable X . The fourth argument “cumulative” is logical. If “cumulative” is 0 or “false,” the function returns the value of the density function of X at x . If “cumulative” is any nonzero value or “true,” the function returns the cumulative probability that X is less than or equal to x [i.e., $P(X \leq x) = P(-\infty < X \leq x)$]. For example, =NORMDIST(2.5, 1.0, 1.5, 0) in any cell of a spreadsheet returns 0.161314 that is the value of the density function of the normal random variable X with mean $\mu_X = 1.0$ and standard deviation $\sigma_X = 1.5$ at $x = 2.5$. As another example, =NORMDIST(2.5, 1.0, 1.5, 1) in any cell of a spreadsheet returns 0.841345 that is the cumulative probability of a normal random variable X with a mean $\mu_X = 1.0$ and a standard deviation $\sigma_X = 1.5$ having a value up to $x = 2.5$ [i.e., $P(X \leq 2.5) = 0.841345$].

The NORMINV(probability, mean, standard_dev) function takes three arguments. The first argument “probability” is the cumulative probability of a normal random variable X having a value up to a value x [i.e., $P(X \leq x)$]. However, $P(X \leq x)$ is known and x is unknown but to be determined. The second argument “mean” is the mean μ_X of the normal random variable X . The third argument “standard_dev” is the standard deviation σ_X of the normal random variable X . The function returns the unknown value x of the normal random variable X . For example, =NORMINV(0.841345, 1.0, 1.5) in any cell of a spreadsheet returns 2.5 that is $x = 2.5$ if the cumulative probability of a normal random variable X with a mean $\mu_X = 1.0$ and a standard deviation $\sigma_X = 1.5$ having a value up to x is 0.841345.

Z SCORE

z score, also called z value, normal score, or standard score, is the standardized value of a normal random variable. The difference between the value of an observation and the mean of the distribution is usually called the *deviation from the mean* of the observation. The z score is then a dimensionless quantity obtained by dividing the deviation from the mean of the observation by the standard deviation of the distribution. In the following, random variables are represented by uppercase letters such as X and Z , and the specific values of the random variable are represented by the corresponding lowercase letters such as x and z .

The Normal Distribution and Standardization

The normal distribution is a family of normal random variables. A normal random variable X with mean or expected value μ_X and variance σ_X^2 has a density function,

$$f(x) = \frac{1}{\sqrt{2\pi\sigma_X^2}} e^{-\frac{(x-\mu_X)^2}{2\sigma_X^2}}, \text{ for } -\infty < x < \infty,$$

Where

$$\pi = 3.1415926535\dots$$

$$\text{and } e = 2.7182818284\dots$$

The mean μ_X and the variance σ_X^2 are the parameters of the normal distribution. The positive square root of σ_X^2 , $\sigma_X = \sqrt{\sigma_X^2}$, is the standard deviation of X . The mean is a *measure of location* or a *measure of central tendency* of the random variable (i.e., where the values of the random variable are concentrated), and the variance is a *measure of variation* of the random variable (i.e., how spread the values of the random variable are). The mean μ_X might take on any real value, and the variance σ_X^2 might take on any positive value. Each pair of the given values of the mean μ_X and the variance σ_X^2 determines a specific member in the normal distribution family. A normal random variable X with mean μ_X and variance σ_X^2 is usually denoted by $X \sim N(\mu_X, \sigma_X^2)$.

For a random variable X with mean μ_X and variance σ_X^2 , the transformation

$$Z = \frac{X - \mu_X}{\sigma_X}$$

is called *standardization* and Z is called the *standardized random variable*. The standardized random variable has a mean $\mu_Z = 0$ and a variance $\sigma_Z^2 = 1$.

If X is normally distributed, then Z is a standard normal random variable. The standard normal random variable Z has a density function

$$f(z) = \frac{1}{\sqrt{2\pi}} e^{-\frac{z^2}{2}}, \text{ for } -\infty < z < \infty$$

and is denoted by $Z \sim N(0,1)$. The standard normal distribution is a special case of the normal distribution. Any normal random variable in the normal distribution family can be transformed into the standard normal random variable through standardization. If X is not normally distributed, Z is still called the standardized random variable but does not have a standard normal distribution.

When plotted, the density function of the normal random variable X and that of the standard normal random variable Z have the same shape but X and Z are on different scales. Figure 1 shows the plot of a normal random variable X with a mean $\mu_X = 10$ and a variance $\sigma_X^2 = 25$ and the plot of the standard normal random variable Z . The curve of the normal distribution is symmetrical about the mean and has its peak at the mean. The normal curve is usually called the *bell curve* or *bell-shaped curve* because of its appearance.

Figure 1 Plots of the Density Functions of a Normal Random Variable X With $\mu_X = 10$ and $\sigma_X^2 = 25$ (Top) and of the Standard Normal Random Variable Z (Bottom)

z Score

Suppose x is the value of an observation, sometimes called the raw score, drawn from the distribution of X . Then the z score, or the standard score, of this observation is determined through standardization; that is,

$$z = \frac{x - \mu_X}{\sigma_X}.$$

The z score is the number of standard deviations an observation is above or below the mean. If the raw score is below the mean, z is negative; otherwise, if the raw score is above the mean, z is positive.

Sometimes the direct comparison of raw scores from different normal distributions is difficult. The z scores make the comparison of observations from different distributions much easier. If the grade that a student gets on a test of a management course is a normal random variable X_1 with a mean $\mu_{X_1} = 66$ and a standard deviation $\sigma_{X_1} = 6$, a grade (raw score) of 78 is very good because of $z_1 = 2$ (i.e., 2 standard deviations above the mean). If the grade that a student gets on a test of a history course is also a normal random variable X_2 with a mean $\mu_{X_2} = 86$ and a standard deviation $\sigma_{X_2} = 8$, a grade (raw score) of 78 is not very good because of $z_2 = -1$ (i.e., 1 standard deviation below the mean). In these examples, the z scores determine the positions of the raw scores in the corresponding distributions and make them comparable cross distributions.

Probabilities

The z scores allow one to find probabilities that an observation from a normal distribution is below a certain value, above a certain value, or in an interval between two certain values using the standard normal probability table. The standard normal probability table is widely available in any textbook in any disciplines wherever probability is used or covered as a topic. The probability that a normal random variable X , with mean μ_X and variance σ_X^2 , is between any two values x_1 and x_2 , is given by

$$\begin{aligned} P(x_1 < X \leq x_2) &= \int_{x_1}^{x_2} f(x) dx \\ &= \int_{x_1}^{x_2} \frac{1}{\sqrt{2\pi\sigma_X^2}} e^{-\frac{(x-\mu_X)^2}{2\sigma_X^2}} dx. \end{aligned}$$

Graphically, this probability is represented by the area between x_1 and x_2 under the normal curve, as shown in Figure 2. Unfortunately, $f(x)$ is not algebraically integrable and $P(x_1 < X \leq x_2)$ cannot be obtained algebraically although any area under the normal curve can be obtained numerically.

Figure 2 Probability Represented by the Area Under the Normal Curve

It is also impractical and unnecessary to list probabilities of normal variables in tables for certain pairs of parameters. Because any general normal random variable can be transformed to the standard normal random variable, the standard normal probability table is the only table needed for the entire normal distribution family.

To find the probability that a general normal random variable X , with mean μ_x and variance σ_x^2 , is between any two values x_1 and x_2 , the following transformation is used:

$$\begin{aligned} P(x_1 < X \leq x_2) \\ &= P\left(\frac{x_1 - \mu_x}{\sigma_x} < \frac{X - \mu_x}{\sigma_x} \leq \frac{x_2 - \mu_x}{\sigma_x}\right) \\ &= P(z_1 < Z \leq z_2). \end{aligned}$$

The standard normal probability table can then be used to find $P(z_1 < Z \leq z_2)$. For example, suppose X is a normal random variable with $\mu_x = 80$ and $\sigma_x^2 = 100$. To find $P(75 < X \leq 96)$,

$$\begin{aligned} P(75 < X \leq 96) \\ &= P\left(\frac{75 - 80}{10} < \frac{X - \mu_x}{\sigma_x} \leq \frac{96 - 80}{10}\right) \\ &= P(-0.50 < Z \leq 1.6). \end{aligned}$$

Using the standard normal probability table, we find $P(-0.50 \leq Z \leq 1.6) = 0.19146 + 0.44520 = 0.63666$. Hence, we have $P(75 < X < 96) = 0.63666$.

Sample Mean and Sample Proportion

Both the mean μ_x and the standard deviation σ_x are population or distribution parameters of the random variable X . Both of these parameters are needed in the computation of z scores. However, knowing these

parameters is unrealistic in practice unless in situations where a census is conducted. In a census, each element of the whole population is measured. Standardized tests, such as the SAT, ACT, GRE, GMAT, and MCAT, might be considered as examples of censuses if the population includes all those who have taken the test. If the population parameters are unknown, sample statistics usually are used to estimate the population parameters. For example, the sample mean $\bar{X}$ might be used to estimate the population mean and the sample variance S_x^2 might be used to estimate the population variance. For a sample with n observations $X_1, X_2, \dots, X_n$, the sample mean $\bar{X}$ is defined as

$$\bar{X} = \frac{1}{n} \sum_{i=1}^n X_i,$$

and the sample variance is defined as

$$S_x^2 = \frac{1}{n-1} \sum_{i=1}^n (X_i - \bar{X})^2.$$

The sample standard deviation is then $S_x = \sqrt{S_x^2}$.

In practice, one needs to make statistical inferences about the population mean using the sample mean. Hence, the random variable of interest is usually the sample mean using the sample mean. Hence, the random variable of interest is usually the sample mean $\bar{X}$ if the population distribution is quantitative. When the population is normal, $\bar{X}$ is exactly normally distributed with a mean equal to the population mean (i.e., $\mu_{\bar{X}} = \mu_x$ and a standard deviation equal to the population standard deviation divided by the square root of the sample size n (i.e., $\sigma_{\bar{X}} = \sigma_x / \sqrt{n}$). Usually $\sigma_{\bar{X}}$ is called the standard error of the mean. Hence, the standardized variable of Z is

$$Z = \frac{\bar{X} - \mu_{\bar{X}}}{\sigma_{\bar{X}} / \sqrt{n}},$$

and the z score of the mean $\bar{x}$ of a given sample is determined by

$$Z = \frac{\bar{X} - \mu_{\bar{X}}}{\sigma_{\bar{X}} / \sqrt{n}},$$

Because μ_x is unknown in practice, a hypothesized μ_0 takes the place of μ_x in computing the z score of $\bar{x}$ in hypothesis testing. The (hypothesized) μ_0 might be obtained from a previous study of the same problem or from other sources. If the population standard deviation is unknown, $\sigma_{\bar{X}}$ is estimated by

$$S_{\bar{X}} = \frac{S_x}{\sqrt{n}}.$$

If the population is normal but the population standard deviation is unknown, the following is called a t score:

$$t = \frac{\bar{X} - \mu_0}{S_X / \sqrt{n}}.$$

It is called a t score because it follows a t distribution with $n-1$ degrees of freedom instead of the standard normal distribution.

If the population is not normal but is not departed markedly from a normal distribution and the sample size is sufficiently large (e.g., $n \geq 30$), the central limit theorem applies and then $\bar{X}$ is approximately normal according to the central limit theorem. In this case, z computed in the following

$$z = \frac{\bar{x} - \mu_0}{S / \sqrt{n}}$$

has approximately a standard normal distribution and, therefore, also is called a z score.

Often, statistical inferences need to be made about the population proportion using the sample proportion $\bar{P}$. Hence, the random variable of interest is the sample proportion $\bar{P}$ if the population distribution is binary. Let X represent the number of successes in a sample of n observations. If the sample is drawn from an infinite population with a population proportion p , X usually has a binomial distribution with parameters n and p . The sample proportion $\bar{P}$ is defined as

$$\bar{P} = \frac{X}{n}.$$

$\bar{P}$ is a special case of the sample mean $\bar{X}$. In practice, p is unknown and is assumed to be p_0 in hypothesis testing. When n is sufficiently large, the central limit theorem applies. Therefore, when $p = p_0$, z computed in the following is a z score:

$$z = \frac{x - np_0}{\sqrt{np_0(1-p_0)}} = \frac{\bar{p} - p_0}{\sqrt{p_0(1-p_0)/n}}.$$

Percentiles

z scores also are used to determine percentiles of the distribution of a random variable X with known mean μ_X and standard deviation σ_X . Percentiles are used widely in statistical result reporting, such as in standardized testing. The 100 a th percentile x_a is a specific value of X such that the cumulative probability of X having a value up to x_a is a [i.e., $P(X \leq x_a) = a$]. Or equivalently, 100 a % of the observations have values less than or equal to x_a . To determine the 100 a th percentile, one first looks up the value of z_a in the

standard normal probability table or determines the z_a value using software, such as Microsoft Excel (Microsoft Corporation, Redmond, WA), such that $P(Z \leq z_a) = a$. Then the 100 a th percentile x_a of X is determined by

$$x_a = \mu_X + z_a \sigma_X.$$

Suppose, for example, X is a normal random variable with $\mu_X = 55$ and $\sigma_X^2 = 144$. To find the 95th percentile of X , one finds $P(Z \leq 1.645) \approx 0.95$ using the standard normal probability table (i.e., $z_a = 1.645$ for $a = 0.95$). Hence, $x_a = \mu_X + z_a \sigma_X = 55 + 1.645(12) = 74.74$.

Spreadsheet Functions

There are built-in functions in commonly used spreadsheet software and statistical software to find probabilities and percentiles of the normal distribution. Two functions are available for the general normal random variables, and two more functions are available for the standard normal random variable in Microsoft Excel.

The function NORMDIST(x , mean, standard_dev, cumulative) finds the value of the density function or cumulative probability for a general normal random variable. The function takes four arguments. The first argument " x " is a specific value x of the normal random variable X . The second argument "mean" is the mean μ_X of the normal random variable X . The third argument "standard_dev" is the standard deviation σ_X of the normal random variable X . The fourth argument "cumulative" is logical. If "cumulative" is 0 or "false," the function returns the value of the density function at x for the normal random variable with the given mean and standard deviation. If "cumulative" is any nonzero value or "true," the function returns the cumulative probability for X to be from $-\infty$ to x [i.e., $P(X \leq x) = P(-\infty < X \leq x)$]. For example, = NORMDIST(2.5, 1.0, 1.5, 0) returns 0.161314 that is the value of the density function at $x = 2.5$ for the normal random variable X with mean $\mu_X = 1.0$ and standard deviation $\sigma_X = 1.5$. As a second example, = NORMDIST(2.5, 1.0, 1.5, 1) returns 0.841345 that is the cumulative probability of a normal random variable X with a mean $\mu_X = 1.0$ and a standard deviation $\sigma_X = 1.5$ having a value up to $x = 2.5$ [i.e., $P(X \leq 2.5) = 0.841345$].

The function NORMINV(probability, mean, standard_dev) finds the percentile of a normal random variable. The function takes three arguments. The first argument "probability" is the cumulative probability of a normal random variable X having a value up to a value x [i.e., $P(X \leq x)$]. However, "probability"

[i.e., $P(X \leq x)$], is known but x is unknown and to be determined. The second argument “mean” is the mean μ_X of the normal random variable X . The third argument “standard_dev” is the standard deviation σ_X of the normal random variable X . The function returns the unknown value x of the normal random variable X . For example, = NORMINV(0.841345, 1.0, 1.5) returns 2.5 that is $x = 2.5$ if the cumulative probability of a normal random variable X with a mean $\mu_X = 1.0$ and a standard deviation $\sigma_X = 1.5$ having a value up to x is 0.841345.

The function to find the probability of the standard normal distribution is NORMSDIST(z). This function takes one argument “ z ” that is the value z of the standard normal random variable Z and returns the cumulative probability that Z is less than or equal to z [i.e., $P(Z \leq z)$]. For example, the entry = NORMSDIST(1.645) in any cell of a Microsoft Excel spreadsheet returns the values 0.950015; that is, $P(Z \leq 1.645) = 0.950015$. If a z score is computed already, this function can be used to find the corresponding cumulative probability of a normal random variable.

The function to find the value of z given the probability that Z is less than or equal to z is NORMSINV(probability). This function takes one argument “probability” that is the probability that the standard normal random variable Z is less than or equal to z and returns the value of z . For example, the entry = NORMSINV(0.950015) in any cell of a Microsoft Excel spreadsheet returns the value 1.645.

z Scores in Financial Analysis

The z scores used in financial analysis for the measurement of financial health and for the prediction of bankruptcy are conceptually different from the z scores in statistics. A z score in financial analysis is a weighted sum of financial ratios. The z -score formulas were developed by Edward I. Altman.

The original z -score bankruptcy formula is

$$Z = 1.2X_1 + 1.4X_2 + 3.3X_3 + 0.6X_4 + 0.999X_5,$$

where

- X_1 = Working Capital / Total Assets
- X_2 = Retained Earnings / Total Assets
- X_3 = Earnings Before Interest and Taxes / Total Assets
- X_4 = Market Value of Equity / Total Liabilities
- X_5 = Sales / Total Assets

A firm is considered to be in the “safe” zone if $Z \geq 2.99$, in the “gray” zone if $1.80 \leq Z < 2.99$, or in the “distress” zone if $Z < 1.80$.

The Z' -score Formula of Bankruptcy for Private Firms is

$$Z' = 0.717X_1 + 0.847X_2 + 3.107X_3 + 0.420X_4 + 0.998X_5,$$

where

- X_1 = (Current Assets – Current Liabilities) / Total Assets
- X_2 = Retained Earnings / Total Assets
- X_3 = Earnings Before Interest and Taxes / Total Assets
- X_4 = Book Value Per Share of Equity / Total Liabilities
- X_5 = Sales / Total Assets

A firm is considered to be in the “safe” zone if $Z' \geq 2.90$, in the “gray” zone if $1.23 \leq Z' < 2.90$, or in the “distress” zone if $Z' < 1.23$.

The Z'' -score Formula of Bankruptcy for Manufacturers, Non-Manufacturer Industrials, and Emerging Market Credits is

$$Z'' = 6.56X_1 + 3.26X_2 + 6.72X_3 + 1.05X_4,$$

where

- X_1 = (Current Assets – Current Liabilities) / Total Assets
- X_2 = Retained Earnings / Total Assets
- X_3 = Earnings Before Interest and Taxes / Total Assets
- X_4 = Book Value of Equity / Total Liabilities

A firm is considered to be in the “safe” zone if, in the “gray” zone if $1.1 \leq Z'' < 2.6$, or in the “distress” zone if $Z'' < 1.1$.

z TEST

The *z* test is a statistical test procedure that uses a sample statistic having a normal distribution. Statistical testing is a way of making statistical inferences about unknown population parameters. The *z* test is usually used to test hypotheses about (a) the mean of a population based on a single sample, (b) the proportion of successes in a population based on a single sample, (c) the difference between the means of two populations based on samples from each population, or (d) the difference between the proportions of successes in two populations based on samples from each population. In the following, capital letters such as *X* and *Z* are used to represent random variables and the corresponding lowercase letters such as *x* and *z* are used to represent specific values of the random variables.

A sample in a *z* test is supposed to be a simple random sample. A simple random sample drawn from a finite population is one where each sample of the same size has the same probability of being chosen and one from an infinite population is one where all the observations in the sample are statistically independent and are from the same distribution.

Two hypotheses are involved in a hypothesis test. The *null hypothesis*, denoted by H_0 , is the hypothesis that cannot be viewed as false unless sufficient evidence to the contrary is obtained. The *alternative hypothesis*, denoted by H_a , is the hypothesis against which the null hypothesis is tested and is viewed as true when the null hypothesis is declared as false. The null hypothesis is the one for which the cost is high when rejected by error. Depending on the applications, there are three types of hypothesis tests—two-tailed (sided) tests, one-tailed (sided) lower tail tests, and one-tailed (sided) upper tail tests.

A correct decision is made if a true hypothesis is accepted or a false hypothesis is rejected. Although it is never known whether a correct decision is made, the probabilities of making errors can be assessed. There are two types of errors in hypothesis testing. A *Type I error* is the kind of error made when rejecting a null hypothesis when it is actually true. A *Type II error* is the kind of error made when not rejecting a null hypothesis when it is actually false. The probability of making a Type I error is usually represented by α [i.e., $\alpha = P(\text{Type I error}) = P(\text{Rejecting } H_0 \mid H_0 \text{ is true})$] and is called the *level of significance*. The two types of errors cannot be controlled at the same time for a given sample size. Therefore, only Type I error is controlled by specifying α for the test. In practice, α is usually set to $\alpha = 0.01$, $\alpha = 0.02$, $\alpha = 0.05$, or $\alpha = 0.10$. Increasing the sample size reduces testing errors but also increases the cost of the study.

A statistical decision rule specifies for each possible outcome of the sample test statistic which alternative, H_0 or H_a , should be concluded. The set of values of the sample test statistic for which the null hypothesis H_0 is not rejected is called the *acceptance region* and that for which the alternative hypothesis H_a is concluded is called the *rejection region*. The decision rule might be established in three different but equivalent ways—*critical values*, *action limits*, and *p values*. When specifying decision rules, z_α is used to represent the value of the standard normal random variable *Z* for a specific α such that $p(Z > z_\alpha) = \alpha$. The value z_α can be found in the standard normal probability table or through a spreadsheet or statistics software.

Test of a Population Mean Based on a Single Sample

A hypothesis test about the mean of a population based on a single sample tests if the true but unknown population mean μ is different from, larger than, or smaller than a known value μ_0 . Without confusion, μ and σ instead of μ_X and σ_X are used to represent the population mean and standard deviation of the random variable *X*, respectively. The sample mean $\bar{X}$ of a simple random sample with sample size *n* is the test statistic. For a sample with *n* observations $X_1, X_2, \dots, X_n$, the sample mean $\bar{X}$ is defined as

$$\bar{X} = \frac{1}{n} \sum_{i=1}^n X_i,$$

and the sample variance is defined as

$$S_X^2 = \frac{1}{n-1} \sum_{i=1}^n (X_i - \bar{X})^2.$$

The sample standard deviation is then $S_X = \sqrt{S_X^2}$. The mean or expected value of $\bar{X}$ is the population mean μ_X (i.e., $\mu_{\bar{X}} = \mu_X$), and the variance of $\bar{X}$ is the population variance divided by *n* (i.e., $\sigma_{\bar{X}}^2 = \frac{\sigma_X^2}{n}$).

Hypotheses

The hypotheses are

$$H_0 : \mu = \mu_0 \quad H_a : \mu \neq \mu_0$$

for a two-tailed test;

$$H_0 : \mu \geq \mu_0 \quad H_a : \mu < \mu_0$$

for a one-tailed lower tail test; and

$$H_0 : \mu \leq \mu_0 \quad H_a : \mu > \mu_0$$

for a one-tailed upper tail test.

When the population is normal and the population standard deviation is known, the test statistic $Z = \frac{\bar{X} - \mu}{\sigma / \sqrt{n}}$ has an exact standard normal distribution regardless of how large the sample size n is. If n is large (e.g., $n \geq 30$), based on the central limit theorem, the standard normal variable Z is the appropriate test statistic because $Z = \frac{\bar{X} - \mu}{\sigma / \sqrt{n}}$ has approximately a standard normal distribution even if the population is not normal. In these cases, the z test is the appropriate test.

Decision Rules Using Critical Values

When critical values are used to set up decision rules, z is computed with $z = \frac{\bar{x} - \mu_0}{\sigma / \sqrt{n}}$.

The decision rule for a two-tailed test, shown in Figure 1, is

Do not reject H_0 if $-z_{\alpha/2} \leq z \leq z_{\alpha/2}$,

Reject H_0 if $z < -z_{\alpha/2}$ or $z > z_{\alpha/2}$

or equivalently,

Do not reject H_0 if $|z| \leq z_{\alpha/2}$,

Reject H_0 if $|z| > z_{\alpha/2}$

The decision rule for a one-tailed lower tail test, shown in Figure 2, is

Do not reject H_0 if $z \geq -z_{\alpha}$,

Reject H_0 if $z \leq -z_{\alpha}$.

The decision rule for a one-tailed upper tail test, shown in Figure 3, is

Do not reject H_0 if $z \leq z_{\alpha}$,

Reject H_0 if $z > z_{\alpha}$.

Decision Rules Using Action Limits

The decision rule for a two-tailed test is

Do not reject H_0 if $\hat{\mu}_L \leq \bar{x} \leq \hat{\mu}_R$,

Reject H_0 if $\bar{x} < \hat{\mu}_L$ or $\bar{x} > \hat{\mu}_R$,

where $\hat{\mu}_L = \mu_0 - z_{\alpha/2} \frac{\sigma}{\sqrt{n}}$ and $\hat{\mu}_R = \mu_0 + z_{\alpha/2} \frac{\sigma}{\sqrt{n}}$ (see Figure 4).

Figure 1 Decision Rule Using Critical Values for a Two-Tailed Test

Figure 2 Decision Rule Using Critical Values for a One-Tailed Lower Tail Test

Figure 3 Decision Rule Using Critical Values for a One-Tailed Upper Tail Test

Figure 4 Decision Rule Using Action Limits for a Two-Tailed Test

The decision rule for a one-tailed lower tail test is

Do not reject H_0 if $\bar{x} \geq \hat{\mu}_L$,

Reject H_0 if $\bar{x} < \hat{\mu}_L$,

where $\hat{\mu}_L = \mu_0 - z_\alpha \frac{\sigma}{\sqrt{n}}$ (see Figure 5, next page).

The decision rule for a one-tailed upper tail test is

Do not reject H_0 if $\bar{x} \leq \hat{\mu}_R$,

Reject H_0 if $\bar{x} > \hat{\mu}_R$,

where $\hat{\mu}_R = \mu_0 + z_\alpha \frac{\sigma}{\sqrt{n}}$ (see Figure 6).

Decision Rules Using *p* Value

The *p* value of a test is the probability of obtaining a value of the test statistic that might have been more extreme in the appropriate direction of the rejection region than was actually observed. Whether the test is one tailed or two tailed, or lower tail or upper tail, the decision rule is always the same, but the ways of computing the *p* values are different. The decision rule is

Figure 5 Decision Rule Using Action Limit for a One-Tailed Lower Tail Test

Figure 6 Decision Rule Using Action Limit for a One-Tailed Upper Tail Test

Do not reject H_0 if *p* value $\geq \alpha$

Reject H_0 if *p* value $< \alpha$.

The *p* value is defined as

$$p \text{ value} = \begin{cases} 2p(\bar{X} > \bar{x}), & \text{if } \bar{x} > \mu_0 \\ 2p(\bar{X} < \bar{x}), & \text{if } \bar{x} < \mu_0 \end{cases}$$

for a two-tailed test;

$$p \text{ value} = p(\bar{X} < \bar{x})$$

for a one-tailed lower tail test; and

$$p \text{ value} = p(\bar{X} > \bar{x})$$

for a one-tailed upper tail test.

When the Population Standard Deviation Is Unknown

In practice, the population standard deviation σ is usually unknown. If the population standard deviation is known, very likely the population mean μ is also known, and hence, a statistical test is not needed. When the population standard deviation is unknown, the sample standard deviation is used. If the population is normally distributed, the *t* test, a different statistical procedure, is used to conduct the test. When the sample size is reasonably large (e.g., $n \geq 30$), the central limit theorem applies so that the test procedure above can be used with σ replaced by s .

Test for a Single Population Proportion When Sample Size Is Large

The *z* test for a single population proportion tests if the unknown population proportion *p* is different, larger than, or smaller than a known value p_0 . Assume a sample of size *n* is randomly selected from a population with a population proportion of successes *p*. The sample frequency (i.e., the number of successes in a sample), denoted by *X*, is a binomial random variable if the population is infinite or finite, but the sample is selected with replacement, or is a hypergeometric random variable, if the population is finite and the sample is selected without replacement, with parameters *n* and *p*. The sample proportion, denoted by $\bar{p}$, is the test statistic and is defined as

$$\bar{p} = \frac{X}{n}.$$

The sample proportion $\bar{p}$ is a point estimator of the population proportion *p*. Because the population is

not normally distributed, the sample size n must be large for the central limit theorem to apply when the following test procedure is used.

The sample proportion $\bar{p}$ is a special sample mean. If X_i is defined as

$$X_i = \begin{cases} 1, & \text{if observation } i \text{ is a success} \\ 0, & \text{if observation } i \text{ is a failure} \end{cases}$$

then $X = \sum_{i=1}^n X_i$. The sample mean $\bar{X}$ is then

$$\bar{X} = \frac{1}{n} \sum_{i=1}^n X_i = \frac{X}{n} = \bar{p}.$$

The expected value of $\bar{p}$ is the population proportion p . The variance of $\bar{p}$ is $\sigma_{\bar{p}}^2 = \frac{p(1-p)}{n}$.

Hypotheses

The hypotheses are

$$H_0 : p = p_0 \quad H_a : p \neq p_0$$

for a two-tailed test;

$$H_0 : p \geq p_0 \quad H_a : p < p_0$$

for a one-tailed lower tail test; and

$$H_0 : p \leq p_0 \quad H_a : p > p_0$$

for a one-tailed upper tail test.

When n is sufficiently large and the true population proportion is p_0 ,

$$Z = \frac{X - np_0}{\sqrt{np_0(1-p_0)}} \text{ or } Z = \frac{\bar{p} - p_0}{\sqrt{p_0(1-p_0)/n}}$$

has approximately a standard normal distribution.

Decision Rule Using the Critical Values

When critical values are used to set up the decision rules, the test statistic z is computed with

$$z = \frac{x - np_0}{\sqrt{np_0(1-p_0)}} \text{ or equivalently } z = \frac{\bar{p} - p_0}{\sqrt{p_0(1-p_0)/n}}.$$

If n is too small and p_0 is too large or too small, Z computed above might be too far from an approximate standard normal distribution. In this case, the original distribution of X should be used to conduct the hypothesis test. As a working rule, the z test can be used if both $np_0 \geq 5$ and $n(1-p_0) \geq 5$ are satisfied.

The decision rule for a two-tailed test is

$$\begin{aligned} &\text{Do not reject } H_0 \text{ if } -z_{\frac{\alpha}{2}} \leq z \leq z_{\frac{\alpha}{2}}, \\ &\text{Reject } H_0 \text{ if } z < -z_{\frac{\alpha}{2}} \text{ or } z > z_{\frac{\alpha}{2}}, \end{aligned}$$

or equivalently,

$$\begin{aligned} &\text{Do not reject } H_0 \text{ if } |z| \leq z_{\frac{\alpha}{2}}, \\ &\text{Reject } H_0 \text{ if } |z| > z_{\frac{\alpha}{2}}. \end{aligned}$$

The decision rule for a one-tailed lower tail test is

$$\begin{aligned} &\text{Do not reject } H_0 \text{ if } z \geq -z_{\alpha}, \\ &\text{Reject } H_0 \text{ if } z < -z_{\alpha}. \end{aligned}$$

The decision rule for a one-tailed upper tail test is

$$\begin{aligned} &\text{Do not reject } H_0 \text{ if } z \leq z_{\alpha}, \\ &\text{Reject } H_0 \text{ if } z > z_{\alpha}. \end{aligned}$$

Decision Rule Using Action Limits

The decision for a two-tailed test is

$$\begin{aligned} &\text{Do not reject } H_0 \text{ if } \hat{p}_L \leq \bar{p} \leq \hat{p}_R, \\ &\text{Reject } H_0 \text{ if } \bar{p} < \hat{p}_L \text{ or } \bar{p} > \hat{p}_R, \end{aligned}$$

$$\text{where } \hat{p}_L = p_0 - z_{\frac{\alpha}{2}} \sqrt{\frac{p_0(1-p_0)}{n}} \quad \text{and} \quad \hat{p}_R = p_0 + z_{\frac{\alpha}{2}} \sqrt{\frac{p_0(1-p_0)}{n}}.$$

The decision rule is for a one-tailed lower tail test is

$$\begin{aligned} &\text{Do not reject } H_0 \text{ if } \bar{p} \geq \hat{p}_L, \\ &\text{Reject } H_0 \text{ if } \bar{p} < \hat{p}_L, \end{aligned}$$

$$\text{where } \hat{p}_L = p_0 - z_{\alpha} \sqrt{\frac{p_0(1-p_0)}{n}}.$$

The decision rule for a one-tailed upper tail test is

$$\begin{aligned} &\text{Do not reject } H_0 \text{ if } \bar{p} \leq \hat{p}_R, \\ &\text{Reject } H_0 \text{ if } \bar{p} > \hat{p}_R, \end{aligned}$$

$$\text{where } \hat{p}_R = p_0 + z_{\alpha} \sqrt{\frac{p_0(1-p_0)}{n}}.$$

Decision Rules Using the p Values

When using the p values, the decision rule is always

Do not reject H_0 if p value $\geq \alpha$,

Reject H_0 if p value $< \alpha$.

The p value is

$$p\text{value} = \begin{cases} 2P(\bar{p} < \bar{p}), & \text{if } \bar{p} < p_0 \\ 2P(\bar{p} > \bar{p}), & \text{if } \bar{p} > p_0 \end{cases}$$

for a two-tailed test;

$$p \text{ value} = p(\bar{p} < \bar{p})$$

for a one-tailed lower tail test; or

$$p \text{ value} = p(\bar{p} > \bar{p})$$

for a one-tailed upper tail test.

Hypothesis Tests for Two Population Means

Sometimes two populations need to be compared. The z test for two population means is used to test whether two populations have the same mean or whether one population has a larger or smaller mean than the other. The population means of the random variables X_1 and X_2 are represented by μ_1 and μ_2 , the sample means are represented by $\bar{X}_1$ and $\bar{X}_2$, the sample variances are represented by S_1^2 and S_2^2 , and the sample sizes are represented by n_1 and n_2 , respectively.

Independent Samples and Normal Populations With Known Equal Variance

A two-tailed test is used to test whether two populations have the same mean. The null and alternative hypotheses are

$$H_0 : \mu_1 = \mu_2 \text{ or } H_0 : \mu_1 - \mu_2 = 0.$$

$$H_a : \mu_1 \neq \mu_2 \quad H_a : \mu_1 - \mu_2 \neq 0$$

One-tailed tests might also be conducted to test whether one population has a larger or smaller mean than the other.

When the two normal populations have the common variance σ^2 , the sampling distribution of $\bar{X}_1 - \bar{X}_2$ is normal with a mean $\mu_{\bar{X}_1 - \bar{X}_2} = \mu_1 - \mu_2$ and a variance

$$\sigma_{\bar{X}_1 - \bar{X}_2}^2 = \sigma^2 \left(\frac{1}{n_1} + \frac{1}{n_2} \right).$$

The test statistic $Z = \frac{\bar{X}_1 - \bar{X}_2}{\sigma_{\bar{X}_1 - \bar{X}_2}}$ has a standard normal distribution.

When using critical values to set up the decision rules, the test statistic z is

$$z = \frac{\bar{x}_1 - \bar{x}_2}{\sigma_{\bar{X}_1 - \bar{X}_2}}.$$

The decision rule is

Do not reject H_0 if $-z_{\frac{\alpha}{2}} \leq z \leq z_{\frac{\alpha}{2}}$,

Reject H_0 if $z < -z_{\frac{\alpha}{2}}$ or $z > z_{\frac{\alpha}{2}}$,

or equivalently,

Do not reject H_0 if $|z| \leq z_{\frac{\alpha}{2}}$,

Reject H_0 if $|z| > z_{\frac{\alpha}{2}}$.

The decision rule using action limits is

Do not reject H_0 if $\hat{d}_L \leq \bar{x}_1 - \bar{x}_2 \leq \hat{d}_R$,

Reject H_0 if $\bar{x}_1 - \bar{x}_2 < \hat{d}_L$ or $\bar{x}_1 - \bar{x}_2 > \hat{d}_R$,

where $\hat{d}_L = -z_{\frac{\alpha}{2}} \sigma_{\bar{X}_1 - \bar{X}_2}$ and $\hat{d}_U = z_{\frac{\alpha}{2}} \sigma_{\bar{X}_1 - \bar{X}_2}$.

Independent Samples and Normal Populations With Unknown Variances

If the population variances σ_1^2 and σ_2^2 are unknown, the t test is used to conduct the test. However, when both n_1 and n_2 are large, the central limit theorem applies and $\bar{X}_1 - \bar{X}_2$ has approximately a normal distribution with a mean

$$\mu_{\bar{X}_1 - \bar{X}_2} = \mu_1 - \mu_2$$

and a variance

$$\sigma_{\bar{X}_1 - \bar{X}_2}^2 = \sigma_{\bar{X}_1}^2 + \sigma_{\bar{X}_2}^2 = \frac{\sigma_1^2}{n_1} + \frac{\sigma_2^2}{n_2}.$$

The test statistic $Z = \frac{\bar{X}_1 - \bar{X}_2}{\sigma_{\bar{X}_1 - \bar{X}_2}}$ has an approximate standard normal distribution. If the population variances are unknown, $\sigma_{\bar{X}_1 - \bar{X}_2}^2$ is estimated with

$$s_{\bar{X}_1 - \bar{X}_2}^2 = s_{\bar{X}_1}^2 + s_{\bar{X}_2}^2 = \frac{s_1^2}{n_1} + \frac{s_2^2}{n_2}.$$

Then the test statistic $Z = \frac{\bar{X}_1 - \bar{X}_2}{S_{\bar{X}_1 - \bar{X}_2}}$ has approximately a standard normal distribution and the test procedure discussed in the preceding discussion can be used.

Matched Samples

Matched samples are drawn in such a way that the elements of the two samples from the two populations are matched carefully in pairs so that the two elements in each pair are as similar as possible with respect to the factors that might influence the variables of interest.

In this case, the test procedure simplifies to those for a single population mean, but the random variable is D with $D = X_1 - X_2$. $D_1, D_2, \dots, D_n$ represent the differences of the paired observations when the sample test statistic is computed.

Hypothesis Tests for Two Population Proportions

As for the difference in population means, the difference in the proportions of two binomial populations is of interest. The two population proportions are represented by p_1 and p_2 . For the two samples, n_1 and n_2 represent the sample sizes, X_1 and X_2 represent the sample frequencies, and $\bar{p}_1$ and $\bar{p}_2$ represent the sample proportions with $\bar{p}_1 = \frac{X_1}{n_1}$ and $\bar{p}_2 = \frac{X_2}{n_2}$, respectively. The expected value or mean of the test statistic $\bar{p}_1 - \bar{p}_2$ is $\mu_{\bar{p}_1 - \bar{p}_2} = p_1 - p_2$, and the variance is

$$\sigma_{\bar{p}_1 - \bar{p}_2}^2 = \sigma_{\bar{p}_1}^2 + \sigma_{\bar{p}_2}^2 = \frac{p_1(1-p_1)}{n_1} + \frac{p_2(1-p_2)}{n_2}.$$

When n_1 and n_2 are both large,

$$Z = \frac{(\bar{p}_1 - \bar{p}_2) - (p_1 - p_2)}{\sqrt{p_1(1-p_1)/n_1 + p_2(1-p_2)/n_2}}$$

has approximately a standard normal distribution. Because p_1 and p_2 are unknown, $\sigma_{\bar{p}_1 - \bar{p}_2}^2$ is estimated by

$$S_{\bar{p}_1 - \bar{p}_2}^2 = \bar{p}_p(1 - \bar{p}_p) \left(\frac{1}{n_1} + \frac{1}{n_2} \right),$$

where $\bar{p}_p$ is the pooled sample proportion (i.e., $\bar{p}_p = \frac{X_1 + X_2}{n_1 + n_2} = \frac{n_1\bar{p}_1 + n_2\bar{p}_2}{n_1 + n_2}$).

Hypotheses

The null and alternative hypotheses for a two-tailed test are

$$H_0 : p_1 = p_2 \text{ or } H_0 : p_1 - p_2 = 0.$$

$$H_a : p_1 \neq p_2 \quad H_a : p_1 - p_2 \neq 0$$

One-tailed hypotheses can be set up to test whether one population has a larger or smaller proportion than the other.

Decision Rules Using Critical Values

With $z = \frac{\bar{p}_1 - \bar{p}_2}{S_{\bar{p}_1 - \bar{p}_2}}$, the decision rule for a two-tailed test is

Do not reject H_0 if $-\frac{z_\alpha}{2} \leq z \leq \frac{z_\alpha}{2}$,

Reject H_0 if $z < -\frac{z_\alpha}{2}$ or $z > \frac{z_\alpha}{2}$.

Decision Rule Using Action Limits

For a two-tailed test, the decision rule is

Do not reject H_0 if $\hat{d}_L \leq \bar{p}_1 - \bar{p}_2 \leq \hat{d}_R$,

Reject H_0 if $\bar{p}_1 - \bar{p}_2 < \hat{d}_L$ or $\bar{p}_1 - \bar{p}_2 > \hat{d}_R$,

where $\hat{d}_L = -\frac{z_\alpha}{2} S_{\bar{p}_1 - \bar{p}_2}$ and $\hat{d}_R = \frac{z_\alpha}{2} S_{\bar{p}_1 - \bar{p}_2}$.

The decision rule can also be set up using p values.

ZELEN'S RANDOMIZED CONSENT DESIGN

The Zelen's randomized consent designs are modifications to a standard randomized controlled trial (RCT), in which participants are asked for consent to take part in the trial *after* randomization has taken place. Marvin Zelen proposed two modifications: In

the single-consent design only those allocated to the intervention group are asked to give consent, and in the double consent design, those in both the intervention and comparison arms are asked for consent.

Randomized consent designs are widely used in the context of cluster randomized trials. With respect to individually randomized trials, they have found little favor with trial methodologists partly for ethical reasons and partly for scientific issues. Crossover is the main scientific problem with Zelen's approach, and even modest crossover rates will result in biased estimates and reductions in statistical power. Nevertheless, there are some instances, such as cancer screening trials, where Zelen's approach will provide a pragmatic estimate of the impact of the intervention, which is closer to that which could be achieved in implementation compared with the conventional trial approach. This entry begins with an overview of RCTs and then discusses Zelen's single- and double-consent designs, including advantages and criticisms of such designs.

Overview

The RCT has earned its position as the methodological gold standard for studies of effectiveness, particularly in health research. Because outcomes are being compared across groups of individuals that have been formed through the process of random allocation, if the groups are of sufficient size, any difference observed between the groups is caused by the intervention. However, this assumes the study is not biased or contaminated.

For example, as an RCT compares different interventions (most commonly, different treatment options), many trial participants will prefer one treatment over another. So-called preference effects can potentially lead to biased results, for example, participants randomized to an intervention they do not want might lead them to (consciously or unconsciously) respond differently to the treatment. A particular version of this has been termed *resentful demoralization*. Resentful demoralization can affect trial continuance; that is, demoralized participants might be more likely to drop out, introducing selection bias. These participants might be more likely to report adverse events or to report more negatively on outcome measures. The effect of resentful demoralization on study outcomes is acknowledged as a potential confounder in open randomized trials (that is, those without blinding to the intervention).

In addition to the potential introduction of bias, there is a longstanding practical problem of recruitment into RCTs—both at the level of engaging physicians/clinicians who will enable recruitment of patients as well as difficulties in recruiting patients themselves. Recruitment difficulty largely stems from problems clinicians might have in explaining to patients core trial concepts—especially equipoise and randomization. This, together with the acknowledgment of the uncertainty relating to patient care, can make the process of fully informed consent problematic. Recruitment difficulties can result in unrepresentative samples, therefore, having implications for external validity.

These difficulties stem from the fact that in most RCTs consent to both treatment and random allocation is sought from participants before randomization. In addressing the issue of recruitment difficulty, which also addresses the problem of resentful demoralization, Zelen proposed two modifications to the usual practice of gaining consent before randomization, known as the single- and double-consent methods.

Single- and Double-Consent Methods

The initial concept he proposed was the single-consent method whereby participants are randomized and *treatment* consent is only obtained from participants who receive the experimental intervention. Control treatment, in this case, is best standard care. Refusal to accept the novel treatment results in the patients receiving the control intervention (see Figure 1). Participants allocated to usual care cannot receive the experimental treatment. Both experimental and control groups might be asked for permission for follow-up and for data to be collected about themselves. Note that consent is only sought to have the experimental treatment. Zelen considered the design to be ethical as participants can still refuse consent to the novel therapy, and refusal means they obtain standard treatment as would be the case in a “normal” randomized trial. Those allocated to standard care, in this design, have no possibility of accessing the novel treatment as is often the case in standard randomized trials.

A modification of the single-consent method to allow those allocated to the standard therapy access to the experimental treatment resulted in the double-consent method. In the double-consent approach, retrospective consent is sought from participants in all the treatment groups, and participants can refuse their allotted treatment and “cross over” to an

Figure 1 Zelen's Single-Consent Design

Source: Adamson, J., Cockayne, S., Puffer, S., & Torgerson, D. J. (2006). Review of randomised trials using the post-randomised consent (Zelen's) design. *Contemporary Clinical Trials*, 27; 305–319. Copyright 2006 by Elsevier, reprinted with permission

alternative treatment arm (Figure 2). This method is potentially advantageous to the trial participant over the standard RCT as he or she will know in advance what treatment he or she will receive. Ron Schellings and colleagues have drawn a distinction between two types of double-consent design—so-called complete-double-consent design, in which participants received full information on treatment alternatives and the incomplete-double-consent design, in which information on the existence of the alternatives is withheld.

Trials of this type (both single and double consent) are commonly known as Zelen's design and fall under the umbrella of randomized consent designs. In both approaches, analysis is by intention-to-treat; that is, participants are retained in their original randomized groups for the analysis.

Advantages

In theory, there are several advantages to using the Zelen approach, in addressing the issues of bias and contamination as outlined. For example, for the recruiting clinician, it makes treatment discussion with the patient more straightforward and closer to "routine"

clinical practice. The allocated treatment pathway is discussed with the patient who might or might not refuse the treatment on offer. Administratively and logistically, this might be more attractive, and it is speculated that this would increase recruitment rates to trials. In addition, the Zelen approach might also result in a more representative sample of participants as all, or a random sample of, eligible participants can be included in the study, and refusal of consent is minimized. Indeed, because of these advantages, Zelen felt that the single-consent method would become widely used.

Regarding patient preferences, an advantage to using the single-consent method is that because, usually, the control patients are unaware of the presence of an alternative therapy, they are less likely to suffer from resentful demoralization and its possible consequences. Furthermore, in some Zelen trials, one or both groups are usually not informed they are taking part in an experiment, and this might reduce the possibility of any bias from the Hawthorne effect—that is, a change in behavior occurring because of trial participation rather than because of any treatment.

Figure 2 Zelen's Double-Consent Design

Source: Adamson, J., Cockayne, S., Puffer, S., & Torgerson, D. J. Review of randomised trials using the post-randomised consent (Zelen's) design. *Contemporary Clinical Trials*, 27, 305–319. Copyright 2006 by Elsevier, reprinted with permission.

Criticisms and Drawbacks

Despite claims that the single-consent design is ethical as access to the new treatment is only available through participation in the trial, Zelen's design (in particular, the single-consent method) was met with a wave of criticism on ethical grounds. In particular, the issue of the inclusion of patients in a trial without their knowledge has been especially controversial. In the double-consent design, participants can always refuse the treatment to which they have been allocated, which is less ethically contentious. However, there might be ethical difficulties in collecting data about participants without their consent, and refusal by participants to allow data collection can introduce selection bias. Some might judge the use of Zelen's method as unethical in any circumstance. Others might take a more pragmatic approach and balance the ethical issues of offering or not offering 100% of participants an untested treatment, when the only realistic method of evaluation is to use the Zelen approach. Indeed, in some circumstances, the use of Zelen's method has been justified on ethical grounds in that it is simply unethical to get informed consent in certain very traumatic circumstances. Zelen's single-consent method is not supported by either the British Medical Research Council or the U.S. Federal Research Institute; however, rates of ethical consent for both this and the modified version remain varied. In general, the double-consent design is more acceptable to ethics committees; Schellings and colleagues noted the rejection rate of the

modified randomized consent design was found to be 47% and 41% in the United Kingdom and the Netherlands, respectively, compared with rejection of the single-consent version (66% in the United Kingdom and 59% in the Netherlands).

In the context of cluster randomized trials, Zelen was correct in his view that the use of randomization before consent would be commonly used. In cluster trials, a group of people (e.g., members of the same general practice) are randomized rather than as individuals. It is common practice to identify clusters and randomize these and then obtain consent from participants after allocation.

The issue of fully informed consent remains a debated issue. To date, there are three systematic reviews of the use of Zelen's design. The earliest by Doug Altman and colleagues concentrated on statistical aspects of the double-consent design (while also touching on other topics) using clinical trials in cancer as exemplars for all of Zelen's trials. Two more recent reviews have been published: Schellings and associates aimed to give a general overview of the use of Zelen's designs, whereas Joy Adamson and colleagues focused on the reasons authors gave for using the method, crossover rates, and the quality of identified trials.

It is difficult to estimate the frequency with which Zelen's designs have been employed, as they are not always easy to identify in the literature. Using different search strategies, the two most recent reviews located 50 trials (between 1977 and 2003) and 58 trials (between 1990 and 2005), respectively. These figures

are in no doubt underestimations of the actual frequency of the use of Zelen's design; suffice it to say, the design has been used infrequently relative to other trial designs. This is contrary to Zelen's prediction that randomized consent designs would dominate the field of RCTs. This is likely to be because of the many criticisms that have been aimed at this particular methodology.

The review by Doug Altman highlighted several serious statistical drawbacks to using the Zelen design. Much of this stems from the participants' ability to refuse the treatment on offer and effectively cross over to the alternative treatment group. Crossover effects introduce another form of bias—dilution bias—which will lead to an underestimation of the true treatment effects in an intention-to-treat analysis. Although this is a problem for all intention-to-treat analyses, the effect is likely to be magnified with the Zelen design. To cope with this, the sample size needs to be correspondingly increased to reduce the likelihood of incurring a Type II error. This inflation factor might offset any participant recruitment advantages. Although crossover can, and does, occur in ordinary RCTs, this crossover is likely to be greater in the Zelen design because participants who refuse one treatment under consideration will not be recruited to a normal RCT. More seriously, in addition to the loss of power is that some participants might refuse to give consent for data collection; this can introduce selection bias. This problem has been particularly noted within the context of cluster randomized trials.

Until the mid-1980s, Zelen's design was mainly used in oncology trials and in the United States and Scandinavia. The review that focused on the use of Zelen's designs since 1990 indicated that most studies have used a Zelen approach to avoid biases inherent when trial participants undertake non- placebo-controlled trials. Contrary to the reason for their conception, enhancing recruitment was not the most common motive for usage. Zelen's method seems to have been used in screening trials to give a more pragmatic estimate of the impact of screening programs. Despite statistical concerns relating to the negative impact of potential crossover between treatments, the review found that they did not seem to be excessive in most trials identified.

Rona Campbell and associates have described another modification to the single-consent design—where consent is still only sought from the intervention group nested within an observational study for which prior consent was obtained. This method has been advocated for such contexts as chronic disease, behavioral interventions, and relatively safe, desirable interventions. It has been successfully applied in a behavioral

intervention and physical therapy for osteoarthritis of the knee, obtaining the appropriate approval from several local research ethics committees.

Randomized consent designs are widely used in the context of cluster randomized trials. With respect to individually randomized trials, they have found little favor with trial methodologists partly for ethical reasons and partly for scientific issues. Crossover is the main scientific problem with Zelen's approach, and even modest crossover rates will result in biased estimates and reductions in statistical power. Nevertheless, there are some instances, such as cancer screening trials, where Zelen's approach will provide a pragmatic estimate of the impact of the intervention, which is closer to that which could be achieved in implementation compared with the conventional trial approach.

1599	Edward Wright publishes a book on navigation suggesting the use of the median to summarize observations.
1620	The Novum Organon is published by Francis Bacon and defines research as an activity that is helpful to the world.
1665	The first scholarly journal is published, <i>Philosophical Transactions</i> .
1733	While exploring coin flipping, Abraham de Moivre studies what becomes known as the normal curve.
1752	The Royal Society of London requires that scientific articles be peer-reviewed before being accepted for journals.
1761	Thomas Bayes suggests a method of estimating likelihood of occurrences that becomes known as Bayes Theorem.
1786	William Playfair introduces line charts and bar charts.
1802	Pierre-Simon Laplace estimates the population of France using sample data.
1805	Adrien-Marie Legendre is the first of several who independently develop the method of least squares to make more precise estimates of population parameters.
1810	The Central Limit Theorem is introduced by Pierre-Simon Laplace.
1830	Charles Babbage complains in print that many of his colleagues fake data.
1835	Adolphe Quetelet describes human traits as normally distributed, varying around a mean.
1879	Wilhelm Wundt establishes the first psychology lab in Germany, which leads to the idea that psychology could be studied as a science.
1885	Louis Pasteur tests a rabies vaccine on a young boy without any animal data to support its safety.
1904	Charles Spearman develops factor analysis.
1905	The first standardized intelligence test, the Binet-Simon Intelligence Test, is introduced to identify students in French schools with intellectual disabilities.

(Continued)

(Continued)

<i>Date</i>	<i>Event</i>
1908	William Sealy Gosset, while working for a brewery, develops a simple method for estimating population means using small samples. Ronald Fisher later refined this formula into the <i>t</i> test.
1913	John Watson publishes an article introducing what he called behaviorism and suggests that as a social science, psychology should be studied objectively through observation of behavior, both human and animal.
1914	Frederick Kelly introduces the Kansas Silent Reading Test, the first test to use the multiple-choice test format to reduce subjectivity in teacher scoring and grading.
1924	Ronald Fisher publishes what becomes known as the <i>F</i> distribution and begins developing the experimental design that allows for analysis of variance.
1925	The book <i>Statistical Methods for Research Workers</i> by Ronald Fisher is published. Among the statistical concepts introduced in the book are meta-analysis, using .05 as the level of significance, and using 1.96 standard deviations or standard errors to produce confidence intervals.
1928	Louis Thurstone publishes “Attitudes Can Be Measured” in the <i>American Journal of Sociology</i> , introducing an interval-level method for measuring attitude.
1932	Rensis Likert publishes “A Technique for the Measurement of Attitudes” in the <i>Archives of Psychology</i> , introducing an attitude assessment procedure that evolved into the very popular “Strongly Disagree to Strongly Agree” scaling format.
1932	The Tuskegee Syphilis Study begins, which infamously withheld treatment for syphilis for its hundreds of African American subjects, so as to study its effects.
1935	Ronald Fisher publishes <i>The Design of Experiments</i> , the first textbook on experimental design.
1942	Edward Guthrie publishes <i>A Theory of Contiguity</i> , which suggests learning could not be explained simply by the idea of conditioning but that the events surrounding stimuli and responses were also important.
1946	The American Institutes of Research (AIR) is founded.
1947	An international code of human subject research ethics, The Nuremberg Code, is adopted.
1950	Abraham Wald publishes the book <i>Statistical Decision Functions</i> .
1950	Z.W. Birnbaum and Monroe Sirken present a method for handling bias due to non-availability of potential respondents.
1957	The launch of the Soviet space satellite <i>Sputnik</i> leads to a huge increase in U.S.-funded technology research.
1959	The term “machine learning” is coined at IBM by Arthur Samuel.
1961	Albert Bandura publishes the first of his Bobo doll studies suggesting children learn vicariously through watching adult behaviors.
1962	Thomas Kuhn publishes <i>The Structure of Scientific Revolutions</i> , which introduces the ideas of research paradigms and paradigm shifts.
1963	Robert Glaser uses the term “criterion-referenced tests” in an article about measuring learning outcomes. Criterion-referenced tests, as opposed to norm-referenced tests, produce scores that are meant to be interpreted against a set of performance standards.

<i>Date</i>	<i>Event</i>
1963	Stanley Milgram begins his <i>obedience to authority</i> studies in which subjects were instructed to give electrical shocks to other subjects. Controversy about the effects on subjects who followed the instructions informs modern human subject protection ethics.
1965	Barney Glaser and Anselm Strauss present the constant comparative method, which later develops as grounded theory.
1966	Donald Campbell and Julian Stanley distinguish between <i>experimental</i> designs that have random assignment to groups and <i>quasi-experimental</i> designs that do not.
1967	Michael Scriven distinguishes between summative evaluation (making a judgment about the effectiveness of a program after it is completed) and formative evaluation (providing feedback during the time a program is still underway).
1968	Benjamin Bloom uses Michael Scriven's terms of <i>summative</i> and <i>formative</i> evaluation to describe summative and formative assessment.
1973	George Box and George Tiao publish the book <i>Bayesian Inference in Statistical Analysis</i> , which reintroduces Bayesian analysis to the mainstream.
1984	Donald Schön publishes the book <i>The Reflective Practitioner</i> , which in its description of how professionals produce quality work, lays the groundwork for design-based research.
1985	Yvonna Lincoln and Egon Guba publish the book <i>Naturalistic Inquiry</i> , which presents a qualitative framework for social science research and provides an alternative to the quantitative paradigm.
1990	The Human Genome Project, which intends to map the entire human gene sequence, begins.
1991	The U.S. Federal Policy for the Protection of Human Subjects is adopted. The Common Rule, as it is called, defines human subjects research and sets forth the requirements for Institutional Review Boards.
1994	A chapter by Anselm Strauss and Juliet Corbin on grounded theory is included in the <i>Handbook of Qualitative Research</i> . Grounded theory emphasizes building theory that is faithful to the data.
1994	Testimony before the U.S. Congress reveals that tobacco company researchers had concluded that nicotine was strongly addictive but kept the results secret.
2010	A widely cited 1998 paper in the journal <i>Lancet</i> claimed an association between the measles, mumps, and rubella vaccine and the onset of autism in children. After the paper was almost universally criticized for a lack of proper scientific methods, the journal retracts the paper and accuses the primary author, Andrew Wakefield, of fraud and various ethical violations including not revealing that the study was funded by an anti-vaccination law firm.
2017	The U.S. Office for Human Research Protections revises the Common Rule, the federal regulation which guides required activities when conducting human subjects research for universities and other federally funded institutions. Among other lessening of restrictions, prior participant permission for use of biological samples is not required. The types of research activities that explicitly need not be reviewed have also increased in number.
